The primary mode of therapy for salicylate toxicity is **urinary alkalinization** . Urinary alkalinization enhances the elimination of salicylates by converting salicylate to its ionized form, “trapping” it in the renal tubules, thus enhancing elimination. In addition, maintaining an alkalemic serum pH decreases CNS penetration of salicylates because charged particles are less able to cross the blood-brain barrier. Alkalinization is achieved by administration of a sodium bicarbonate infusion at approximately 2 times maintenance fluid rates. *The goals of therapy include a urine pH of 7.5-8, a serum pH of 7.45-7.55, and decreasing serum salicylate levels.* In general, in the presence of an acidosis, an aspirin-poisoned patient's status can be directly related to the patient's serum pH: the lower the pH, the greater the relative amount of salicylate in the uncharged, nonpolar form and the greater the penetration of the blood-brain barrier by the drug. Careful attention should also be paid to serial potassium levels in any patient on a bicarbonate infusion, since potassium will be driven intracellularly and hypokalemia impairs alkalinization of the urine. For these reasons, potassium is often added to the bicarbonate drip. Repeat doses of charcoal may be beneficial because of the often delayed and erratic absorption of aspirin.

Parenteral glucose should be provided to any salicylate-poisoned patients with altered mental status because they may have CNS hypoglycemia (i.e., neuroglycopenia) not seen in a peripheral serum glucose test.

In patients with severe toxicity, hemodialysis may be required. Indications for dialysis include severe acid-base abnormalities (specifically severe acidosis and acidemia), a rising salicylate level (despite adequate decontamination and properly alkalinized urine), pulmonary edema, cerebral edema, seizures, and renal failure. Serum salicylate concentrations alone are not a clear indicator of the need for dialysis and should always be interpreted along with the clinical status of the patient.

Ibuprofen and Other Nonsteroidal Antiinflammatory Drugs (NSAIDs).

Ibuprofen and other NSAIDs are often involved in unintentional and intentional overdoses because of their widespread availability and common use as analgesics and antipyretics. Fortunately, serious effects after acute NSAID overdose are rare because of their wide therapeutic index.

Pathophysiology.

NSAIDs inhibit prostaglandin synthesis by reversibly inhibiting the activity of cyclooxygenase (COX), the primary enzyme responsible for the biosynthesis of prostaglandins. In therapeutic use, side effects include GI irritation, reduced renal blood flow, and platelet dysfunction. To minimize these side effects, NSAID analogs have been developed that are more specific for the inducible form of COX (the COX-2 isoform) than the constitutive form, COX-1. However, overdose of the more selective COX-2 inhibitors (e.g., celecoxib [Celebrex]) is treated the same as overdose of nonspecific COX inhibitors (e.g., ibuprofen) because at higher doses, COX-2–selective agents lose their COX inhibitory selectivity.

Ibuprofen, the primary NSAID used in pediatrics, is well tolerated, even in overdose. In children, acute doses of <200 mg/kg rarely cause toxicity, but ingestions of >400 mg/kg can produce more serious effects, including altered mental status and metabolic acidosis.

Clinical and Laboratory Manifestations.

Symptoms usually develop within 4-6 hr of ingestion and resolve within 24 hr. If toxicity does develop, it is typically manifested as nausea, vomiting, and abdominal pain. Although GI bleeding and ulcers have been described with chronic use, they are rare in the setting of acute ingestion. After massive ingestions, patients can develop marked CNS depression, anion gap metabolic acidosis, renal insufficiency, and (rarely) respiratory depression. Seizures have also been described, especially after overdose of mefenamic acid. Specific drug levels are not readily available, nor do they inform management decisions. Renal function studies, acid-base balance, complete blood count (CBC), and coagulation parameters should be monitored after very large ingestions. Co-ingestants, especially APAP, should be ruled out after any intentional ingestion.

Treatment.

Supportive care, including use of antiemetics and acid blockade as indicated, is the primary therapy for NSAID toxicity. Decontamination with activated charcoal should be considered if a patient presents within 1-2 hr of a potentially toxic ingestion. There is no specific antidote for this class of drugs. Given the high degree of protein binding and excretion pattern of NSAIDs, none of the modalities used to enhance elimination is particularly useful in managing these overdoses. Unlike in patients with salicylate toxicity, urinary alkalinization is not helpful for NSAID toxicity. Patients who develop significant clinical signs of toxicity should be admitted to the hospital for ongoing supportive care and monitoring. Patients who remain asymptomatic for 4-6 hr after ingestion may be considered medically cleared.

Prescription Opioids.

Opioids are a frequently abused class of medications in both IV and oral forms. The opioid epidemic gripping the United States and other countries is discussed in Chapter 140 . Two specific oral opioids, buprenorphine and methadone, merit mention because of potential life-threatening toxicity in toddlers with ingestion of even 1 pill. Both agents are used in managing opioid dependence, although **buprenorphine** is the drug of choice. **Methadone** is also widely used in the treatment of chronic pain, meaning multiday prescriptions can be filled. Both drugs are readily available for illicit purchase and potential abuse. Both drugs are of great potential toxicity to a toddler, especially buprenorphine because of its long half-life and high potency.

Pathophysiology.

Methadone is a lipophilic synthetic opioid with potent agonist effects at μ-opioid receptors, leading to both its desired analgesic effects and undesired side effects, including sedation, respiratory depression, and impaired GI motility. Methadone is thought to cause QTc interval prolongation through interactions with the human ether-a-go-go–related gene (hERG)-encoded potassium rectifier channel. Its duration of effect for pain control averages only about 8 hr, whereas the dangerous side effects can occur up to 24 hr from the last dose and longer after overdose. Methadone has an average half-life >25 hr, which may be extended to >50 hr in overdose.

Suboxone is a combination of buprenorphine, a potent opioid with partial agonism at μ-opioid receptors and weak antagonism at κ-opioid receptors, and naloxone. Naloxone has poor oral bioavailability but is included in the formulation to discourage diversion for IV use, during which it can precipitate withdrawal. Suboxone is formulated for buccal or sublingual administration; consequently, toddlers can absorb significant amounts of drug even by sucking on a tablet. Buprenorphine has an average half-life of 37 hr.

Clinical and Laboratory Manifestations.

In children, methadone and buprenorphine ingestions can manifest with the classic opioid toxidrome of respiratory depression, sedation, and miosis. Signs of more severe toxicity can include bradycardia, hypotension, and hypothermia. Even in therapeutic use, methadone is associated with a prolonged QTc interval and risk of torsades de pointes. Accordingly, an ECG should be part of the initial evaluation after ingestion of methadone or any unknown opioid. Neither drug is detected on routine urine opiate screens, although some centers have added a separate urine methadone screen. Levels of both drugs can be measured, although this is rarely done clinically and is seldom helpful in the acute setting. An exception may be in the cases involving concerns about neglect or abuse, at which point urine for gas chromatography/mass spectroscopy, the legal gold standard, should be sent to confirm and document the presence of the drug.

Treatment.

Patients with significant respiratory depression or CNS depression should be treated with the opioid antidote **naloxone** (see Table 77.7). In pediatric patients who are not chronically taking opioids, the full reversal dose of 1-2 mg should be used. In contrast, opioid-dependent patients should be treated with smaller initial doses (0.04-0.4 mg), which can then be repeated as needed to achieve the desired clinical response, avoiding abrupt induction of withdrawal. Because the half-life of methadone and buprenorphine is much longer than that of naloxone, patients can require multiple doses of naloxone. These patients may benefit from a continuous infusion of naloxone, typically started at two thirds of the reversal dose per hour and titrated to maintain an adequate respiratory rate and level of consciousness. Patients who have ingested methadone should be placed on a cardiac monitor and have serial ECGs to monitor for the development of a prolonged QTc interval. If a patient does develop a prolonged QTc, management includes close cardiac monitoring, repletion of electrolytes (potassium, calcium, and magnesium), and having a defibrillator readily available should the patient develop torsades de pointes.

Given the potential for clinically significant and prolonged toxicity, any toddler who has ingested methadone, even if asymptomatic, should be admitted to the hospital for at least 24 hr of monitoring. Some experts advocate a similar approach to management of buprenorphine ingestions, even in the asymptomatic patient. All such cases should be discussed with a PCC or medical toxicologist before determining disposition.

Cardiovascular Medications

β-Adrenergic Receptor Blockers.

β-Blockers competitively inhibit the action of catecholamines at the β-adrenergic receptor. Therapeutically, β-blockers are used for a variety of conditions, including hypertension, coronary artery disease, tachydysrhythmias, anxiety disorders, migraines, essential tremor, and hyperthyroidism. Because of its lipophilicity and blockade of fast sodium channels, **propranolol** is considered to be the most toxic member of the β-blocker class. Overdoses of water-soluble β-blockers (e.g., atenolol) are associated with milder symptoms.

Pathophysiology.

In overdose, β-blockers decrease chronotropy and inotropy in addition to slowing conduction through atrioventricular nodal tissue. Clinically, these effects are manifested as bradycardia, hypotension, and heart block. Patients with reactive airways disease can experience bronchospasm as a result of blockade of β_2 -mediated bronchodilation. β_2 -Blockers interfere with glycogenolysis and gluconeogenesis, which can sometimes lead to hypoglycemia, especially in patients with poor glycogen stores (e.g., toddlers).

Clinical and Laboratory Manifestations.

Toxicity typically develops within 6 hr of ingestion, although it may be delayed after ingestion of sotalol or slow-release (SR) preparations. The most common features of severe poisoning are bradycardia and hypotension. Lipophilic agents, including propranolol, can enter the CNS and cause altered mental status, coma, and seizures. Overdose of β-blockers with membrane-stabilizing properties (e.g., propranolol) can cause QRS interval widening and ventricular dysrhythmias.

Evaluation after β-blocker overdose should include an ECG, frequent reassessments of hemodynamic status, and blood glucose. Serum levels of β-blockers are not readily available for routine clinical use and are not useful in management of the poisoned patient.

Treatment.

In addition to supportive care and GI decontamination as indicated, **glucagon** is theoretically the preferred antidote of choice for β-blocker toxicity (see Table 77.7). Glucagon stimulates adenyl cyclase and increases levels of cyclic adenosine monophosphate (cAMP) independent of the β-receptor. Glucagon is typically given as a bolus and, if this is effective, followed by a continuous infusion. In practice, glucagon is often only marginally effective, limited by its proemetic effects, especially at the high doses typically required. Other potentially useful interventions include calcium, vasopressors, and high-dose insulin. Seizures are managed with benzodiazepines, and QRS widening should be treated with sodium bicarbonate. Children who ingest 1 or 2 water-soluble β-blockers are unlikely to develop toxicity and can typically be discharged to home if they remain asymptomatic over a 6 hr observation period. Children who ingest SR products, highly lipid-soluble agents, and sotalol can require longer periods of observation before safe discharge. Any symptomatic child should be admitted for ongoing monitoring and directed therapy.

Calcium Channel Blockers.

Calcium channel blockers (CCBs) are used for a variety of therapeutic indications and have the potential to cause severe toxicity, even after exploratory ingestions. Specific agents include verapamil, diltiazem, and the dihydropyridines (e.g., amlodipine, nifedipine). Of these, diltiazem and verapamil are the most dangerous in overdose because of their higher lipophilicity and direct cardiac suppressant effects.

Pathophysiology.

CCBs antagonize L -type calcium channels, inhibiting calcium influx into myocardial and vascular smooth muscle cells. Verapamil works primarily by slowing inotropy and chronotropy and has no effect on systemic vascular resistance (SVR). Diltiazem has effects both on the heart and the peripheral vasculature. The dihydropyridines exclusively diminish SVR. Verapamil and diltiazem can significantly diminish myocardial contractility and conduction, with diltiazem also lowering SVR. By contrast, dihydropyridines will decrease the SVR, leading to vasodilation and reflex tachycardia, although this receptor selectivity may be lost after a large overdose. Because the same L -type calcium channels blocked by CCBs are also on the pancreatic islet cells, any patient significantly poisoned with a CCB usually is hyperglycemic.

Clinical and Laboratory Manifestations.

The onset of symptoms typically is soon after ingestion, although it may be delayed with ingestions of SR products. Overdoses of CCBs lead to hypotension, accompanied by bradycardia, normal heart rate, or even tachycardia, depending on the agent. A common feature of CCB overdose is the patient exhibiting profound hypotension with preserved consciousness.

Initial evaluation should include an ECG, continuous and careful hemodynamic monitoring, and rapid measurement of serum glucose levels. Both the absolute degree of hyperglycemia and the percentage increase in serum glucose have been correlated with the severity of CCB toxicity in adults. The development of hyperglycemia can even precede the development of hemodynamic instability. Blood levels of CCBs are not readily available and are not useful in guiding therapy.

Treatment.

Once initial supportive care has been instituted, GI decontamination should begin with activated charcoal as appropriate. WBI may be beneficial in a stable patient after ingestion of an SR product. Calcium channel blockade in the smooth muscles of the GI tract can lead to greatly diminished motility; thus any form of GI decontamination should be undertaken with careful attention to serial abdominal tests.

Calcium salts, administered through a peripheral IV line as calcium gluconate or a central line as calcium chloride, help to overcome blocked calcium channels. **High-dose insulin euglycemia therapy** is considered the antidote of choice for CCB toxicity. An initial bolus of 1 unit/kg of regular insulin is followed by an infusion at 0.5-1 unit/kg/hr (see Table 77.7). The main mechanism of high-dose insulin euglycemia is to improve the metabolic efficiency of a poisoned heart that is in need of carbohydrates for energy (instead of the usual free fatty acids), but has minimal circulating insulin. Blood glucose levels should be closely monitored, and supplemental glucose may be given to maintain euglycemia, although this is rarely necessary in the severely poisoned patient.

Additional therapies include judicious IV fluid boluses and vasopressors (often in very high doses). Cardiac pacing is rarely of value. Lipid emulsion therapy (discussed earlier) is a potentially lifesaving intervention, especially for patients poisoned with the more lipid-soluble CCBs, verapamil and diltiazem. In extreme cases an intraaortic balloon pump or extracorporeal membrane oxygenation (ECMO) are potential rescue devices. Given the potential for profound and sometimes delayed toxicity in toddlers after ingestion of 1 or 2 CCB tablets, hospital admission and 12-24 hr of monitoring for all of these patients is strongly recommended.

Clonidine.

Although originally intended for use as an antihypertensive, the number of clonidine prescriptions in the pediatric population has greatly increased because of its reported efficacy in the management of attention-deficit/hyperactivity disorder (ADHD), tic disorders, and other behavioral disorders. With this increased use has come a significant rise in pediatric ingestions and therapeutic misadventures. Clonidine is available in pill and transdermal patch forms.

Pathophysiology.

Clonidine, along with the closely related agent **guanfacine** , is a centrally acting α_2 -adrenergic receptor agonist with a very narrow therapeutic index. Agonism at central α_2 receptors decreases sympathetic outflow, producing lethargy, bradycardia, hypotension, and apnea. Toxicity can develop after ingestion of only 1 pill or after sucking on or swallowing a discarded transdermal patch. Even a “used” transdermal patch might contain as much as one-third to one-half the original amount of drug.

Clinical and Laboratory Manifestations.

The most common clinical manifestations of clonidine toxicity are lethargy, miosis, and bradycardia. Hypotension, respiratory depression, and apnea may be seen in severe cases. Very early after ingestion, patients may be hypertensive in the setting of agonism at peripheral α-receptors and resulting vasoconstriction. Symptoms develop relatively soon after ingestion and typically resolve within 24 hr. Serum clonidine concentrations are not readily available and are of no clinical value in the acute setting. Although signs of clinical toxicity are common after clonidine overdose, death from clonidine alone is extremely unusual.

Treatment.

Given the potential for significant toxicity, most young children warrant referral to a healthcare facility for evaluation after unintentional ingestions of clonidine. Gastric decontamination is usually of minimal value because of the small quantities ingested and the rapid onset of serious symptoms. Aggressive supportive care is imperative and is the cornerstone of management. Naloxone, often in high doses, has shown variable efficacy in treating clonidine toxicity. Other potentially useful therapies include atropine, IV fluid boluses, and vasopressors. Symptomatic children should be admitted to the hospital for close cardiovascular and neurologic monitoring. Also, in a patient receiving chronic clonidine or guanfacine therapy, rapid discontinuation of the drug, or even missing 1 or 2 doses, could lead to potentially dangerous elevations in blood pressure.

Digoxin.

Digoxin is a cardiac glycoside extracted from the leaves of *Digitalis lanata* . Other natural sources of cardiac glycosides include *Digitalis purpura* (foxglove), *Nerium oleander* (oleander), *Convallaria majalis* (lily of the valley), Siberian ginseng, and the *Bufo marinus* toad. Therapeutically, digoxin is used in the management of heart failure and some supraventricular tachydysrhythmias. Acute overdose can occur in the setting of dosing errors (especially in younger children), unintentional or intentional medication ingestion, or exposure to plant material containing digitalis glycosides. Regarding exposure to such plants, toxicity is unusual unless the poison is concentrated in the form of a tea. Chronic toxicity can result from alteration of the digoxin dose, alteration in digoxin clearance as a result of renal impairment, or drug interactions.

Pathophysiology.

Digoxin blocks the sodium-potassium adenosine triphosphatase (Na^+ ,K^+ -ATPase) pump, leading to intracellular loss of K^+ and gain of Na^+ and calcium (Ca^{2+}). This resulting rise in Ca^{2+} available to the contractile myocardium improves inotropy. An increase in myocardial automaticity leads to subsequent atrial, nodal, and ventricular ectopy. Digoxin also affects nodal conduction, leading to a prolonged refractory period, decreased sinus node firing, and slowed conduction through the atrioventricular node. Impaired Na^+ /K^+ exchange results in dangerously high levels of serum K^+ . Overall, digoxin overdose manifests as a combination of slowed or blocked conduction and increased ectopy.

Clinical and Laboratory Manifestations.

Nausea and vomiting are common initial symptoms of acute digoxin toxicity, manifesting within 6 hr of overdose. Cardiovascular manifestations include bradycardia, heart block, and a wide variety of dysrhythmias. CNS manifestations consist of lethargy, confusion, and weakness. Chronic toxicity is more insidious and may also manifest as altered mental status and visual disturbances (rare).

Initial assessment should include an ECG, serum digoxin level, serum potassium, and kidney function tests. The serum digoxin level should be assessed at least 6 hr after ingestion and carefully interpreted in the setting of clinical symptoms, because the digoxin level alone does not entirely reflect the severity of intoxication. In acute ingestions, serum potassium is an independent marker of morbidity and mortality, with levels >5.5 mEq/L predicting poor outcomes. In chronic toxicity, serum K^+ concentration is less useful as a prognostic marker and may be altered from concomitant use of diuretics.

Digoxin has a very narrow therapeutic index. Therapeutic plasma digoxin concentrations are 0.5-2.0 ng/mL; a level >2 ng/mL is considered toxic and >6 ng/mL is considered potentially fatal (in chronic poisonings). As with all serum levels of intoxicants, one must be careful to interpret the number in the context of the scenario of the poisoning and the status of the patient. An acutely poisoned patient may have a very high serum level and minimal to no symptoms, whereas a patient with a chronic or acute on chronic poisoning will usually be sicker with a lower serum level.

Numerous drug interactions affect plasma digoxin concentrations. Medications known to increase serum digoxin concentrations include the macrolides, erythromycin and clarithromycin, spironolactone, verapamil, amiodarone, and itraconazole.

Treatment.

Initial treatment includes good general supportive care and gastric decontamination with activated charcoal if the ingestion was recent. An antidote for digoxin, digoxin-specific antibody fragments (Fab: Digibind or DigiFab) is available (see Table 77.7). Fab fragments bind free digoxin in both the intravascular and the interstitial spaces to form a pharmacologically inactive complex that is subsequently eliminated renally. Indications for Fab fragments include life-threatening dysrhythmias, K^+ value >5-5.5 mEq/L, serum digoxin level >15 ng/mL at any time or >10 ng/mL 6 hr after ingestion, clinically significant hypotension or other CV instability, altered mental state, and renal failure. Atropine is potentially useful in managing symptomatic bradycardia. Although dogma states that patients on digoxin with severe hyperkalemia and QRS widening on the ECG should not receive calcium salts, this has not been supported in the literature. Once stabilized, consultation with a cardiologist is recommended in the management of patients receiving chronic digoxin therapy, because administration of Fab fragments can lead to recurrence of the patient's underlying dysrhythmias or dysfunction.

Iron.

Historically, iron was a common cause of childhood poisoning deaths. However, preventive measures such as childproof packaging have significantly decreased the rates of serious iron toxicity in young children. Iron-containing products remain widely available, with the most potentially toxic being adult iron preparations and prenatal vitamins. The severity of an exposure is related to the amount of *elemental iron* ingested. Ferrous sulfate contains 20% elemental iron, ferrous gluconate 12%, and ferrous fumarate 33%. Multivitamin preparations and children's vitamins rarely contain enough elemental iron to cause significant toxicity. Furthermore, nonionic forms of iron, carbonyl iron and iron polysaccharide also do not cause significant toxicity.

Pathophysiology.

Iron is directly corrosive to the GI mucosa, leading to hematemesis, melena, ulceration, infarction, and potential perforation. Early iron-induced hypotension is caused by massive volume losses, increased permeability of capillary membranes, and vasodilation mediated by free iron. Iron accumulates in tissues, including the Kupffer cells of the liver and myocardial cells, leading to hepatotoxicity, coagulopathy, and cardiac dysfunction. Metabolic acidosis develops in the setting of hypotension, hypovolemia, and iron's direct interference with oxidative phosphorylation and the Krebs cycle. Pediatric patients who ingest >40 mg/kg of elemental iron should be referred to medical care for evaluation, although moderate to severe toxicity is typically seen with ingestions >60 mg/kg.

Clinical and Laboratory Manifestations.

Iron toxicity is described in 5 often-overlapping stages. The **1st stage** , 30 min to 6 hr after ingestion, consists of profuse vomiting and diarrhea (often bloody), abdominal pain, and significant volume losses leading to potential hypovolemic shock. Patients who do not develop GI symptoms within 6 hr of ingestion are unlikely to develop serious toxicity. The **2nd stage** , 6-24 hr after ingestion, is often referred to as the “quiescent phase” since the GI symptoms typically have resolved. However, careful clinical examination can reveal subtle signs of hypoperfusion, including tachycardia, pallor, and fatigue. During the **3rd stage** , 12-36 hr after ingestion, patients develop multisystem organ failure, shock, hepatic and cardiac dysfunction, acute lung injury, and profound metabolic acidosis. Death usually occurs during the 3rd stage. The **4th stage** (hepatic) results in fulminant liver failure and coagulopathy about 2-5 days after ingestion. The **5th stage** , 4-6 wk after ingestion, is marked by formation of strictures and signs of GI obstruction.

Symptomatic patients and patients with a large exposure by history should have serum iron levels drawn 4-6 hr after ingestion. Serum iron concentrations of <500 µg/dL 4-8 hr after ingestion suggest a low risk of significant toxicity, whereas concentrations of >500 µg/dL indicate that significant toxicity is likely. Additional laboratory evaluation in the ill patient should include arterial or venous blood gas, CBC, serum glucose level, liver transaminases, and coagulation parameters. Careful attention should be paid to the patient's hemodynamic status. An abdominal radiograph might reveal the presence of iron tablets, although not all formulations of iron are radiopaque.

Treatment.

Close clinical monitoring, combined with aggressive supportive and symptomatic care, is essential to the management of iron poisoning. Activated charcoal does not adsorb iron, and WBI remains the decontamination strategy of choice. **Deferoxamine** , a specific chelator of iron, is the antidote for moderate to severe iron intoxication (see Table 77.7). Indications for deferoxamine treatment include a serum iron concentration >500 µg/dL or moderate to severe symptoms of toxicity (e.g., acidosis), regardless of serum iron concentration. Deferoxamine is preferably given by continuous IV infusion at 15 mg/kg/hr. Hypotension is a common side effect of deferoxamine infusion and is managed by slowing the rate of the infusion and administering fluids and vasopressors as needed. Prolonged deferoxamine infusion (>24 hr) has been associated with pulmonary toxicity (acute respiratory distress syndrome, ARDS) and *Yersinia* sepsis. The deferoxamine-iron complex can color the urine reddish (“vin rosé”), although the degree of this coloration should not guide therapy. Deferoxamine is typically continued until clinical symptoms and acidosis resolve. Consultation with a PCC or medical toxicologist can yield guidelines for discontinuing deferoxamine.

Oral Hypoglycemics

Oral medications used in the management of type 2 diabetes include sulfonylureas, biguanides (e.g., metformin), thiazolidinediones, and meglitinides. Of these, only the sulfonylureas and meglitinides have the potential to cause profound hypoglycemia in both diabetic and nondiabetic patients. These classes of medications are widely prescribed and thus readily available for both unintentional and intentional exposures. In toddlers, ingestion of a single sulfonylurea tablet can lead to significant toxicity.

Pathophysiology.

Sulfonylureas work primarily by enhancing endogenous insulin secretion. In binding to the sulfonylurea receptor, these drugs induce closure of K^+ channels, leading to membrane depolarization, opening of Ca^{2+} channels, and stimulation of Ca^{2+} -mediated insulin release. Even in therapeutic use, the duration of hypoglycemic action can last up to 24 hr.

Clinical and Laboratory Manifestations.

Hypoglycemia and symptoms associated with hypoglycemia are the primary clinical manifestations of sulfonylurea toxicity. These signs and symptoms can include diaphoresis, tachycardia, lethargy, irritability, coma, seizures, and even focal neurologic findings. As with other hyperinsulinemic states, sulfonylurea overdoses are associated with a nonketotic hypoglycemia. In the majority of patients, hypoglycemia develops within 6 hr of ingestion but can be delayed up to 16-18 hr after ingestion. Toddlers are particularly susceptible to hypoglycemia during an overnight fast.

Treatment.

Patients with symptomatic hypoglycemia should be promptly treated with dextrose. In patients with mild symptoms, oral dextrose may be sufficient. However, patients with severe symptoms or profound hypoglycemia should be treated with a bolus of IV dextrose. Continuous dextrose infusions and repeated IV dextrose boluses should be avoided if possible, because this can stimulate further insulin release and lead to recurrent and prolonged hypoglycemia. Instead, the preferred antidote for persistent (i.e., requiring ≥2 doses of IV dextrose) sulfonylurea toxicity is **octreotide** (see Table 77.7). Octreotide is a somatostatin analog that inhibits insulin release. Octreotide is given intravenously (IV) or subcutaneously (SC), typically in doses of 1-2 µg/kg (50-100 µg in teens or adults) every 6-8 hr.

Given the potential for significant hypoglycemia, toddlers with witnessed or suspected sulfonylurea ingestions should be admitted to the hospital for serial glucose measurements for at least 12 hr, including an overnight fast. Patients of any age who develop hypoglycemia are also candidates for admission given the prolonged duration of hypoglycemic activity. Prophylactic IV dextrose infusions are not recommended because they can mask the symptoms of toxicity and stimulate further insulin secretion. Patients who require IV dextrose and/or octreotide should be monitored until they can demonstrate euglycemia for at least 8 hr off all therapy.

With the increasing numbers of adolescents with type 2 diabetes, pediatricians should be familiar with the toxic effects of **metformin** as well. Although metformin does not cause hypoglycemia, its association with lactic acidosis is well documented (metformin-associated lactic acidosis, MALA). This state typically arises after a large overdose in which the agent interferes with the liver's ability to clear lactic acid. Dangerously high serum lactate levels can result, leading to hemodynamic instability. Hemodialysis is usually the best option for patients with severe MALA.

Psychiatric Medications: Antidepressants

Selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline, paroxetine, citalopram) are the most commonly prescribed class of antidepressants. This trend largely results from their wide therapeutic index and more favorable side effect profile compared with older agents such as tricyclic antidepressants (TCAs; amitriptyline, clomipramine, desipramine, doxepin, nortriptyline, imipramine) and monoamine oxidase inhibitors (MAOIs). Other agents include the serotonin-norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine) and atypical antidepressants (e.g., bupropion).

Tricyclic Antidepressants.

Although now prescribed less often for depression, TCAs remain in use for a variety of other conditions, including chronic pain syndromes, enuresis, ADHD, and obsessive-compulsive disorder. TCAs can cause significant toxicity in children, even with ingestion of 1 or 2 pills (10-20 mg/kg).

Pathophysiology.

TCAs achieve their desired antidepressant effects primarily through blockade of norepinephrine and serotonin reuptake. TCAs have complex interactions with other receptor types. Antagonism at muscarinic acetylcholine receptors leads to clinical features of the anticholinergic toxidrome. Antagonism at peripheral α-receptors leads to hypotension and syncope. Key to the toxicity of TCAs is their ability to block fast sodium channels, leading to impaired cardiac conduction and arrhythmias.

Clinical and Laboratory Manifestations.

Cardiovascular and CNS symptoms dominate the clinical presentation of TCA toxicity. Symptoms typically develop within 1-2 hr of ingestion, and serious toxicity usually manifests within 6 hr of ingestion. Patients can have an extremely rapid progression from mild symptoms to life-threatening dysrhythmias. Patients often develop features of the **anticholinergic toxidrome** , including delirium, mydriasis, dry mucous membranes, tachycardia, hyperthermia, urinary retention, and slow GI motility. CNS toxicity can include lethargy, coma, myoclonic jerks, and seizures. Sinus tachycardia is the most common cardiovascular manifestation of toxicity; however, patients can also develop widening of the QRS complex, premature ventricular contractions, and ventricular dysrhythmias. Refractory hypotension is a poor prognostic indicator and is the most common cause of death in TCA overdose.

An ECG is a readily available bedside test that can help determine the diagnosis and prognosis of the TCA-poisoned patient (Fig. 77.2 ; see Table 77.6). A QRS duration >100 msec identifies patients who are at risk for seizures and cardiac arrhythmias. An R wave in lead aVR of ≥3 mm is also an independent predictor of toxicity. Both ECG parameters are superior to measured serum TCA concentrations for identifying patients at risk for serious toxicity, and obtaining levels is rarely helpful in management of the acutely ill patient.

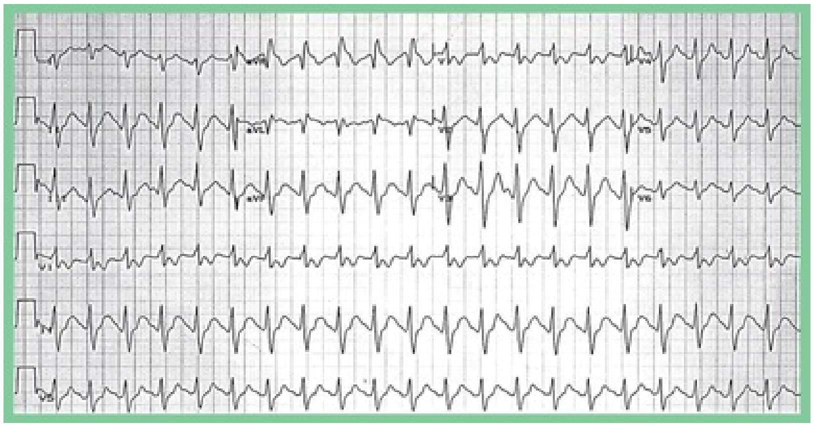

FIG. 77.2 **Electrocardiographic findings in tricyclic antidepressant toxicity. Note the tachycardia, widened QRS interval (144 msec), and prominent R wave in lead aVR. These findings are consistent with blockade of fast sodium channels.**

Treatment.

Initial attention should be directed to supporting vital functions, including airway and ventilation as needed. Gastric decontamination can be accomplished with activated charcoal in appropriate patients. Treating clinicians should obtain an ECG as soon as possible and follow serial ECGs to monitor for progression of toxicity. The 4 primary effects described next are seen at the bedside.

1 Altered Mental State.

TCA-poisoned patients can become deeply comatose relatively quickly, so careful and prompt attention to the airway and placement of an endotracheal tube is of paramount importance. The airway should be secured before any GI decontamination efforts.

2 Widened QRS on ECG.

TCAs, as well as with other agents (e.g., diphenhydramine, cocaine), will block the fast Na^+ channels on the myocardial cells, slowing the upstroke of the QRS complex. Because the effect on Na^+ channels is greatest within the 1st 6 hr, frequent ECGs (i.e., every 20-30 min) during this period are important. As the QRS approaches 160 msec, the risk of the patient developing monomorphic ventricular tachycardia rises to 30%. Sodium, usually in the form of sodium bicarbonate, is the antidote of choice. *Indications for sodium bicarbonate include a QRS duration ≥110 msec, ventricular dysrhythmias, and hypotension* . Multiple bolus doses of sodium bicarbonate, 1-2 mEq/kg each, may be needed to narrow the QRS to <110 msec. Some prefer then to place the patient on an infusion of sodium bicarbonate, but this may not be necessary if the QRS is carefully monitored after the initial doses and repeat bolus dosing is provided as needed during the 1st 6-12 hr. Hypertonic (3%) saline and/or lipid emulsion therapy may be beneficial in refractory cases.

3 Hypotension.

A direct-acting vasopressor such as norepinephrine or epinephrine is the agent of choice. Boluses of IV crystalloid fluids should be used with caution to prevent fluid overload.

4 Seizures.

Likely a result of the anticholinergic effects of TCAs, seizures are relatively common, typically brief, and should be treated with agents targeting the GABA-receptor complex in the brain. Benzodiazepines are the agent of choice.

Asymptomatic children should receive appropriate decontamination and have continuous cardiac monitoring and serial ECGs for at least 6 hr after exposure. If any manifestations of toxicity develop, the child should be admitted to a monitored setting. Children who remain completely asymptomatic with normal serial ECGs may be candidates for discharge after that monitoring period.

Selective Serotonin Reuptake Inhibitors.

In overdose, SSRIs are considerably less toxic than TCAs. SSRIs are unlikely to cause significant toxicity in exploratory ingestions. Some data suggest that initiating SSRI therapy is associated with an increased risk of suicidal ideation and behavior (see Chapter 40).

Pathophysiology.

SSRIs selectively block the reuptake of serotonin in the CNS. In contrast to TCAs and atypical antidepressants, SSRIs do not directly interact with other receptor types.

Clinical and Laboratory Manifestations.

In overdose, the principal manifestations of toxicity are sedation and tachycardia. Cardiac conduction abnormalities (primarily QTc prolongation) and seizures have been described in significant overdoses, especially after ingestions of citalopram. An ECG should be part of the initial assessment after SSRI ingestion. Serum creatine kinase (CK) levels are almost always elevated in a patient with clinically significant **serotonin syndrome** . Although seen more often after therapeutic use or overdose of several serotonergic agents in combination, the serotonin syndrome has also been described in ingestion of SSRIs alone (Table 77.11). Clinically, serotonin syndrome describes a spectrum of altered mental status, autonomic instability, fever, and neuromuscular hyperactivity (hyperreflexia, tremors, clonus in lower extremities > upper extremities). One or all of these signs may be present to varying degrees.

Table 77.11

Drugs Associated With the Serotonin Syndrome

DRUG TYPE	DRUGS
Selective serotonin reuptake inhibitors	Sertraline, fluoxetine, fluvoxamine, paroxetine, citalopram
Antidepressant drugs	Trazodone, nefazodone, buspirone, clomipramine, venlafaxine
Monoamine oxidase inhibitors	Phenelzine, moclobemide, clorgyline, isocarboxazid
Anticonvulsants	Valproate
Analgesics	Meperidine, fentanyl, tramadol, pentazocine
Antiemetic agents	Ondansetron, granisetron, metoclopramide
Antimigraine drugs	Sumatriptan
Bariatric medications	Sibutramine
Antibiotics	Linezolid (a monoamine oxidase inhibitor), ritonavir (through inhibition of cytochrome P450 enzyme isoform 3A4)
Nonprescription	Dextromethorphan

cough and cold remedies	
Drugs of abuse	Methylenedioxymethamphetamine (MDMA, “Ecstasy”), lysergic acid diethylamide (LSD), 5-methoxydiisopropyltryptamine (“foxy methoxy”), Syrian rue (contains harmine and harmaline, both monoamine oxidase inhibitors)
Dietary supplements and herbal products	Tryptophan, *Hypericum perforatum* (St. John's wort), *Panax ginseng* (ginseng)
Other	Lithium

From Boyer EW, Shannon M: The serotonin syndrome, *N Engl J Med* 352:1112–1120, 2005.

Treatment.

Initial management includes a careful assessment for signs and symptoms of serotonin syndrome and an ECG. Most patients simply require supportive care and observation until their mental status improves and tachycardia, if present, resolves. Management of serotonin syndrome is directed by the severity of symptoms; possible therapeutic interventions include benzodiazepines in mild cases and intubation, sedation, and paralysis in patients with severe manifestations (e.g., significant hyperthermia). Because agonism at the 5-HT$_{2A}$ serotonin receptor is thought to be primarily responsible for the development of serotonin syndrome, use of the 5-HT$_{2A}$ receptor antagonist cyproheptadine may also be helpful. Cyproheptadine is only available in an oral form.

Atypical Antidepressants.

The atypical antidepressant class includes agents such as venlafaxine and duloxetine (SNRIs), bupropion (dopamine, norepinephrine, and some serotonin reuptake blockade), and trazodone (serotonin reuptake blockade and peripheral α-receptor antagonism). The variable receptor affinities of these agents lead to some distinctions in their clinical manifestations and management.

Clinical and Laboratory Manifestations.

In overdose, **venlafaxine** and other SNRIs have been associated with cardiac conduction defects, including QRS and QTc prolongation, and seizures. **Bupropion** warrants special consideration because it is one of the most common etiologies of toxicant-induced seizures in the United States. After ingestion of SR or extended-release (ER) preparations, seizures can occur as late as 18-20 hr after ingestion. In addition, bupropion can cause tachycardia, agitation, and QRS and QTc prolongation. These cardiac effects are thought to result from a reduction in cardiac intracellular coupling caused by inhibition at gap junctions in the heart. Mortality results from not only status epilepticus but also the cardiac conduction disturbances causing ventricular tachycardia. Bupropion is of growing concern with the rising popularity of the drug, especially in the ER formulation. In addition to sedation and signs of serotonin excess, trazodone overdose may be associated with hypotension from blockade of peripheral α-receptors.

Treatment.

Management is directed to clinical signs and symptoms. QRS and QTc interval prolongation after bupropion poisoning is typically resistant to the standard treatments of sodium bicarbonate and magnesium. Seizures are often brief and self-limited but can be treated with benzodiazepines if necessary. A patient poisoned with bupropion who shows unstable hemodynamics with prolonged ECG intervals or persistent seizure activity should receive Intralipid emulsion therapy. Because of the potential for delayed seizures, asymptomatic patients who have ingested an SR preparation of bupropion should be admitted to a monitored setting for at least 20-24 hr. Trazodone-associated hypotension typically responds to fluids, though it can require vasopressors in extreme cases.

Monoamine Oxidase Inhibitors.

Although now rarely used therapeutically, MAOIs remain important agents given their potential for serious and delayed toxicity. Ingestions of only 1 or 2 pills (6 mg/kg) are associated with toxicity in children. Clinical manifestations initially include hypertension, hyperthermia, tachycardia, muscle rigidity, and seizures, followed up to 24 hr later by hemodynamic instability and CV collapse. *Any child who ingests a MAOI should be admitted to a monitored setting for at least 24 hr, regardless of symptoms.* Management includes blood pressure control, cooling and benzodiazepines for hyperthermia, serial monitoring of CK and renal function, and fluid and vasopressor therapy for hemodynamic instability.

Psychiatric Medications: Antipsychotics

Clinicians are increasingly prescribing antipsychotic medications in the pediatric population. Antipsychotics are usually classified as either typical or atypical. In general, typical agents are associated with more side effects and toxicity than the atypical agents.

Pathophysiology.

Typical or “traditional” antipsychotics (haloperidol, droperidol, thioridazine, chlorpromazine, fluphenazine) are characterized by their antagonism at D_2 dopamine receptors. In therapeutic use, these agents are associated with extrapyramidal symptoms, tardive dyskinesia, and development of the **neuroleptic malignant syndrome (NMS)** . The *atypical* agents (aripiprazole, clozapine, quetiapine, risperidone, ziprasidone) were developed with relatively less dopamine (D_2 -receptor) antagonism in the nigrostriatum in an effort to avoid these side effects and improve their efficacy in managing the “negative” symptoms of schizophrenia. Instead, these agents have complex and varied interactions with multiple receptor types, including α-receptors, serotonin receptors, muscarinic acetylcholine receptors, and histamine receptors.

Clinical and Laboratory Manifestations.

Typical antipsychotic toxicity usually includes sedation, tachycardia, and QTc prolongation. Patients can present with acute dystonia, akathisia, and NMS, although these are seen less frequently in acute overdoses than in therapeutic use. The phenothiazines (e.g., thioridazine) can cause widening of the QRS interval from blockade of fast sodium channels. Clinically, NMS can be difficult to distinguish from serotonin syndrome.

Although the presentation of atypical antipsychotic toxicity can vary based on the receptor affinities of the specific agent, sedation, tachycardia, and QTc prolongation are common. Peripheral α-receptor blockade (e.g., with quetiapine) is associated with hypotension. In therapeutic use, clozapine is associated with agranulocytosis.

Diagnostic testing should include an ECG. Patients with hyperthermia or muscle rigidity should have a serum CK level sent to monitor for possible rhabdomyolysis. Antipsychotic levels are not readily available and are not helpful in managing acute poisoning.

Management.

Initial management involves assessing and supporting vital functions. In some patients, CNS depression may be so profound as to require intubation for airway control. Acute dystonia is treated with diphenhydramine and benztropine. Management of NMS includes conscientious supportive care, IV fluids, cooling, benzodiazepines, and bromocriptine or dantrolene in severe cases. QTc prolongation is managed with repletion of electrolytes (especially calcium, magnesium, and potassium), continuous cardiac monitoring, prevention of bradycardia (overdrive pacing, isoproterenol, atropine), and defibrillation if the patient develops torsades de pointes. Seizures typically are well controlled with benzodiazepines. Hypotension usually responds to boluses of IV fluids, although vasopressor therapy is necessary in some patients.

Household Products

Caustics

Caustics include acids and alkalis as well as a few common oxidizing agents (see Chapter 353). Strong acids and alkalis can produce severe injury even in small-volume ingestions.

Pathophysiology.

Alkalis produce a *liquefaction necrosis*, allowing further tissue penetration of the toxin and setting the stage for possible perforation. **Acids** produce a *coagulative necrosis,* which limits further tissue penetration, although perforation can still occur. The severity of the corrosive injury depends on the pH and concentration of the product as well as the length of contact time with the product. Agents with a pH of <2 or >12 are most likely to produce significant injury.

Clinical Manifestations.

Ingestion of caustic materials can produce injury to the oral mucosa, posterior pharynx, vocal cords, esophagus, and stomach. Patients can have significant esophageal injury even in the absence of visible oral burns. Symptoms include pain, drooling, vomiting, abdominal pain, and difficulty swallowing or refusal to swallow. Laryngeal injury can manifest as stridor and respiratory distress, necessitating intubation. In the most severe cases, patients can present in shock after perforation of a hollow viscus. Circumferential burns of the esophagus are likely to cause strictures when they heal, which can require repeated dilation or surgical correction and long-term follow-up for neoplastic changes in adulthood. Caustics on the skin or in the eye can cause significant tissue damage.

Treatment.

Initial treatment of caustic exposures includes thorough removal of the product from the skin or eye by flushing with water. *Emesis and lavage are contraindicated* . Activated charcoal should not be used because it does not bind these agents and can predispose the patient to vomiting and subsequent aspiration. Stridor or other signs of respiratory distress should alert the provider to the need for a thorough evaluation of the airway for potential intubation or surgical airway management. Endoscopy can be performed within 12-24 hr of ingestion for prognostic and diagnostic purposes in symptomatic patients or those with suspected injury on the basis of history and known characteristics of the ingested product. Endoscopy's role is purely diagnostic. Whether the risks of the procedure are justified is debatable. Expectant management with a period of nothing by mouth (NPO) and proton pump inhibitor therapy is likely appropriate for the majority of patients *without* airway burns or signs of mediastinitis or peritonitis. Endoscopy is contraindicated in such patients, who instead require immediate surgical consultation. Corticosteroids or prophylactic antibiotics are not beneficial.

Pesticides

Cholinesterase-Inhibiting Insecticides.

The most commonly used insecticides in agriculture are **organophosphates** and **carbamates** ; both are inhibitors of cholinesterase enzymes: acetylcholinesterase (AChE), pseudocholinesterase, and erythrocyte AChE. Most pediatric poisonings occur as the result of unintentional exposure to insecticides in and around the home or farm. The chemical warfare weapons known as “nerve agents” are also organophosphate compounds with a similar mechanism of action but much greater potency.

Pathophysiology.

Organophosphates and carbamates produce toxicity by binding to and inhibiting AChE, preventing the degradation of acetylcholine (ACh) and resulting in its accumulation at nerve synapses. If left untreated, organophosphates form an irreversible bond to AChE, permanently inactivating the enzyme. This process, called *aging* , occurs over a variable time period depending on the characteristics of the specific organophosphate. A period of weeks to months is required to regenerate inactivated enzymes. In contrast, carbamates form a temporary bond to the enzymes, typically allowing reactivation of AChE within 24 hr.

Clinical and Laboratory Manifestations.

Clinical manifestations of organophosphate and carbamate toxicity relate to ACh accumulation at peripheral nicotinic and muscarinic synapses and in the CNS. Symptoms of carbamate toxicity are usually less severe than those seen with organophosphates. A commonly used mnemonic for the symptoms of cholinergic excess at muscarinic receptors is **DUMBBELS** : diarrhea/defecation, urination, miosis, bronchorrhea/bronchospasm, bradycardia, emesis, lacrimation, and salivation. Nicotinic signs and symptoms include muscle weakness, fasciculation, tremors, hypoventilation (diaphragm weakness), hypertension, tachycardia, and dysrhythmias. Severe manifestations include coma, seizures, shock, arrhythmias, and respiratory failure.

Diagnosis of poisoning is based primarily on history and physical exam findings. Red blood cell cholinesterase and pseudocholinesterase activity levels can be measured in the laboratory. These are only helpful when compared to the patient's known baseline. As such, these assessments are typically limited to farmworkers undergoing ongoing occupational surveillance.

Treatment.

Basic decontamination should be performed, including washing all exposed skin with soap and water and immediately removing all exposed clothing. Activated charcoal is unlikely to be of benefit because these are liquids that are rapidly absorbed. Basic supportive care should be provided, including fluid and electrolyte replacement, intubation, and ventilation if necessary. The use of succinylcholine for rapid sequence intubation should be avoided because the same cholinesterase enzymes that are poisoned metabolize this neuromuscular blocking agent, leading to prolonged paralysis.

Two antidotes are useful in treating cholinesterase inhibitor poisoning: atropine and pralidoxime (see Table 77.7). **Atropine** , which antagonizes the muscarinic ACh receptor, is useful for both organophosphate and carbamate intoxication. Often, large doses of atropine must be administered by intermittent bolus or continuous infusion to control symptoms. Atropine dosing is primarily targeted to drying the respiratory secretions. **Pralidoxime** breaks the bond between the organophosphate and the enzyme, reactivating AChE. Pralidoxime is only effective if it is used before the bond ages and becomes permanent. Pralidoxime is not necessary for carbamate poisonings because the bond between the insecticide and the enzyme degrades spontaneously.

Without treatment, symptoms of organophosphate poisoning can persist for weeks, requiring continuous supportive care. Even with treatment, some patients develop a delayed polyneuropathy and a range of chronic neuropsychiatric symptoms.

Pyrethrins and Pyrethroids.

Pyrethrins are derived from the chrysanthemum flower and along with pyrethroids, synthetic derivatives, are the most commonly used pesticides in the home. Although >1,000 pyrethrins and pyrethroids exist, <20 are available in the United States, with **permethrin** being the most common. Exposure to these compounds occurs by inhalation, dermal absorption, or ingestion. Ingestion is the predominant route and typically occurs by eating contaminated foods. Permethrin is also a prescribed medication for the treatment of scabies and lice.

Pathophysiology.

Pyrethrins and pyrethroids prolong the open state of the voltage-gated Na^+ channel conduction, which is the main mechanism resulting in its pesticide activity. Pyrethrins have minimal toxicity in mammals because of rapid metabolism, higher affinity for the insect Na^+ channel, and decreased activity at higher temperatures seen in warm-blooded animals. Since pyrethroids were specifically manufactured to be more stable in the environment, they have a higher likelihood of toxicity.

Clinical and Laboratory Manifestations.

Pyrethrin exposures can lead to allergic reactions ranging from dermatitis to urticaria to anaphylaxis. Acute exposure can result in headache, nausea, dizziness, tremors, ataxia, choreoathetosis, loss of consciousness, and seizures. The severity of the symptoms depends on the magnitude of the exposure. Reports of acute lung injury have also occurred after pyrethroid exposures, although this is likely from the other components of the insecticide, such as surfactants and solvents. Paresthesias limited to the cutaneous exposure area can also occur following a dermal exposure. Chronic exposures have not been shown to result in any clinical manifestations. Although one can test for urinary pyrethroid metabolites, this is only useful for monitoring occupational exposure and has no role for the acute exposure.

Treatment.

Initial treatment should focus on decontamination, which involves removing all clothing and irrigation of exposed areas. Allergic reactions are treated the same as for antihistamines and corticosteroids. Systemic toxicity should be treated with excellent supportive care, using benzodiazepines for tremors and seizures.

Hydrocarbons

Hydrocarbons include a wide array of chemical substances found in thousands of commercial products. Specific characteristics of each product determine whether exposure will produce systemic toxicity, local toxicity, both, or neither. Nevertheless, aspiration of even small amounts of certain hydrocarbons can lead to serious, potentially life-threatening toxicity.

Pathophysiology.

The most important manifestation of hydrocarbon toxicity is *aspiration pneumonitis* through inactivation of the type II pneumocytes and resulting in surfactant deficiency (see Chapter 425). Aspiration usually occurs during coughing and gagging at the time of ingestion or vomiting after the attempted ingestion of an aliphatic hydrocarbon. The propensity of a hydrocarbon to cause aspiration pneumonitis is inversely proportional to its viscosity, and directly proportional to its volatility. Compounds with low viscosity and high volatility, such as mineral spirits, naphtha, kerosene, gasoline, and lamp oil, spread rapidly across surfaces and cover large areas of the lungs when aspirated. Only small quantities (<1 mL) of such chemicals need be aspirated to produce significant injury. Pneumonitis does not result from dermal absorption of hydrocarbons or from ingestion in the absence of aspiration. Gasoline and kerosene are poorly absorbed, but they often cause considerable irritation of the GI mucosa as they pass through the intestines.

Certain hydrocarbons have unique toxicities and can cause symptoms after ingestion, inhalation, or dermal exposures. Several chlorinated solvents, most notably carbon tetrachloride, can produce hepatic toxicity. **Methylene chloride** , found in some paint removers, is metabolized to carbon monoxide. **Benzene** is known to cause cancer, most often acute myelogenous leukemia, after long-term exposure. Nitrobenzene, aniline, and related compounds can produce methemoglobinemia. A number of **volatile** hydrocarbons, including toluene, propellants, refrigerants, and volatile nitrites, are frequently abused by inhalation. Some of these substances, principally the **halogenated** hydrocarbons (which contain a chlorine, bromine, or fluorine), can sensitize the myocardium to the effects of endogenous catecholamines. This can result in dysrhythmias and "sudden sniffing death." Chronic abuse of these agents can lead to cerebral atrophy, neuropsychologic changes, peripheral neuropathy, and kidney disease (see Chapter 140).

Clinical and Laboratory Manifestations.

Transient, mild CNS depression is common after hydrocarbon ingestion or inhalation. Aspiration is characterized by coughing, which usually is the 1st clinical finding. Chest radiographs may initially be normal, but they often show abnormalities within 6 hr of exposure in patients who have aspirated. Respiratory symptoms can remain mild or progress rapidly to acute respiratory distress syndrome (ARDS) and respiratory failure. Fever and leukocytosis are common accompanying signs in patients with pneumonitis and do not necessarily imply bacterial superinfection. Chest radiographs can remain abnormal long after the patient is clinically normal. Pneumatoceles can appear on the chest radiograph 2-3 wk after exposure.

After inhalational exposures to halogenated hydrocarbons, patients can present with ventricular dysrhythmias, often refractory to conventional management. Recurrent inhalation of the aromatic hydrocarbon **toluene** can lead to a type IV renal tubular acidosis.

Treatment.

Emesis and lavage are contraindicated given the risk of aspiration . Activated charcoal is not useful because it does not bind the common hydrocarbons and can also induce vomiting. If hydrocarbon-induced pneumonitis develops, respiratory treatment is supportive (see Chapter 425). Neither corticosteroids nor prophylactic antibiotics have shown any clear benefit. Standard mechanical ventilation, high-frequency ventilation, and extracorporeal membrane oxygenation (ECMO) have all been used to manage the respiratory failure and ARDS associated with severe hydrocarbon-induced pneumonitis.

Patients with dysrhythmias in the setting of halogenated hydrocarbon inhalation should be treated with β-blockers (usually esmolol) to block the effects of endogenous catecholamines on the sensitized myocardium.

Toxic Alcohols

Methanol is found in windshield washer fluids, deicers, paint removers, fuel additives, liquid fuel canisters, and industrial solvents. **Ethylene glycol** is found in antifreeze. Unintentional ingestion is the most common exposure in children, and small-volume ingestions of concentrated products can theoretically cause toxicity. The pathophysiology, acid-base derangements, and treatment of both chemicals are similar, although they differ in their primary end-organ toxicity. In both cases the metabolites of the parent compounds are responsible for the serious clinical effects that can follow exposure.

Isopropyl alcohol (rubbing alcohol), found in hand sanitizers, causes intoxication similar to that associated with ethanol but can also cause a hemorrhagic gastritis and myocardial depression in massive ingestions. Unlike ethylene glycol and methanol, isopropyl alcohol is metabolized to a ketone and does not cause a metabolic acidosis. Management is similar to that of ethanol ingestions (see Chapter 140) and is not further discussed here.

Methanol

Pathophysiology.

Methanol is oxidized in the liver by alcohol dehydrogenase to formaldehyde, which is further oxidized to formic acid by aldehyde dehydrogenase. Toxicity is caused primarily by formic acid, which inhibits mitochondrial respiration.

Clinical and Laboratory Manifestations.

Drowsiness, mild inebriation, nausea, and vomiting develop early after methanol ingestion. The onset of serious effects, including profound metabolic acidosis and visual disturbances, is often delayed up to 12-24 hr as the parent methanol undergoes metabolism to its toxic metabolites. This metabolism is further slowed if *ethanol* has also been ingested, since the liver will preferentially metabolize ethanol. Visual disturbances include blurred or cloudy vision, constricted visual fields, decreased acuity, and the “feeling of being in a snowstorm” and appear only after acidosis is well established. These visual defects may be reversible if treated early, but untreated can lead to permanent blindness. On examination, dilated pupils, retinal edema, and optic disc hyperemia may be noted. Initially, patients have an elevated osmolar gap, then develop an anion gap metabolic acidosis as the parent compound is metabolized to formic acid.

In young children, determining if a significant exposure has occurred is usually difficult based on history. Methanol blood levels are available at some laboratories and should be sent after a concerning exposure. If methanol blood levels are not readily available, estimation of an osmolar gap may be used as a surrogate marker, but a normal osmolar gap does not rule out ingestion of any alcohol. Serum osmolality is measured by the freezing-point depression method and compared with a calculated serum osmolarity.

Treatment.

Treatment is as discussed for ethylene glycol toxicity.

Ethylene Glycol

Pathophysiology.

Ethylene glycol is oxidized by alcohol dehydrogenase in the liver to glycolaldehyde, which is further converted to glycolic acid by aldehyde dehydrogenase. Glycolic acid is responsible for the metabolic acidosis and is further metabolized to glyoxylic and then to oxalic acid. Oxalic acid combines with serum and tissue calcium, forming calcium oxalate crystals that deposit throughout the body, especially in the renal parenchyma, leading to acute tubular necrosis.

Clinical and Laboratory Manifestations.

Early symptoms include nausea, vomiting, CNS depression, and inebriation. Delayed manifestations include an anion gap metabolic acidosis, hypocalcemia, and acute kidney injury. Even later, patients can develop cranial nerve palsies.

Both ethylene glycol and methanol can produce profound, life threatening metabolic acidosis and acidemia, with measured serum bicarbonates that may even be nondetectable. The onset of the acidosis is delayed up to 4-12 hr after ethylene glycol ingestion and may be delayed further with any concomitant ingestion of ethanol. Ethylene glycol blood concentrations are technically difficult to perform and are available only at some larger reference laboratories. In the absence of readily available ethylene glycol concentrations, calculation of the osmolar gap may be helpful as a surrogate marker.

Examination of the urine with a Wood lamp is neither sensitive nor specific for ethylene glycol ingestion. The earliest sign on a urinalysis of ethylene glycol poisoning is usually hematuria. Calcium oxalate crystals can be seen on urine microscopy but might not be evident early after exposure. Electrolytes (including calcium), acid-base status, kidney function, and ECG should be closely monitored in poisoned patients.

Treatment.

Because methanol and ethylene glycol are rapidly absorbed, gastric decontamination is generally not of value. The classic antidote for methanol and ethylene glycol poisoning was ethanol, a preferential substrate for alcohol dehydrogenase, thus preventing the metabolism of parent compounds to toxic metabolites. **Fomepizole** , a potent competitive inhibitor of alcohol dehydrogenase, has almost entirely replaced ethanol because of its ease of administration, lack of CNS and metabolic effects, and overall excellent patient tolerability profile (see Table 77.7). A serum concentration must be interpreted along with the time removed from exposure. A patient with a methanol level of 20 mg/dL 24 hr after exposure had a much larger dose than a patient with the same level only 1 hr after ingestion. Classic indications for fomepizole include ethylene glycol or methanol level >20 mg/dL (assuming no ethanol is present), history of potentially toxic ingestion (e.g., any intentional overdose), or history of ingestion with evidence of acidosis. There are few disadvantages to giving the initial dose of fomepizole to patients with a concerning history of ingestion or lab findings, and given the dosing schedule of fomepizole (every 12 hr), this strategy buys the clinician time to confirm or exclude the diagnosis before giving a 2nd dose. Adjunctive therapy includes folate (methanol toxicity), pyridoxine (ethylene glycol toxicity), and sodium bicarbonate infusion for both (if acidemic). If a child has had an unintentional exposure and the alcohol level cannot be obtained, a reasonable approach is to follow serum chemistries every 4 hr until 12 hr after the exposure. If the bicarbonate level on the chemistry panel does not fall in that period, a toxic exposure is unlikely (assuming no ethanol is present).

Hemodialysis effectively removes ethylene glycol, methanol, and their metabolites (except calcium oxalate) and corrects acid-base and electrolyte disturbances. Fomepizole should be given both before and immediately after dialysis. Indications for dialysis include a methanol level >50 mg/dL, acidosis, severe electrolyte disturbances, and renal failure. However, in the absence of acidosis and kidney failure, even massive ethylene glycol ingestions have been managed without dialysis. Methanol, however, because its elimination in the setting of alcohol dehydrogenase inhibition is prolonged, often warrants dialysis to remove the parent compound. Therapy (fomepizole and/or dialysis) should be continued until ethylene glycol and methanol levels are <20 mg/dL. While the visual effects from methanol poisoning are usually permanent, the kidney injury from ethylene glycol injury is not. Patients requiring hemodialysis after ethylene glycol poisoning will almost always recover complete renal function within 2-6 wk. Consultation with a PCC, medical toxicologist, and nephrologist may be helpful in managing toxic alcohol ingestions.

Plants

Exposure to plants, both inside the home and outside in backyards and fields, is one of the most common causes of unintentional poisoning in children. Fortunately, the majority of ingestions of plant parts (leaves, seeds, flowers) result in either no toxicity or mild, self-limiting effects. However, ingestion of certain plants can lead to serious toxicity (Table 77.12).

Table 77.12

Commonly Ingested Plants With Significant Toxic Potential

PLANT	SYMPTOMS	MANAGEMENT
Autumn crocus (*Colchicum autumnale*)	Vomiting Diarrhea Initial leukocytosis followed by bone marrow failure Multisystem organ failure	Activated charcoal decontamination Aggressive fluid resuscitation and supportive care
Belladonna alkaloids: jimson weed (*Datura stramonium*) Belladonna (“deadly nightshade”; *Atropa belladonna*)	Anticholinergic toxidrome Seizures	Supportive care, benzodiazepines Consider physostigmine if patient is a threat to self or others; only use if no conduction delays on ECG
Cardiac glycoside–containing plants (foxglove, lily of the valley, oleander, yellow oleander, etc)	Nausea Vomiting Bradycardia Dysrhythmias (AV block, ventricular ectopy) Hyperkalemia	Digoxin-specific Fab fragments
Jequirity bean and other abrin-containing species (e.g., rosary pea, precatory bean)	Oral pain Vomiting Diarrhea Shock Hemolysis Renal failure	Supportive care, including aggressive volume resuscitation and correction of electrolyte abnormalities
Monkshood (*Aconitum* species)	Numbness and tingling of lips/tongue Vomiting Bradycardia	Atropine for bradycardia Supportive care
Oxalate-containing plants: *Philodendron, Dieffenbachia, Colocasia*	Local tissue injury Oral pain	Supportive care, pain control

(“elephant ear”)	Vomiting	
Poison hemlock *(Conium maculatum)*	Vomiting Agitation followed by CNS depression Paralysis Respiratory failure	Supportive care
Pokeweed	Hemorrhagic gastroenteritis Burning of mouth and throat	Supportive care
Rhododendron	Vomiting Diarrhea Bradycardia	Atropine for symptomatic bradycardia Supportive care
Tobacco	Vomiting Agitation Diaphoresis Fasciculations Seizures	Supportive care
Water hemlock (*Cicuta* species)	Abdominal pain Vomiting Delirium Seizures	Supportive care, including benzodiazepines for seizures
Yew (*Taxus* species)	GI symptoms QRS widening Hypotension CV collapse	Supportive care Atropine for bradycardia Sodium bicarbonate does not appear to be effective

AV, Atrioventricular; CNS, central nervous system; CV, cardiovascular; ECG, electrocardiogram; Fab, fragment, antigen binding; GI, gastrointestinal.

The potential toxicity of a particular plant is highly variable, depending on the part of the plant involved (flowers are generally less toxic than the root or seed), the time of year, growing conditions, and the route of exposure. Assessment of the potential severity after an exposure is also complicated by the difficulty in properly identifying the plant. Many plants are known by several common names, which can vary among communities. Poison control centers have access to professionals who can assist in properly identifying plants. They also are well versed in the common poisonous plants in their service area and the seasons when they are more abundant. For these reasons, consultation with the local PCC may be very helpful in the management of these ingestions.

For potentially toxic plant ingestions, consider decontamination with activated charcoal in patients who present within 1-2 hr of ingestion; otherwise, treatment is primarily supportive and based on symptoms. The most common manifestation of toxicity after plant ingestion is GI upset, which can be managed with antiemetics and fluid and electrolyte support. Table 77.12 outlines management strategies for a few specific toxicities.

Toxic Gases

Carbon Monoxide

Although many industrial and naturally occurring gases pose a health risk by inhalation, the most common gas involved in pediatric exposures is carbon monoxide. CO is a colorless, odorless gas produced during the combustion of any carbon-containing fuel; the less efficient the combustion, the greater the amount of CO produced. Wood-burning stoves, kerosene heaters, old furnaces, hot-water heaters, closed-space fires, and automobiles are a few of the potential sources of CO.

Pathophysiology.

CO binds to hemoglobin with an affinity >200 times that of oxygen, forming carboxyhemoglobin (HbCO). In doing so, CO displaces oxygen and creates a conformational change in hemoglobin that impairs the delivery of oxygen to the tissues, leading to tissue hypoxia. HbCO levels are not well correlated with clinical signs of toxicity, likely because CO interacts with multiple proteins in addition to hemoglobin. CO binds to cytochrome oxidase, disrupting cellular respiration. CO displaces nitric oxide (NO) from proteins, allowing NO to bind with free radicals to form the toxic metabolite peroxynitrite, leading to lipid peroxidation and cellular damage. NO is also a potent vasodilator, in part responsible for clinical symptoms such as headache, syncope, and hypotension.

Clinical and Laboratory Manifestations.

Early symptoms are nonspecific and include headache, malaise, nausea, and vomiting. These symptoms are often misdiagnosed as indicating flu or food poisoning. At higher exposure levels, patients can develop mental status changes, confusion, ataxia, syncope, tachycardia, and tachypnea. Severe poisoning is manifested by coma, seizures, myocardial ischemia, acidosis, cardiovascular collapse, and potentially death. Physical examination should focus on the cardiovascular and neurologic systems because these are the most detrimentally effected by CO. Emergency department evaluation should include arterial or venous blood gas analysis with HbCO determined by CO-oximetry, CK level in severely poisoned patients, pregnancy test, and ECG in any patient with cardiac symptoms.

Treatment.

Prevention of CO poisoning is paramount and should involve educational initiatives and the use of home CO detectors. Treatment of CO poisoning focuses on the administration of 100% oxygen to enhance elimination of CO. In ambient air the average half-life of HbCO is 4-6 hr. This is dramatically reduced to 60-90 min by providing 100% oxygen at normal atmospheric pressures by non-rebreather face mask. Severely poisoned patients might benefit from **hyperbaric oxygen (HBO)** , which decreases the half-life of HbCO to 20-30 min and is thought also to decrease the risk of delayed neurologic sequelae. Although the clinical benefits and referral guidelines for HBO therapy remain controversial, frequently cited indications include syncope, coma, seizure, altered mental status, acute coronary syndrome, HbCO level >25%, abnormal cerebellar examination, and pregnancy. Consultation with a PCC, medical toxicologist, or HBO facility can assist clinicians in determining which patients could benefit from HBO therapy. Sequelae of CO poisoning include persistent and delayed cognitive and cerebellar effects. HBO advocates believe that the risk of such sequelae is minimized through the delivery of 100% oxygen at 3 atm of pressure. Patients typically receive oxygen, by non-rebreather mask or hyperbaric chamber, for 6-24 hr.

Hydrogen Cyanide

Pathophysiology.

Cyanide inhibits cytochrome-*c* oxidase, part of the electron transport chain, interrupting cellular respiration and leading to profound tissue hypoxia. Patients may be exposed to hydrogen cyanide (HCN) gas in the workplace (manufacturing of synthetic fibers, nitriles, and plastics) or by smoke inhalation in a closed-space fire.

Clinical and Laboratory Manifestations.

Onset of symptoms is rapid after a significant exposure. Clinical manifestations of toxicity include headache, agitation/confusion, sudden loss of consciousness, tachycardia, cardiac dysrhythmias, and metabolic acidosis. Cyanide levels can be measured in whole blood but are not readily available at most institutions. A severe lactic acidosis (lactate >10 mmol/L) in fire victims suggests cyanide toxicity. Impaired oxygen extraction by tissues is implied by elevated mixed-venous oxyhemoglobin saturation, another laboratory finding suggesting cyanide toxicity.

Treatment.

Treatment includes removal from the source of exposure, rapid administration of high concentrations of oxygen, and antidotal therapy. The cyanide antidote kit (no longer manufactured) includes nitrites (amyl nitrite and sodium nitrite) used to produce methemoglobin, which then reacts with cyanide to form cyanomethemoglobin. The 3rd part of the kit is sodium thiosulfate, given to hasten the metabolism of cyanomethemoglobin to hemoglobin and the less toxic thiocyanate. In patients for whom induction of methemoglobinemia could produce more risk than benefit, the sodium thiosulfate component of the kit may be given alone.

The U.S. Food and Drug Administration (FDA) has approved **hydroxocobalamin** for use in known or suspected cyanide poisoning (see Table 77.7). This antidote reacts with cyanide to form the nontoxic cyanocobalamin (vitamin B_{12}), which is then excreted in urine. Side effects of hydroxocobalamin include red discoloration of the skin and urine, transient hypertension, and interference with colorimetric lab assays. *Hydroxocobalamin has an overall safety profile that appears superior to that of the cyanide antidote kit and thus is the preferred antidote for cyanide poisoning.*

Miscellaneous Toxic Agents Found in the Home

Nicotine-Containing Products

Nicotine poisoning has become increasingly common with the recent advent of vaporizer (“vaping”) and e-cigarette devices. Although there are many nicotine-containing products (patches, gums, snuff, chewing tobacco, sprays, lozenges), tobacco cigarettes remain the main source of exposure. Prescription medications (varenicline and cytisine) are available that are partial nicotine receptor agonists. For children, some of the most concerning exposures are from the bottles of liquid nicotine used to refill vaping and e-cigarette devices. These bottles typically do not have childproof caps and contain a large amount of concentrated nicotine.

Pathophysiology.

Nicotine acts on nicotinic ACh receptors in the nervous system, neuromuscular junctions, and adrenal medulla, stimulating neurotransmitter release. Nicotine's effects on the dopaminergic reward pathway play a significant role in its addictive properties. The effects of nicotine are dose dependent; at lower doses it primarily acts on the brain, causing stimulation. At higher doses, nicotine overstimulates receptors, leading to inhibition and resulting in neuromuscular and nervous system blockade.

Clinical and Laboratory Manifestations.

Clinical effects of nicotine also depend on the dose. At low doses typically achieved through smoking, nicotine results in cognitive and mood enhancement, increased energy, and appetite suppression. At higher doses, significant toxicity follows a biphasic pattern, where cholinergic stimulation symptoms predominate and are later followed by inhibition. The first signs of nicotine poisoning are nausea, vomiting, diarrhea, and often muscle fasciculations. Tachycardia and hypertension occur initially, although in severe poisoning these progress to bradycardia, hypotension, coma, and respiratory muscle failure, which typically leads to death if not treated. Serum and urinary levels of nicotine and its metabolite cotinine can be obtained, but these rarely are available in real time and therefore have little effect on diagnosis and management.

Treatment.

Treatment of nicotine poisoning focuses on maximizing symptomatic and supportive care. Aggressive airway management should be the priority, especially in severe poisonings, because death usually occurs from respiratory muscle paralysis. IV fluids with escalation to vasopressors should be used for hypotension. Seizures should be managed with benzodiazepines, barbiturates, or propofol.

Single-Use Detergent Sacs

Commonly known as laundry “pods” for clothing, these products resemble candy to many children. When bitten into, a relatively large dose of concentrated detergent is expelled under pressure onto the posterior pharynx and vocal cords. This can lead to stridor and other signs of respiratory distress. Occasionally, and for unknown reasons, these children may also develop altered mental status. Supportive care with attention to any airway and breathing issues is warranted. Admission to the hospital is often indicated. Importantly, these are not considered caustic ingestions; the pH of these products is in the neutral zone. As such, upper GI endoscopy is rarely indicated. Curiously, laundry detergent drank from a bottle is rarely of significant concern.

Electric Dishwasher Detergent

Especially when in the form of crystals, these products are highly alkaline (pH >13), and exposure by ingestion can cause significant burns to the vocal cords and GI tract. Admission for expectant management or upper GI endoscopy is usually indicated.

Magnets

Most foreign body ingestions pass through the GI tract once known to have passed into the stomach. However, ingestion of ≥2 magnets (unless very weak refrigerator-style magnets) cause concern for bowel obstruction and perforation. Admission for attempted retrieval by endoscopy or clearance by WBI should be considered.

Batteries

Any disk or button-style battery lodged in the esophagus or airway should be considered a true emergency warranting immediate referral to an endoscopist for removal. These batteries can cause necrosis of the tissues in which they are lodged by continued electrical discharge and leaking of their contents (the former is likely the primary method of injury). Mucosal contact for even 2 hr might induce necrosis. Once past the lower esophageal sphincter, button or even larger batteries (e.g., AA, AAA) can usually be allowed to pass through the GI tract with close follow-up.

CHAPTER 78

Complementary Therapies and Integrative Medicine

Paula M. Gardiner, Caitlin M. Neri

Integrative medicine focuses on promoting physical, mental, emotional, spiritual, social, and educational well-being in the context of a medical home in a healthy family and community. The foundations of integrative medicine are health-promoting practices such as optimal nutrition and dietary supplements to prevent deficiencies, avoidance of addictive substances (e.g., nicotine, illicit drugs), physical activity, adequate sleep, a healthy environment, and supportive social relationships. Evidence-based **complementary therapies** such as dietary supplements, massage, chiropractic, other forms of bodywork, yoga, meditation practices, hypnosis, guided imagery, biofeedback, and acupuncture may also be used. Although prayer and healing rituals are sometimes included under the rubric of complementary and integrative therapies, they are not covered in this chapter.

Not including multivitamins and mineral supplements such as iron and calcium, an estimated 10–40% of healthy children and >50% of children with chronic conditions use integrative medicine in the United States. The prevalence could be even higher because these treatments usually occur without disclosure to the children's primary care physician. Common therapies include dietary supplements, deep breathing, guided imagery, mediation, biofeedback, hypnosis, yoga, acupuncture, massage, and aromatherapy.

Use of complementary therapies is most common among youth with chronic, incurable, or recurrent conditions such as cancer, depression and other mental health conditions, asthma, autism, headaches, abdominal pain, and other chronic painful conditions. Children's hospitals and pediatric subspecialty programs are increasingly offering integrative medicine strategies alongside traditional medicine, as part of the care of children in both inpatient and outpatient settings.

In a 2014 survey the American Pain Society identified 48 pediatric chronic pain clinics, with most offering some type of integrative medicine or behavioral health strategies with conventional medicine. For example, integrative therapies are increasingly being used in pediatric chronic pain clinics to treat functional bowel disorders. Recent reviews include supplements (e.g., ginger, peppermint oil) and mind-body techniques (e.g., hypnotherapy, biofeedback, acupuncture/acupressure) with traditional medical management for these common pediatric conditions.

Dietary Supplements

Under the 1994 U.S. Dietary Supplement Health and Education Act, a **dietary supplement** is a product taken by mouth that contains a *dietary ingredient* intended to supplement the diet. These may include vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glands, and metabolites. Dietary supplements are the most frequently used complementary therapies for children and adolescents (Table 78.1). Some uses are common and recommended, such as vitamin D supplements for breastfed infants and probiotics to prevent antibiotic-associated diarrhea, whereas other uses are more controversial, such as using herbal products to treat otitis media.

Table 78.1

Commonly Used Dietary Supplements in Pediatrics

PRODUCT	**USES**
VITAMINS	
B_2 (riboflavin)	Migraine headache prophylaxis
B_6 (pyridoxine)	Pyridoxine-dependent epilepsy; neuropathy; nausea associated with pregnancy
B_9 (folate)	Prevention of neural tube defects
D	Prevention of rickets; treatment of vitamin D deficiencies
Multivitamins	General health promotion
MINERALS	
Iodine (salt)	Prevent goiter and mental retardation
Iron	Prevent and treat iron-deficiency anemia
Magnesium	Constipation, asthma, migraine prevention
Zinc	Diarrhea in nutrient-poor populations
HERBS	
Aloe vera	Mild burns
Chamomile	Mild sedative, dyspepsia
Echinacea	Prevention of upper respiratory infections

Ginger	Nausea
Lavender (aromatherapy)	Mild sedative
Peppermint	Irritable bowel syndrome
Tea tree oil	Antibacterial (acne remedies), pediculicide (lice)
OTHER	
Melatonin	Insomnia
Omega-3 fatty acids	ADHD, allergies, inflammation, anxiety and mood disorders
Probiotics	Antibiotic-associated diarrhea; *Clostridium difficile* –associated diarrhea; constipation; irritable bowel syndrome; pouchitis; inflammatory bowel disorders

ADHD, Attention-deficit/hyperactivity disorder.

In the United States, dietary supplements do not undergo the same stringent evaluation and postmarketing surveillance as prescription medications. Although they may not claim to prevent or treat specific medical conditions, product labels may make *structure-function* claims. For example, a label may claim that a product “promotes a healthy immune system,” but it may not claim to cure the common cold.

According to the 2012 National Health Interview Survey, 5% of U.S. children used non-vitamin/mineral dietary supplements. (e.g., fish oil, melatonin, prebiotics, probiotics) Use of dietary supplements is most common among children whose families have higher income and education and whose parents use supplements, among older children, and among those with chronic conditions.

Despite this widespread use, many patients and their parents who use dietary supplements do not talk with their physician about their use. Several guidelines have called for more complete dietary supplement history taking by healthcare professionals. The Joint Commission recommends that clinicians routinely ask patients about their use of dietary supplements and include this information as part of the medication reconciliation process.

Dietary Supplement Safety

Dietary supplements may have safety issues in children, but toxicity is much less common with nonprescription dietary supplements than with prescription medications (Table 78.2). Toxicity depends on dose, use of other therapies, and the child's underlying medical condition. Current use of a dietary supplement (e.g., ephedra for weight loss) may not reflect its traditional use (e.g., ephedra as a component of a traditional Chinese medicine tea in small doses to improve allergic or respiratory symptoms). Moreover, herbs that are apparently safe for most adults may be more hazardous in specific conditions (e.g., newborns, patients with impaired renal or hepatic function), under special circumstances (e.g., after organ transplantation or other surgery), or when combined with prescription medications. Some natural products are toxic in and of themselves. Even when a product is safe when used correctly, it can cause mild or severe toxicity when used incorrectly. For example, although peppermint is a commonly used and usually benign gastrointestinal spasmolytic included in after-dinner mints, it can exacerbate gastroesophageal reflux.

Table 78.2

Clinical Toxicity of Selected Herbs

COMMON NAME	BOTANICAL NAME	THERAPEUTIC USES	POTENTIAL TOXICITY
Aconite (monkshood, wolfsbane)	*Aconitum* spp.	Sedative, analgesic, antihypertensive	Cardiac arrhythmias
Aloe	*Aloe* spp.	Burns, skin diseases	Nephritis, GI upset
Betel nut	*Areca catechu*	Mood elevation	Bronchoconstriction, oral cancers
Bloodroot	*Sanguinaria canadensis*	Emetic, cathartic, eczema	GI upset, vertigo, visual disturbances
Chaparral (greasewood)	*Larrea tridentata*	Aging, free radical scavenging	Hepatitis
Compound Q	*Trichosanthes kirilowii*	Anthelmintic, cathartic	Diarrhea, hypoglycemia, CNS toxicity
Dandelion	*Taraxacum officinale*	Diuretic, heartburn remedy	Anaphylaxis
Figwort (xuan shen)	*Scrophularia* spp.	Antiinflammatory, antibacterial	Cardiac stimulation
Ginseng	*Panax quinquefolium*	Antihypertensive, aphrodisiac, stimulant, mood elevation, digestive aid	Ginseng abuse syndrome
Goldenseal	*Hydrastis canadensis*	Digestive aid, mucolytic, anti-infective	Uterine, cardiac stimulation; GI upset, leukopenia
Hellebore	*Veratrum* spp.	Antihypertensive	Vomiting, bradycardia, hypotension
Hyssop	*Hyssopus officinalis*	Asthma, mucolytic	Seizures
Juniper	*Juniperus communis*	Hallucinogen	GI upset, seizures, renal injury, hypotension, bradycardia
Kava kava	*Piper methysticum*	Sedative	Inebriation
Kombucha		Stimulant	Metabolic acidosis, hepatotoxicity, death
Licorice	*Glycyrrhiza* spp.	Indigestion	Mineralocorticoid effects
Lily of the valley	*Convallaria* spp.	Cardiotonic	GI (nausea, vomiting), cardiac arrhythmias
Linn (willow)	*Salix caprea*	Purgative	Hemolysis with glucose-6-phosphate dehydrogenase

			deficiency
Lobelia (Indian tobacco)	*Lobelia* spp.	Stimulant	Nicotine intoxication
Ma Huang	*Ephedra sinica*	Stimulant	Sympathetic crisis, especially with monamine oxidase inhibitors
Mandrake	*Mandragora officinarum*	Hallucinogen	Anticholinergic syndrome
Mormon tea	*Ephedra nevadensis*	Stimulant, asthma, antipyretic	Hypertension, sympathomimetic
Nutmeg	*Myristica fragrans*	Hallucinogen, abortifacient	Hallucinations, GI upset
Oleander	*Nerium oleander*	Cardiac stimulant	Cardiac arrhythmias
Passionflower	*Passiflora caeruliea*	Hallucinogen	Hallucinations, seizures, hypotension
Periwinkle	*Vinca* spp.	Antiinflammatory, diabetes	Alopecia, seizures, hepatotoxicity
Pokeweed	*Phytolacca* spp.	Arthritis, chronic pain	GI upset, seizures, death
Sabah	*Sauropus androgynus*	Weight loss, vision	Pulmonary injury
Sage	*Salvia* spp.	CNS stimulant	Seizures
Snakeroot	*Rauwolfia serpentina*	Sedative, antihypertensive	Bradycardia, coma
Squill	*Urginea maritima*	Arthritis, cardiac stimulant	Seizures, arrhythmias, death
Thorn apple (jimsonweed)	*Datura stramonium*	Hallucinations	Anticholinergic
Tonka bean	*Dipteryx odorata*	Anticoagulant	Bleeding diathesis
Valerian root	*Valeriana* spp.	Sedative	Sedation, obtundation
Wild (squirting) cucumber	*Ecballium elaterium*	Constipation, antiinflammatory, rheumatic disease	Airway obstruction
Wormwood (mugwort)	*Artemisia* spp.	Stimulant, hallucinogen	Hallucinations, seizures, uterine stimulation
Yohimbine	*Corynanthe yohimbe*	Aphrodisiac, stimulant	Hypertension, sympathetic crisis

CNS, Central nervous system; GI, gastrointestinal.

From Kingston RL, Foley C: Herbal, traditional, and alternative medicines. In *Haddad and Winchester's clinical management of poisoning and drug overdose,* ed 4, Philadelphia, 2007, Saunders/Elsevier, p 1081.

Although there are good manufacturing practices for dietary supplements in the United States, dietary supplement labels might not accurately reflect the contents or concentrations of ingredients. Because of natural variability, variations of 10-1,000–fold have been reported for several popular herbs, even across lots produced by the same manufacturer. Herbal products may be contaminated with pesticides, microbial agents or products, or the wrong herb misidentified during harvesting. Products from developing countries (e.g., Ayurvedic products from South Asia) might contain toxic levels of mercury, cadmium, arsenic, or lead, either from unintentional contamination during manufacturing or from intentional additions by producers who believe that these metals have therapeutic value. Approximately 30–40% of Asian patent medicines include potent pharmaceuticals, such as analgesics, antibiotics, hypoglycemic agents, or corticosteroids; typically the labels for these products are not written in English and do not note the inclusion of pharmaceutical agents. Even conventional mineral supplements, such as calcium, have been contaminated with lead or had significant problems with product variability.

Many families use supplements concurrently with medications, posing hazards of interactions (Table 78.3). Using the same principles of drug-drug interactions can help determine if a supplement-drug interaction is a concern. For example, St. John's wort induces CYP3A4 activity of the cytochrome P450 enzyme system and thus can enhance elimination of most drugs that use this pathway, including digoxin, cyclosporine, protease inhibitors, oral contraceptives, and numerous antibiotics, leading to subtherapeutic serum levels.

Table 78.3

Common Herbal Dietary Supplement (HDS)–Drug Interactions

HDS	DRUGS	POTENTIAL CONSEQUENCES/REACTIONS
Aloe vera	Glibenclamide (glyburide)	↑ Oral aloe vera gel can cause additive glycemic-lowering effects when taken concurrently with a hypoglycemic agent.
Bitter orange	Phenelzine	↑ Risk of hypertensive crisis
Garlic	Ritonavir	↓ Effect of ritonavir
	Saquinavir	↓ Effect of saquinavir
Licorice	Warfarin	↑ Risk of bleeding
Grapefruit	Calcium channel blockers	Grapefruit juice has been found to increase bioavailability of certain drugs by inhibition of cytochrome P450 (CYP) 3A4 isozyme in liver and gut wall.
Melatonin	Zolpidem	↑ Sedative effects
Valerian	Alprazolam, phenobarbital	↑ Central nervous system depression
Goldenseal	Inhibition of CYP2D6 and CYP3A4	May affect approximately 50% of common pharmaceutical agents
St. John's wort	Cyclosporine, tacrolimus, warfarin, protease inhibitors, digoxin, theophylline, venlafaxine, oral contraceptives	May decrease drug effectiveness

↓, Decreasing; ↑, increasing.

Dietary Supplement Efficacy

Evidence about the effectiveness of dietary supplements to prevent or treat pediatric problems is mixed, depending on the product used and condition treated. Some herbal products may be helpful adjunctive treatments for common childhood problems; some herbs have proved helpful for colic (fennel and the combination of chamomile, fennel, vervain, licorice, and balm mint), nausea (ginger), irritable bowel syndrome (peppermint), and diarrhea (probiotics).

Massage and Chiropractic

Massage is usually provided at home by parents and in clinical settings by professional massage therapists, physical therapists, and nurses. **Infant massage** is routinely provided in many neonatal intensive care units to promote growth and development in preterm infants. Massage also has been demonstrated to be beneficial for pediatric patients with asthma, insomnia, colic, cystic fibrosis, or juvenile arthritis and patients undergoing cancer therapy. **Massage therapy** is generally safe. Professional massage practice is regulated by state government and may be in the form of a license, registration, or certification. More than 40 states license massage therapists, with licensure being the strictest form of regulation, making it illegal for any nonlicensed professional to practice massage therapy.

Chiropractic healthcare deals with the diagnosis, treatment, and prevention of disorders of the neuromusculoskeletal system and their effects on general health. Currently, >60,000 chiropractors have licensure in the United States, with licensure in all 50 states. Most medical insurance companies cover chiropractic funding. Children and families seek chiropractic care for common childhood conditions such as asthma, infantile colic, nocturnal enuresis, constipation, and headache. A recent consensus update on chiropractic care in children overall found limited support in a small number of high-quality studies for effectiveness of chiropractic care for such common childhood conditions. With respect to safety, the evidence is also limited; however, published cases of serious adverse events in infants and children receiving chiropractic care are rare. If children and families are seeking chiropractic care, it is appropriately done in collaboration with the child's pediatric primary care provider to ensure patient safety.

Mind-Body Therapies

Mind-body therapies such as slow, deep breathing, meditation, guided imagery, biofeedback, hypnosis, tai chi, and yoga are also frequently used complementary therapies in pediatrics. These practices can be learned informally through books, YouTube videos, compact discs, digital video discs, smartphone apps, or classes, as well as in therapeutic sessions with health professionals, such as psychologists and social workers (Table 78.4). Substantial research suggests that such practices can aid in reducing anxiety, insomnia, and stress-related conditions, including migraine headaches and functional abdominal pain. These therapies can also help patients struggling with chronic pain.

Table 78.4

Commonly Used Mind-Body Practices in Pediatrics

PRACTICE	USES
Biofeedback	Preventing migraine headaches; reducing stress and anxiety; encopresis/constipation treatment; treatment of stress incontinence; neurofeedback is experimental for ADHD.
Deep breathing	Relaxation; stress management
Guided imagery	Stress management; anxiety reduction; pain relief
Hypnosis	Correcting habit disorders; preventing headaches; managing pain
Meditation	Stress management; improving concentration
Tai chi	Improving balance, coordination, concentration, and discipline
Yoga	Improving balance, coordination, and concentration

ADHD, Attention-deficit/hyperactivity disorder.

Acupuncture

Modern acupuncture incorporates treatment traditions from China, Japan, Korea, France, and other countries. In the United States, acupuncturists are licensed to practice in 45 states. Acupuncture can be delivered to pediatric patients in hospital and clinic settings to treat a variety of ailments. Acupuncture is particularly useful for children experiencing pain, and acupuncture services are offered alongside conventional medicine and psychology by >50% of North American academic pediatric chronic pain programs. The technique that has undergone most scientific study involves penetrating the skin with thin, solid, metallic needles manipulated by hand or by electrical stimulation. Variants include rubbing (**shiatsu**), heat (**moxibustion**), lasers, magnets, pressure (**acupressure**), or electrical currents.

Although pediatric patients may be averse to needles, when approached in a developmentally appropriate way by an acupuncturist trained in pediatrics, children are often amenable to acupuncture and report that it is helpful. Acupuncture can offer significant benefits in the treatment of recurrent headache, anxiety, back and other types of pain, depression, abdominal pain, and nausea. As with any needle therapy, infections and bleeding are rare but can occur, and more serious complications, such as pneumothorax, occur in <1 in 30,000 treatments.

Cannabis

Because marijuana has been legalized in many states for both recreational (adult) use and medical use, caregivers and families have inquired about the potential health benefits of cannabis for both children and adults. At this time, no pediatric studies support any health benefit of cannabis for children. Furthermore, significant safety concerns remain, since detrimental effects of marijuana on the developing brain have been documented.

It is important to note that in some children with severe refractory **epilepsy** , oral **cannabidiol** , a nonpsychoactive component in marijuana, has provided improvement in seizure control. On a case-by-case basis, this is a reasonable consideration for families facing this rare and difficult challenge, and additional research is required in this area, especially since the purity and regulation of marijuana and its commercially available component products are variable. Most of the recent pediatric literature on cannabis describes an increase in accidental ingestions in young children, presumably in association with the increase in products now available for adult use; this is an additional safety risk for pediatricians to consider.

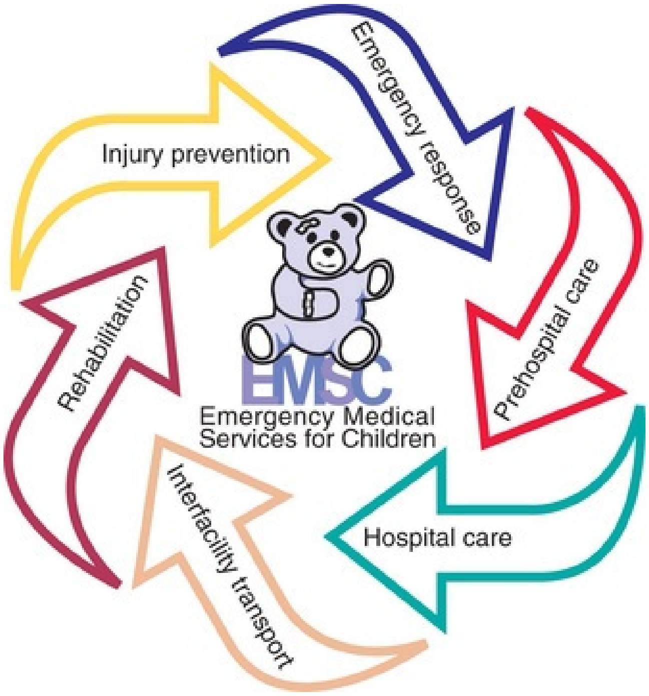
Emergency Medical Services for Children

Joseph L. Wright, Steven E. Krug

The overwhelming majority of the 27 million children who present annually for emergency care in the United States are seen at community hospital emergency departments (EDs). Visits to children's hospital EDs account for just 10% of initial emergency care encounters. This distribution suggests that the greatest opportunity to optimize care for acutely ill or injured pediatric patients, on a population basis, occurs broadly as part of a systems-based approach to emergency services, an approach that incorporates the unique needs of children at every level. Conceptually, emergency medical services for children are characterized by an integrated, continuum-of-care model (Fig. 79.1). The model is designed such that patient care flows seamlessly from the primary care medical home through transport and on to hospital-based definitive care. It includes the following 5 principal domains of activity:



Injury prevention
Emergency response
Prehospital care
Hospital care
Interfacility transport
Rehabilitation
EMSC
Emergency Medical Services for Children

FIG. 79.1 **The emergency medical services for children (EMSC) continuum of care. Seriously ill and injured children interface with a large number of healthcare personnel as they move through the EMSC system.**

1. Prevention, primary and secondary
2. Out-of-hospital care, both emergency response and prehospital transport
3. Hospital-based care: ED and inpatient, including critical care
4. Interfacility transport, as necessary, for definitive or pediatric medical and surgical subspecialty care (see Chapter 79.1)
5. Rehabilitation

The federal **Emergency Medical Services for Children (EMSC)** program of the Health Resources and Services Administration's Maternal and Child Health Bureau has stewarded improvements in the care of children in the context of the continuum-of-care model. The programmatic mission of the EMSC program is as follows:

◆ To ensure state-of-the-art emergency medical care for ill or injured children and adolescents of all ages.

◆ To ensure that pediatric services are well integrated into an emergency medical services (EMS) system and backed by optimal resources.

◆ To ensure that the entire spectrum of emergency services—including primary prevention of illness and injury, acute care, and rehabilitation—is provided to infants, children, adolescents, and young adults.

Primary Care Physician and Office Preparedness

The primary care physician (PCP) has multiple important roles in the EMS system. Through anticipatory guidance, the PCP can help shape the attitudes, knowledge, and behaviors of parent and child, with the primary goal of preventing acute medical events, such as injury and status asthmaticus. The point-of-care initiation for many acute problems is often the PCP office. From the standpoint of personnel, equipment, training, and protocols, the PCP office setting must be adequately prepared to initially manage acute and emergency exacerbations of common pediatric conditions, such as respiratory distress and seizures. Furthermore, on rare occasion, the PCP office environment may be confronted with a child in clinical extremis who requires resuscitative intervention and stabilization. It is therefore incumbent on the PCP not only to ensure access to EMS, that is, 911 system activation, but also to ensure that there is adequate, on-site psychomotor skill preparation to deal with such an emergency. **Office preparedness** requires training and continuing education for staff members, protocols for emergency intervention, ready availability of appropriate resuscitation drugs and equipment, and knowledge of local EMS resources and ED capabilities. PCPs can also play a pivotal role in informing and advocating for pediatric emergency and disaster readiness in local EMS agencies, schools and childcare programs, and community hospitals; this is particularly important in rural communities.

Staff Training and Continuing Education

It is a reasonable expectation that all office staff, including receptionists and medical assistants, be trained in cardiopulmonary resuscitation (CPR) with their certification maintained annually. Nurses and physicians should also have training in a systematic approach to pediatric resuscitation. Core knowledge may be obtained through standardized courses in **advanced life support (ALS)** offered by national medical associations and professional organizations. Frequent practice and timely recertification is important for knowledge retention and skill maintenance. Examples include the Pediatric Advanced Life Support (PALS) and Pediatric Emergency Assessment, Recognition and Stabilization (PEARS) courses sponsored by the American Heart Association (AHA), the Advanced Pediatric Life Support (APLS) course sponsored by the American Academy of Pediatrics (AAP) and American College of Emergency Physicians (ACEP), and the Emergency Nurses Pediatric Course (ENPC) sponsored by the Emergency Nurses Association (ENA).

Protocols

Standardized protocols for telephone triage of seriously ill or injured children are essential. When a child's clinical status is in question and prehospital care is available, ambulance transport in the care of trained personnel is always preferable to transport by other means (e.g., private vehicle). This obviates the potentially serious medical consequences of relying on unskilled and distraught parents without the ability to provide even **basic life support (BLS)** measures to an unstable child during transport to an ED. Practitioners can work with their local pediatric emergency care resource center (e.g., children's hospital, academic medical center, trauma center) to develop and maintain written protocols for office-based management of a range of conditions, including anaphylaxis, cardiopulmonary arrest, head trauma, ingestions, shock, status asthmaticus, status epilepticus, and upper airway obstruction. Regular practice using mock code scenarios improves office-based practitioner and office staff confidence and self-efficacy in managing these problems.

Resuscitation Equipment

Availability of necessary equipment is a vital part of an emergency response. Every physician's office should have essential resuscitation equipment and medications packaged in a pediatric resuscitation cart or kit (Table 79.1). This cart or kit should be checked on a regular basis and kept in an accessible location known to all office staff. Outdated medication, a laryngoscope with a failed light source, or an empty oxygen tank represents a potential catastrophe in a resuscitation scenario. Such an incident can be easily avoided if an equipment checklist and regular maintenance schedule are implemented. A pediatric kit that includes posters, laminated cards, or a color-coded length-based resuscitation tape specifying emergency drug doses and equipment size are invaluable in avoiding critical therapeutic errors during resuscitation.

Table 79.1

Recommended Drugs and Equipment for Pediatric Office Emergencies

DRUGS/EQUIPMENT	PRIORITY
DRUGS	
Oxygen	E
Albuterol for inhalation	E
Epinephrine (1 : 1,000 [1 mg/mL])	E
Activated charcoal	S
Antibiotics	S
Anticonvulsants (diazepam/lorazepam)	S
Corticosteroids (parenteral/oral)	S
Dextrose (25%)	S
Diphenhydramine (parenteral, 50 mg/mL)	S
Epinephrine (1 : 10,000 [0.1 mg/mL])	S
Atropine sulfate (0.1 mg/mL)	S
Naloxone (0.4 mg/mL)	S
Sodium bicarbonate (4.2%)	S
INTRAVENOUS FLUIDS	
Normal saline (0.9 NS) *or* lactated Ringer solution (500 mL bags)	S
5% dextrose, 0.45 NS (500 mL bags)	S
EQUIPMENT FOR AIRWAY MANAGEMENT	
Oxygen and delivery system	E
Bag-valve-mask (450 mL and 1,000 mL)	E
Clear oxygen masks, breather and non-rebreather, with reservoirs (infant, child, adult)	E
Suction device, tonsil tip, bulb syringe	E
Nebulizer (or metered-dose inhaler with spacer/mask)	E
Oropharyngeal airways (sizes 00-5)	E
Pulse oximeter	E
Nasopharyngeal airways (sizes 12-30F)	S
Magill forceps (pediatric, adult)	S
Suction catheters (sizes 5-16F and Yankauer suction tip)	S
Nasogastric tubes (sizes 6-14F)	S
Laryngoscope handle (pediatric, adult) with extra batteries, bulbs	S
Laryngoscope blades (straight 0-2; curved 2-3)	S
Endotracheal tubes (uncuffed 2.5-5.5; cuffed 6.0-8.0)	S
Stylets (pediatric, adult)	S

Esophageal intubation detector or end-tidal carbon dioxide detector	S
EQUIPMENT FOR VASCULAR ACCESS AND FLUID MANAGEMENT	
Butterfly needles (19-25 gauge)	S
Catheter-over-needle device (14-24 gauge)	S
Arm boards, tape, tourniquet	S
Intraosseous needles (16 and 18 gauge)	S
Intravenous tubing, micro-drip	S
MISCELLANEOUS EQUIPMENT AND SUPPLIES	
Color-coded tape or preprinted drug doses	E
Cardiac arrest board/backboard	E
Sphygmomanometer (infant, child, adult, thigh cuffs)	E
Splints, sterile dressings	E
Automated external defibrillator with pediatric capabilities	S
Spot glucose test	S
Stiff neck collars (small/large)	S
Heating source (overhead warmer/infrared lamp)	S

E, Essential; S, strongly suggested.

From Frush K, American Academy of Pediatrics, Committee on Pediatric Emergency Medicine: Policy statement-preparation for emergencies in the offices of pediatricians and pediatric primary care providers, *Pediatrics* 120:200–212, 2007. Reaffirmed *Pediatrics* 128:e748, 2011.

To facilitate emergency response when a child needs rapid intervention in the office, all personnel should have designated roles. Organizing a “code team” within the office ensures that necessary equipment is made available to the physician in charge, that an appropriate medical record detailing all interventions and the child's response is generated, and that the 911 call for EMS response or a transport team is made in a timely fashion.

Transport

Once the child has been stabilized, a decision must be made on how best to transport a child to a facility capable of providing definitive care. If a child has required airway or cardiovascular support, has altered mental state or unstable vital signs, or has significant potential to deteriorate en route, it is not appropriate to send the child via privately owned vehicle, regardless of proximity to a hospital. Even when an ambulance is called, it is the PCP's responsibility to initiate essential life support measures and to attempt to stabilize the child before transport.

In metropolitan centers with numerous public and private ambulance agencies, the PCP must be knowledgeable about the level of service provided by each. The availability of BLS vs ALS services, the configuration of the transport team, and pediatric expertise vary greatly among agencies and across jurisdictions. BLS services provide basic support of airway, breathing, and circulation, whereas

ALS units are capable of providing resuscitation drugs and procedural interventions as well. Some communities may have only BLS services available, whereas others may have a 2-tiered system, providing both BLS and ALS. It may be appropriate to consider **medical air transport** when definitive or specialized care is not available within an immediate community or when ground transport times are prolonged. In that case, initial transport via ground to an appropriate helicopter landing zone or a local hospital for interval stabilization may be undertaken, pending arrival of the air transport team. Independent of whether a child is to be transported by air or ground, copies of the pertinent medical records and any imaging or laboratory studies should be sent with the patient, and a call made to the physicians at the receiving facility to alert them to the referral and any treatments administered. Such notification is not merely a courtesy; direct physician-to-physician communication is essential to ensure adequate transmission of patient care information, to allow mobilization of necessary resources in the ED, and to redirect the transport if the emergency physician believes that the child would be more optimally treated at a facility with specialized services.

Pediatric Prehospital Care

Prehospital care refers to emergency assistance rendered by trained emergency medical personnel before a child reaches a treating medical facility. The goals of prehospital care are to further minimize systemic insult or injury through a series of well-defined and appropriate interventions and to embrace principles that ensure patient safety. Most U.S. communities have a formalized EMS system; the organizational structure and nature of emergency medical response depend greatly on local demographics and population base. EMS may be provided by volunteers or career professionals working in a fire department–based or independent 3rd service response system. Key points to recognize in negotiation of the juncture between the community physician and the local EMS system include access to the system, provider capability, and destination determination.

Access to the EMS System

Virtually all Americans have access to the 911 telephone service that provides direct access to a dispatcher who coordinates police, fire, and EMS responses. Some communities have an enhanced telephone 911 system, in which the location of the caller is automatically provided to the dispatcher, permitting emergency response even if the caller, such as a young child, cannot give an address. The extent of medical training for these dispatchers varies among communities, as do the protocols by which they assign an emergency response level (BLS vs ALS). In some smaller communities, no coordinated dispatch exists, and emergency medical calls are handled by the local law enforcement agency.

When activating the 911 system, the physician must make clear to the dispatcher the nature of the medical emergency and the condition of the child. In many communities, emergency medical dispatchers are trained to ask a series of questions per protocol that determines the appropriate level of provider to be sent.

Provider Capability

There are many levels of training for prehospital EMS providers, ranging from individuals capable of providing only first aid to those trained and licensed to provide ALS. All EMS personnel, whether basic *emergency medical technicians* (EMTs) or paramedics, receive some training in pediatric emergencies; however, pediatric cases constitute approximately 10% of all EMS transports.

First responders may be law enforcement officers or firefighters, who are dispatched to provide emergency medical assistance, or bystanders. Public safety personnel have a minimum of 40 hr of training in first aid and CPR. Their role is to provide rapid response and stabilization pending the arrival of more highly trained personnel. In some smaller communities, this may be the only prehospital emergency medical response available.

In the United States the bulk of emergency medical response is provided by EMTs, who may be volunteers or paid professionals. Basic EMTs may staff an ambulance after undergoing a training program of approximately 100 hr. They are licensed to provide BLS services but may receive further training in some jurisdictions to expand their scope of practice to include intravenous catheter placement and fluid administration, management of airway adjuncts, and use of an automated external defibrillator (AED).

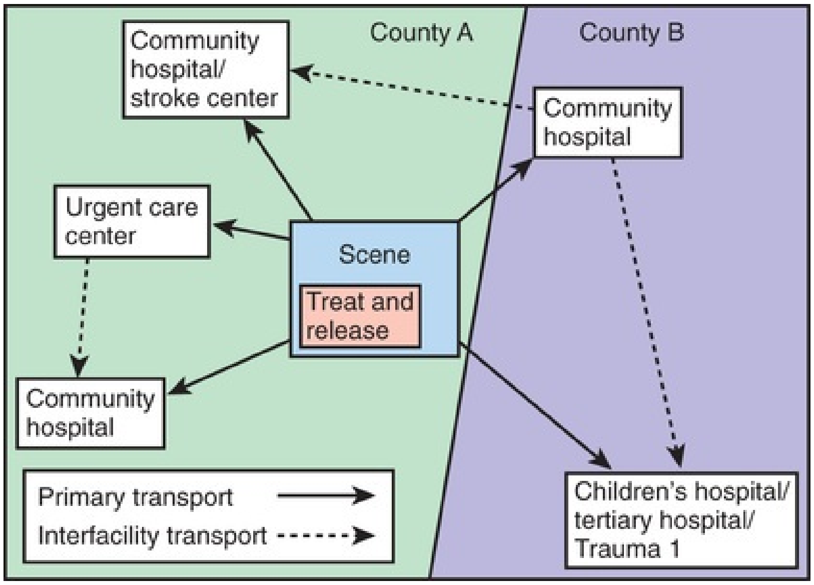
Paramedics, or EMT-Ps, represent the highest level of EMT response, with medical training and supervised field experience of approximately 1,000 hr. Paramedic skills include advanced airway management, including endotracheal intubation; placement of peripheral, central, or intraosseous lines; intravenous administration of drugs; administration of nebulized aerosols; needle thoracostomy; and cardioversion and defibrillation. These professionals provide ALS services, functioning out of an ambulance equipped as a mobile intensive care unit (ICU). In the joint policy statement *Equipment for Ground Ambulances* , the AAP, ACEP, American College of Surgeons Committee on Trauma, EMSC, ENA, National Association of EMS Physicians, and National Association of EMS Officials have published guideline standards for essential ambulance equipment, medications, and supplies necessary to provide BLS and ALS care across the age spectrum. This essential equipment list represents one of the reference standards that the federal EMSC program has adopted as a performance measure for state-level operational readiness to care for children in an EMS system.

Both basic EMTs and paramedics function under the delegated licensing authority of a supervisory EMS medical director. This physician oversight of prehospital practice is broadly characterized under the umbrella term *medical control.* **Direct** , or **online** , **medical control** refers to medical direction either at the scene or in real time via voice or video transmission. **Indirect** , or **offline** , **medical control** refers to the administering of medical direction before and after the provision of care. Offline activities, such as provider education and training, protocol development, and medical leadership of quality assurance/quality improvement programs, represent areas in need of greater pediatric input. As a measure of the degree to which EMSC permanence is being established in state EMS systems, the federal EMSC program has required demonstration of participation in online and offline medical direction activities for pediatric patients and the presence of an EMSC advisory committee at the state level. These advisory bodies are well positioned to support EMS agencies in their pediatric readiness as well as provide a forum for the active engagement of pediatric care experts at a system level.

Destination Determination

The destination to which a pediatric patient is transported may be defined by parental preference, provider preference, or jurisdictional protocol, which is typically predicated on field assessment of anatomic and physiologic criteria and, in the case of trauma, mechanism of injury. In communities served by an organized trauma or regionalized EMS system that incorporates pediatric designation based on objectively verified hospital capabilities, seriously ill or injured children may be triaged by protocol to the highest-level center reachable within a reasonable amount of time. The mantra is to deliver the child to the *right care in the right time* , even if it requires bypassing closer hospitals. An exception is the child in full cardiorespiratory arrest, for whom expeditious transport to the nearest facility is always warranted.

Regionalization in the context of EMS is defined as a geographically organized system of services that ensures access to care at a level appropriate to patient needs while maintaining efficient use of available resources. This system concept is especially germane in the care of children, given the relative scarcity of facilities capable of managing the full range and scope of pediatric conditions (Fig. 79.2). Regionalized systems of care coordinated with emergency medical dispatch, field triage, and EMS transport have demonstrated efficacy in improving outcomes for **pediatric trauma** patients, especially for younger children and for children with isolated head injury. Emerging evidence also suggests a similar benefit conferred to children in **shock** identified in the field who are preferentially transported to hospital EDs with documented pediatric ALS capability. The existence of statewide or regional standardized systems that formally recognize hospitals able to stabilize and/or manage pediatric medical emergencies is another federal EMSC performance measure against which operational capacity to provide optimal pediatric emergency care in the United States is currently being evaluated.



County A

Primary transport
Interfacility transport

FIG. 79.2 Transport options within a coordinated, regionalized emergency medical

services system model. The objective is to ensure access to definitive care at a level appropriate to meet patient needs. *Solid arrows,* Primary transport; *dotted arrows* , interfacility transport. (Adapted from Institute of Medicine, Committee on the Future of Emergency Care in the U.S. Health System: *Hospital-based emergency care: at the breaking point* , Washington, DC, 2006, National Academies Press.)

In communities that do not have a hospital with the equipment and personnel resources to provide definitive pediatric inpatient care, **interfacility transport** of a child to a regional center should be undertaken after initial stabilization (see Chapter 79.1).

The Emergency Department

The ability of hospital EDs to respond to the emergency care of children varies and depends on a number of factors in addition to availability of equipment and supplies. Training, awareness, and experience of the staff as well as access to pediatricians and medical and surgical subspecialists also play a key role. The majority of children who require emergency care are evaluated in community hospitals by physicians, nurses, and other healthcare providers with variable degrees of pediatric training and experience. Although children account for approximately 25% of all ED visits, only a fraction of these encounters represent true emergencies. Because the volume of critical pediatric cases is low, emergency physicians and nurses working in lower-volume community hospital EDs often have limited opportunity to reinforce their knowledge and skills in the assessment of ill or injured children and in pediatric resuscitation. Indeed, 50% of U.S. hospital EDs provide care for <10 children per day. General pediatricians from the community or pediatric hospitalists may be consulted when a seriously ill or injured child presents to the ED, and they should have a structured approach to the initial evaluation and treatment of an unstable child of any age, regardless of the underlying diagnosis. *Early recognition of life-threatening abnormalities in oxygenation, ventilation, perfusion, and central nervous system function and rapid intervention to correct those abnormalities are key to successful resuscitation and stabilization of the pediatric patient.*

The **National Pediatric Readiness Project (NPRP)** , a 2013–2014 survey of pediatric readiness in U.S. EDs, found higher readiness levels (as measured by compliance with published guidelines) in larger-volume EDs and in hospitals with a physician and/or nurse pediatric emergency care coordinator. Further information about the NPRP, including data by state, may be found on the website of the EMSC Innovation and Improvement Center, https://emscimprovement.center/ .

Baseline readiness standards must be met by all EDs that care for children, to ensure that children receive the best emergency care possible. Specific recommendations on equipment, supplies, and medications for the ED are listed and updates available on the AAP website. Table 79.2 lists sample policies, procedures, and protocols specifically addressing the needs of children in the ED.

Table 79.2

Guidelines for Pediatric-Specific Policies, Procedures, and Protocols for the Emergency Department (ED)

Illness and injury triage
Pediatric patient assessment and reassessment
Documentation of pediatric vital signs, abnormal vital signs, and actions to be taken for abnormal vital signs
Immunization assessment and management of the underimmunized patient
Sedation and analgesia for procedures, including medical imaging
Consent (including situations in which a parent is not immediately available)
Social and mental health issues
Physical or chemical restraint of patients
Child maltreatment (physical and sexual abuse, sexual assault, and neglect) mandated reporting criteria, requirements, and processes
Death of the child in the ED
Do-not-resuscitate orders
Family-centered care, including:

1. Involving families in patient care decision-making and in medication safety processes.
2. Family presence during all aspects of emergency care, including resuscitation.
3. Education of the patient, family, and regular caregivers.
4. Discharge planning and instruction.
5. Bereavement counseling.

Communication with patient's medical home or primary healthcare provider

Medical imaging policies that address age- or weight-appropriate dosing for children receiving studies that impart ionizing radiation, consistent with ALARA (as low as reasonably achievable) principles

All-hazard disaster preparedness plan that addresses the following pediatric issues:

  a. Availability of medications, vaccines, equipment, and appropriately trained providers for children in disasters.
  b. Pediatric surge capacity for both injured and noninjured children.
  c. Decontamination, isolation, and quarantine of families and children of all ages.
  d. A plan that minimizes parent-child separation and includes system tracking of pediatric patients, allowing for the timely reunification of separated children with their families.
  e. Access to specific medical and mental health therapies, as well as social services, for children in the event of a disaster.
  f. Disaster drills, which should include a pediatric mass casualty incident at least every 2 yr.
  g. Care of children with special healthcare needs.
  h. A plan that includes evacuation of pediatric units and pediatric specialty units.

Adapted from Gausche-Hill M, Krug SE, American Academy of Pediatrics Committee on Pediatric Emergency Medicine; American College of Emergency Physicians Pediatric Committee; Emergency Nurses Association Pediatric Committee: Joint policy statement—guidelines for care of children in the emergency department, *Pediatrics* 124:1233–1243, 2009. Reaffirmed *Pediatrics* 132:e281, 2013.

The way the family supports the child during a crisis, and consequently how the family is supported in the ED when caring for the child, are critical to patient recovery, family satisfaction, and mitigation of behavioral and mental health impact. Commitment to patient- and family-centered care in the ED ensures that the patient and family experience guides the practice of culturally sensitive care and promotes patient dignity, comfort, and autonomy. In the ED setting, particular issues, such as family presence, deserve specific attention. Surveys of parents have indicated that most want to be with their child during invasive procedures and even during resuscitation. Allowing their presence has been shown to reduce parental and patient anxiety and does not interfere with procedure performance. Patient- and family-centered care practices are also strongly associated with improved care quality and patient safety.

Disaster Preparedness

Throughout a catastrophic event, natural or human-made, several unique factors place children at disproportionate, increased risk. During an average workday, an estimated 69 million U.S. children are separated from their families, in schools and childcare centers, where mass casualty events can easily occur. This separation adds the additional challenge of safe and timely reunification of children with family during or after an incident. Furthermore, in the event of a biologic, chemical, or radionuclear attack, unique anatomic, developmental, and physiologic features make children especially vulnerable to absorption, ingestion, or inhalation of toxic agents and related morbidity and mortality.

Similar to day-to-day emergency readiness for ill and injured children, pediatric disaster preparedness requires advance considerations of the unique vulnerabilities and needs of children within planning, and exercises, at local, state, regional and even national levels. Pediatric planning considerations include training of first responders and other care providers, patient triage, decontamination, surge capacity and capability, medical countermeasures (medications, vaccines, equipment, supplies), evacuation, transport, sheltering, and family reunification. Planning for children should occur at all levels of the healthcare system, including the medical home, urgent care centers, EMS, acute care hospitals, pediatric tertiary hospitals, alternate care facilities, and rehabilitation services. While the NPRP noted meaningful progress in day-to-day emergency readiness, no improvement was found in disaster preparations, with less than half of U.S. hospitals having a disaster plan addressing the needs of children. Beyond acute medical treatment needs, pediatric planning must also consider the typically broad mental and behavioral health impact disasters have on children and families. Pediatric plans must also be in place for locations where children congregate, such as schools and childcare.

At the local, state, or regional level, healthcare coalitions have been identified as an optimal forum for disaster planning; core participants should include local or state public health departments, emergency management authorities, EMS agencies, and hospitals. Many other key stakeholder groups should be involved in coalition planning, such as healthcare professional organizations. To ensure that the needs of children are effectively considered, it has been recommended that disaster planning at all levels include pediatric subject matter experts. Pediatricians are an obvious source for this expertise and are also uniquely positioned to educate families about emergency readiness, particularly families with special needs children. The presence of an intact medical home during a public health emergency, and after a disaster has occurred, will contribute enormously toward response, recovery, and community resiliency. Lastly, community practice and healthcare system readiness and resiliency begin with *personal readiness planning* engaged by healthcare providers and support staff.

The AAP's Children and Disasters website* contains toolkits, checklists and other resources pertinent to pediatric readiness within the community, schools, the medical home, and hospitals; educational materials are also available for families. Reliable information and excellent disaster readiness resources may also located on the websites of the EMSC Innovation and Improvement Center (https://emscimprovement.center), U.S. Centers for Disease Control and Prevention (https://emergency.cdc.gov), U.S. Department of Health and Human Services (https://www.phe.gov/preparedness/Pages/default.aspx), and U.S. Federal Emergency Management Agency (https://www.fema.gov).

Interfacility Transport of the Seriously Ill or Injured Pediatric Patient

Corina Noje, Bruce L. Klein

Keywords

air ambulance
family-centered care
medical control physician
pediatric transport medicine
telemedicine

Patients often seek treatment at facilities that lack sufficient expertise to treat their conditions, necessitating transfer to more appropriate specialty centers. This is especially pronounced in pediatrics. Emergency medical services (EMS) providers or parents usually take children to local emergency departments (EDs) first, where their conditions and physiologic stabilities are assessed. Although bringing a child directly to the local ED may be proper logistically, local EDs can be less than ideal for pediatric emergencies. Children account for 27% of all ED visits, but only 6% of EDs have all the necessary supplies for pediatric emergencies. Also, general EDs are less likely to have pediatric expertise or policies in place for the care of children. Outcomes for critically ill children treated in pediatric intensive care units (PICUs) are better than for those treated in adult ICUs. When pediatric critical care is required, transport to a regional PICU is indicated. In addition, often the type of subspecialty care needed (e.g., pediatric orthopedics) is available only at the pediatric center.

Pediatric transport medicine consists of the interfacility transfer of infants, children, and adolescents from community facilities to pediatric centers that can provide the needed level of expertise. Transport is performed by professionals proficient in pediatric transport using age-equipped ground, rotorcraft, or fixed-wing ambulances. Pediatric transport medicine is a multidisciplinary field comprising pediatric critical care and **pediatric emergency medicine** (PEM) physicians (and, sometimes for very young infants, neonatologists); nurses, respiratory therapists, and paramedics with advanced training for pediatric transport; and communications specialists. The goal is to deliver quality pediatric care to the region's children, while optimizing the use of regional resources. For the individual child, the aim is to stabilize and, when appropriate, begin treating as soon as possible—that is, at the local ED and during transport, well before arrival at the referral center.

Models for pediatric transport services vary depending on the needs and available resources in a geographic region, but all should have certain basic components: a network of community hospitals and regional pediatric centers; an established communications and dispatch system that easily facilitates transfer to the pediatric center; ground and/or air ambulances; medical and nursing leadership from pediatric critical care or PEM (or neonatology); experienced pediatric **medical control physicians (MCPs)** ; a multidisciplinary team of pediatric transport professionals specially trained to provide the appropriate level of care required during transport; operational and clinical policies and procedures that guarantee safe, state-of-the-art, and timely pediatric critical care transport; and a database for quality and performance assessment.

Communications and Dispatch Center

Communications are one of the most vital components of a regional transport system. Treating a critically ill or injured child is generally an uncommon event for most community physicians. Therefore, they need to know *whom* , *how* , and *when* to call for assistance in the stabilization and transfer of a pediatric patient. The communications and dispatch center provides a single telephone number for such calls.

The communications and dispatch center coordinates communications among the outlying facility, receiving unit, MCP, transport team, and other consultants. This center may be part of a hospital unit (e.g., ED, PICU), self-contained in a single institution (e.g., Emergency Communications and Information Center), or based offsite as a freestanding center coordinating communications and dispatch for multiple transport programs.

Staffing varies depending on the type of center. On-duty nurses or physicians may receive calls at unit-based models with low volumes. In contrast, dedicated communications specialists usually staff self-contained or freestanding centers, which tend to be busier. The communications specialist has numerous responsibilities, including answering the referring physician's call promptly; documenting essential patient demographic information; arranging for immediate consultation with the MCP; dispatching the transport team to the referring facility expeditiously; updating the referring facility with any changes in the arrival time; and coordinating medical control and other necessary transport-related calls. The transport team must be equipped with a cellular telephone or radio for immediate contact with the receiving and referring facilities. Furthermore, with advances in technology and wireless communication systems, **telemedicine** —either *interactive* (synchronous) or *store and forward* (asynchronous)—is being used during pediatric transport; certain programs have incorporated it into their routine transport operations.

Medical Control Physician

The MCP is involved in the clinical care and safe transport of the patient from the time of referral through arrival at the receiving hospital unit. The MCP's oversight increases once the transport team arrives at the referring facility. The MCP should have expertise in pediatric critical care or PEM (or sometimes neonatology). Besides having the knowledge required to stabilize a critically ill or injured child, the MCP must be familiar with the transport environment; the transport team members’ resources and capabilities; the program's policies and procedures; and the region's geography, medical resources, and regulations regarding interhospital transport. The MCP must possess good interpersonal and communication skills and must be able to maintain collegiality with the referring hospital's staff during a potentially difficult and stressful situation.

Once a transport call is received, the MCP must be immediately available to confer with the referring physician. Although the MCP may have other responsibilities, these transport responsibilities take priority in order to avoid undue delays when transferring a critically ill child. Often the MCP recommends further testing or therapeutic interventions that can be delivered by the referring hospital before the transport team arrives. The MCP may seek additional guidance from other specialists, as necessary. Because the child's condition may change rapidly, the MCP must remain ready to give additional advice. All conversations and recommendations regarding the care of the patient should be documented. Some centers record these conversations.

After discussion with the referring physician—and when warranted, with the transport staff—the MCP determines the best team composition and vehicle for transport. The MCP usually does not accompany the team but remains available, by phone or radio (and sometimes through telemedicine), to supervise care.

Transport Team

Transport team composition varies among programs—and sometimes within an individual program. The team's composition is based on a variety of factors, including the child's age; the severity of the illness or injury; the distance to the referring facility; the transport vehicle used; the team members’ advanced practice scope and abilities; the referrer's (reasonable or unreasonable) insistence that a physician be present; the program's historical professional makeup; and the region's staffing regulations. Team members are generally physicians, nurse practitioners, nurses, respiratory therapists, and paramedics who have expertise in pediatric critical care, PEM, or neonatology (in some cases), as well as advanced education and training in those cognitive and procedural areas important for pediatric critical care transport. There is a lower incidence of transport-related morbidity for critically ill and injured children transported by pediatric specialty teams than for those transported by generalist teams. Nevertheless, in-transit critical events occur in almost 1 in 8 pediatric critical care transports.

Various scoring systems have been developed to predict the need for a physician during transport. It seems that a team member's training, experience, and skill in treating critically ill patients are more important considerations than that team member's professional degree. Team members must understand basic pediatric pathophysiology and collectively must be able to assess and monitor a critically ill or injured child; manage the airway and provide respiratory support; obtain vascular access; perform point-of-care testing; and administer medications typically used in pediatric critical care transport. They must be familiar with the physiologic alterations as well as practical difficulties of the transport environment and, importantly, must be comfortable working in an out-of-hospital setting. Physicians are less often deployed on transport teams in part because of the advanced training that other healthcare professionals on the transport team receive.

The transport team should have a designated team leader who, in addition to the team leader's many other responsibilities, interacts with the MCP during the transport. Once the team arrives at the referring facility, the team should reassess the child's condition, review all of the pertinent diagnostic studies and therapies, and discuss the situation with the referring staff and parents. If the patient's condition has changed significantly, the team leader may need to contact the MCP for additional advice. Otherwise, the team leader should generally notify the MCP before starting to bring the child to the receiving facility. Any care delivered by the team during transport should be documented, and copies of all medical records—including laboratory data, radiographs, and scans—should accompany the child to the pediatric center. The receiving unit must be updated prior to arrival so it can finalize preparations for the patient.

Ground vs Air Ambulance

Transport vehicle options include ground, rotorcraft, and fixed-wing ambulances. Vehicle selection depends on the child's emergency needs; transport team's capabilities; any out-of-ordinary staffing or equipment requirements (e.g., for extracorporeal membrane oxygenation, inhaled nitric oxide or heliox); referring facility's abilities; distance; terrain; traffic patterns; ground or air ambulance availability; helicopter landing pad or airport access; weather conditions; and expense.

The transport vehicle must be equipped with electrical power, oxygen, and suction and must have sufficient space for the equipment and supplies that the team brings along—stretcher or isolette, monitor, ventilator, oxygen tank(s), medication pack(s), infusion pumps, and more. Compared with helicopters, ambulances are more spacious and able to carry more weight, so they can accommodate larger teams and more equipment. Another advantage of ground ambulance transport is the ability to stop en route if the patient's condition deteriorates; this may facilitate the performance of certain interventions, such as intubation.

An airplane may be able to fly to an area when distance (>150 miles), altitude, or weather precludes helicopter use. However, the use of an airplane necessitates several ambulance transfers, with their attendant delays and potential complications. There also are delays when the plane must fly from a remote base to the program's jurisdiction.

Transport Physiology

When possible, the transport team tries to provide the same care during transport as the patient would receive in the specialty center. This can be difficult, however, because of limitations in personnel, equipment, and space, as well as other environmental challenges.

The team and child are subjected to variable intensities of background noise and vibration while traveling in the vehicle cabin. **Noise** can impair the team's ability to auscultate breath sounds and heart sounds or accurately measure the blood pressure manually—another reason for monitoring vital signs mechanically and relying on other assessment modalities, such as the level of mentation, skin color, and capillary refill. For rotor transports in particular, the crew and patient should wear helmets or headphones (or another wearable noise attenuator, such as MiniMuffs, Natus Medical, San Carlos, CA) to mitigate noise. **Motion** and **vibration** are additional transport hazards and can lead to increased metabolic rate, shortness of breath, and fatigue in the patient, as well as motion sickness in the patient and staff.

On fixed-wing or certain rotary-wing transports, the patient may suffer adverse physiologic effects from **altitude** . With increasing altitude, the barometric (atmospheric) pressure decreases and gas expands to occupy a greater volume due to decreased pressure exerted on it. Therefore, as barometric pressure drops with altitude, the partial pressures of inspired oxygen (PiO_2) and, consequently, arterial oxygen (PaO_2) decrease, as does the arterial oxygen-hemoglobin saturation (SpO_2). For example, at 8,000 feet—an elevation at which unpressurized airplanes may fly, as well as the effective cabin altitude for many pressurized airplanes flying at 35,000 to 40,000 feet—the barometric pressure, PiO_2 , PaO_2 , and SpO_2 fall to 565 mm Hg, 118 mm Hg, 61 mm Hg, an 93%, respectively. In comparison, the barometric pressure, PiO_2 , PaO_2 , and Sp $_2$ are 760 mm Hg, 159 mm Hg, 95 mm Hg, and 100% at sea level. Although healthy individuals usually tolerate these changes well, patients with respiratory insufficiency, pulmonary hypertension, significant blood loss, or shock may decompensate and should receive supplemental oxygen and/or have the cabin pressured at sea level.

Gases expand 10–15% at the few-thousand feet where helicopters typically fly, and approximately 30% at 8,000 feet. Gases within the body itself also expand as the altitude increases. The degree of gas expansion must be considered during transport via air of any patient with a pneumocephalus, pneumothorax, bowel obstruction, or another condition involving entrapped gas. Before transport, a pneumothorax should be decompressed and a nasogastric tube inserted for ileus.

Safety

Safety is of paramount importance and mandates constant vigilance by everyone involved. Accident rates for pediatric air and ground transport are estimated at approximately 1 in 1,000 transports. The team should routinely attend pilot briefs, as well as perform safety inspections of the vehicles and equipment, aided by checklists. When in doubt, the MCP should solicit input from the staff about whether to transport via air or ground ambulance or to employ lights and sirens, decisions that cannot be taken lightly. The pilot's or driver's judgment as to the safety of proceeding during inclement weather or with a mechanical problem must not be overruled.

Organizations such as the Federal Aviation Administration (FAA) and the National Transportation Safety Board (NTSB), play a role in ensuring safe interfacility transport. The **Commission on Accreditation of Medical Transport Systems (CAMTS)** is an independent, peer-review organization established in 1990 in response to the number of air medical accidents in the 1980s. CAMTS, through voluntary participation, audits and accredits fixed-wing, rotary-wing, and ground interfacility medical transport services.

Family-Centered Care

Family-centered care represents a philosophy that respects the important role that family members play in a child's care. It recognizes family members and healthcare providers as partners in caring for the child. Family presence during transport is beneficial because it provides support to children in stressful situations and assists healthcare providers in delivering care to patients with complex and chronic medical problems.

As care is transitioned from the referring hospital, it is the transport team's responsibility to maintain family-centered care. The team meets with family members to explain the transport process, help obtain consent, and discuss anticipated management. When possible, the transport team should attempt to accommodate a family member's presence onboard. However, the family member and child may need to be separated when the child is critically ill and rapid transport is essential, or in case of space or weight limitations in the air or ground ambulance. In these situations, it is important that family members have a clear understanding of how the child will be cared for during the separation.

Referring Hospital Responsibilities

Transfer of a child to another facility requires written documentation by the referring physician of the need and reasons for transfer, including a statement that the risks and benefits, as well as any alternatives, have been discussed with the parents. Informed consent should be obtained from the parent/legal guardian before transfer.

Federal law under the Emergency Medical Treatment and Active Labor Act (EMTALA), part of the Consolidated Omnibus Budget Reconciliation Act (COBRA), imposes specific requirements that a patient presenting to an ED be given a medical screening examination without regard to ability to pay. If on examination an emergency medical condition is found, the hospital is required to stabilize the patient or to transfer the patient to another facility if unable to stabilize the patient or if requested by the patient. The primary requirement is that the referring physician must certify that the medical risks of transfer are outweighed by its potential benefits. The receiving hospital must agree to accept the patient if it has the space and staff to provide the necessary level of care. The transferring hospital is responsible for arranging for the transfer and ensuring that it is performed by qualified medical personnel with appropriate equipment. The transferring hospital must also send copies of the patient's medical records and test results, even those that become available after the transfer is complete.

Some referring hospitals have entered into transfer agreements with specialty centers to facilitate the smooth and safe transfer of pediatric patients. Having prepared forms for all the above purposes also aids in the transfer process.

Each hospital needs to review its facility's guidelines; if established guidelines do not exist, the Emergency Medical Services for Children National Resource Center in partnership with the Emergency Nurses Association and the Society of Trauma Nurses has developed the “Inter Facility Transfer Tool Kit for the Pediatric Patient” (www.pediatricreadiness.org). This tool kit includes the essentials for comprehensively and safely transferring the pediatric patient to the most appropriate level of care in a timely manner.

Educational Outreach

Besides safe and rapid transport, regional pediatric transport programs (and their specialty centers) have an obligation to provide educational opportunities to community healthcare providers so that these providers can acquire the necessary skills to evaluate and stabilize a critically ill or injured child until the transport team arrives. These learning activities may include transport case reviews; lectures on pediatric acute care topics; resuscitation and related programs such as the Pediatric Advanced Life Support (PALS) course, Advanced Pediatric Life Support (APLS) course, Pediatric Education for Prehospital Professionals (PEPP) course, and S.T.A.B.L.E. (sugar and safe care, temperature, airway, blood pressure, lab work, emotional support) program; and rotations through the specialty center's pediatric ED and PICU. These activities also help cement relationships with the referring facility's staff.

79.2

Outcomes and Risk Adjustment of Pediatric Emergency Medical Services

Robert C. Tasker, Evaline A. Alessandrini

Keywords

calibration
discrimination
PRISA II
PRISM
RePEAT
risk adjustment

Health services research has documented wide variation in the likelihood that patients receive quality, evidence-based healthcare, and this can negatively impact the health of children and youth (see Chapter 2). The complexities of delivering high-quality healthcare are magnified in the emergency department

(ED). Patients are in crisis, EDs are often overcrowded, patient–physician relationships are based on brief interactions, and the varieties of complaints and diagnoses are immense. Practitioners want to know whether the system is working well, and whether local performance is good compared with a recognized benchmark or standard. Physicians can make their practice better only if they can make the appropriate measurements. However, no two places of practice are the same, so besides assessing raw outcomes (e.g., times, mortality, patient satisfaction), practitioners also need to make some adjustment for severity of illness, case mix, or risk of morbidity (e.g., one ED's practice and cases may differ significantly from a theoretical standard being used as a benchmark for “best practice”).

Outcome Measures in Emergency Medical Services for Children

Pediatric emergency medical systems must support the development of national standards for emergency care performance measurement. The *Donabedian structure-process-outcome model* has set the framework for most contemporary quality measurement and improvement activities. **Structural** elements provide indirect quality-of-care measures related to a physical setting and resources. **Process** indicators provide a measure of the quality of care and services by evaluating the method or process by which care is delivered, including both technical and interpersonal components. **Outcome** elements describe valued results related to lengthening life, relieving pain, reducing disabilities, and satisfying the consumer.

A true *outcome-based* approach describes observable measures such as mortality, risk of organ system failure, and disability. An alternative approach is a *resource-based* outcome measure with a definition related to the level of care required. Children who are more ill, in general, require more resources. Thus, resource use across groups of patients reflects relative **severity of illness** in the groups, provided clinicians have a similar approach to practice. Examples of resource-based outcomes include need for hospital admission (ED disposition), ED length-of-stay, costs, and diagnostic and therapeutic interventions performed in the ED. This approach, certainly provides a measurement of activity, but child healthcare providers do not really know whether the patient receiving the therapeutic interventions or resources actually needed them (i.e., data may also reflect physician behavior or [lack of] experience). Therefore, some other assessment is needed that incorporates information on *how sick* the patient is, or their specific diagnosis.

Table 79.3 provides a list of outcome measures for pediatric ED care developed by **Emergency Medical Services for Children Innovation and Improvement Cente** r supported by the Health Resources and Services Administration of the U.S. Department of Health and Human Services.

Table 79.3

Stakeholder-Endorsed Outcome Measures for Pediatric Emergency Care

- Overall patient satisfaction with ED visit—nurses
- Overall patient satisfaction with ED visit—physicians
- Parent/caregiver understanding of ED discharge instructions
- ED length of stay for patients <18 yr of age
- Percentage of patients <18 yr of age left without being seen (LWBS)
- Effective pediatric procedural sedation
- Acute fracture patients with documented reduction in pain within 90 min of ED arrival
- Improvement in asthma severity score for patients with acute exacerbations
- ED revisit within 48 hr resulting in admission
- Medication error rates
- Global sentinel never events
- Unplanned return visit within 72 hr for the same/related asthma exacerbation
- Failure to achieve seizure control within 30 min of ED arrival
- Return visits within 48 hr resulting in admission for all urgent and emergency patients

Risk Adjustment

The purpose of measuring outcomes in the ED is to evaluate **performance** and therefore to offer EDs and other components of the healthcare system the opportunity to make effective improvements over time, using a benchmark within and between units. When making comparisons over time, one must ensure that patient-related attributes (e.g., age, preexisting conditions associated with outcome of interest, severity of illness) has not changed; otherwise one may be looking at changes in demography and case mix rather than any change in performance. The approach is to make some form of *risk adjustment* to *level the playing field* , so that comparison of outcomes is as fair and meaningful as possible. Because children present to EDs with illnesses of varying acuity, severity is inextricably linked to outcomes. Severity typifies the concept of *risk* —the higher the severity, the higher the risk of a given outcome. Without risk adjustment, EDs with sicker patients may appear to have poorer outcomes.

In the population of children admitted to a pediatric intensive care unit (PICU), 2 models, the **Pediatric Risk of Mortality** (PRISM) and **Pediatric Index of Mortality** (PIM),– have been developed and validated against the outcome of death during PICU admission and, in the case of PRISM IV, against functional outcome. These models or prediction algorithms, use a composite of a priori known high- or low-risk diagnoses, as well as acute physiology measurements taken around the time of presentation. In PRISM IV the data collection is from 2 hr before to 4 hr after admission, or the 1st 4 hr of care. The main concept is that deranged physiology reflects underlying severity of illness; the other features of the patient (e.g., age, diagnoses, postintervention status) modify the relationship between physiologic status and risk and enable accurate and reliable estimates of mortality and morbidity risks. Importantly, in the PRISM methodology, physiologic status is not conflated with therapies (e.g., mechanical ventilation) used at presentation (i.e., in the initial window for assessment). Historically, the measure used after the initial window of assessment with its laboratory and clinical evaluation was a period of intervention in the PICU, lasting a median of 2 days, and then discharge survival. However, the mortality rate in many U.S. PICUs is now <2.5%, and thus the need for algorithms that also include development of morbidity, now approximately 5%. The PRISM IV methodology has been validated using a *trichotomous* outcome (i.e., death, new morbidity, no new morbidity) at hospital discharge.

The previous approach is not well suited for the population presenting to the ED. Interventions may have already occurred in the prehospital setting, or physiology may have stabilized. Mortality rate is very low, and the other outcome measures may reflect what happens on the PICU or during hospital ward care. A number of disease-specific acuity scoring systems are available for use in the ED population, predominantly for those involved in trauma (e.g., Injury Severity Score, Trauma Score, Pediatric Trauma Score).

Risk Adjustment Tools in the ED

In the ED the choice of a risk adjustment tool depends on the outcomes of interest. Two general risk adjustment tools have been developed specifically for PEM, the second-generation Pediatric Risk of Admission (PRISA II) score and the Revised Pediatric Emergency Assessment Tool (RePEAT).

Pediatric Risk of Admission II

PRISA II uses components of acute and chronic medical history and physiology to determine the probability of hospitalization. The outcome measure of interest is *mandatory hospital admission* (admissions utilizing therapies best delivered as an inpatient). Table 79.4 lists the patient-related attributes contributing to the PRISA II risk adjustment score. Analytic models, including the PRISA II score, have good **calibration** (how well the probabilities predicted from the model correlated with the observed outcomes in the population) and **discrimination** (the ability to categorize subjects correctly into the categories of interest) with respect to mandatory hospital admission. Construct validity of the PRISA score has been demonstrated by measuring rates of the secondary outcomes: mandatory admission, PICU admission, and mortality. As the probability of hospital admission rises, the proportion of patients with these increasing care requirements also increases. This finding supports the use of the PRISA II score as a measure of severity of illness. PRISA II has also been used to demonstrate racial/ethnic differences in severity-adjusted hospitalization rates. One study demonstrated that teaching hospitals had higher-than-expected severity-adjusted admission rates than nonteaching hospitals.

Table 79.4

Elements of the PRISA II Score

- Age <90 days
- Minor injury
- Abdominal pain in an adolescent

- Immunodeficiency
- Indwelling medical device
- Controller asthma medication
- Referral status
- Temperature
- Decreased mental status
- Low systolic blood pressure (<70 neonates and infants; <83 children; <100 adolescents)
- High diastolic blood pressure (>59 neonates and infants; >70 children; >90 adolescents)
- Low serum bicarbonate value (<20 mEq/L)
- High potassium value (>4.9 mEq/L)
- High blood urea nitrogen value (>80 mg/dL)
- High white blood cell count (>20,000/mm^3)
- Oxygen therapy other than during inhaled bronchodilator treatments
- Low bicarbonate and high potassium values

Revised Pediatric Emergency Assessment Tool

RePEAT uses a limited set of data collected at the time of ED triage to model severity of illness as reflected by the level of care provided in the ED, for example, routine assessment (clinical examination only ± nonprescription medicine) vs specific ED care (ED diagnostics and/or therapeutics) vs hospital admission. It is assumed that patients needing a higher level of care have a higher severity of illness. Table 79.5 lists the patient-related attributes contributing to the RePEAT risk adjustment score. Analytic models such as RePEAT have good calibration and discrimination with respect to predicting ED care and hospital admission. Furthermore, analytic models that compare costs and ED length of stay between EDs are improved by adjustment for severity of illness using the RePEAT score. RePEAT is a reasonable objective marker of severity of illness that could be used in the administrative process comparing outcomes between EDs.

Table 79.5

Elements of the RePEAT Score

- Age
- Chief complaint
- Triage category
- Current use of prescription medications
- Arrival via EMS (ground/air)
- Heart rate
- Respiratory rate
- Temperature

triage

The maturity of **pediatric emergency medicine** (PEM) in any given area depends on the healthcare priorities and resources of that geographic or physical setting. The places in which emergency care takes place range from the community (for those with no access to organized medical care) to state-of-the-art pediatric EDs in populated centers. The scope ranges from care of the individual patient to the management of populations of children involved in large-scale disasters. Barriers to quality care are different in each situation and in each part of the world, with the implication for the astute international PEM practitioner that solutions must be targeted to the local context of healthcare within a given environment.

Continuum-of-Care Model

This Emergency Medical Services for Children (EMSC) framework can also be applied to discussion of emergency care for children on a global level (see Chapter 79). With medical infrastructures that may not be consistent or well organized, or that have been weakened by civil strife, natural disasters, or economic loss, the focus of child health in the developing world has mostly been on prevention and acute care.

Prevention

Infectious Diseases

International child health has focused mainly on reducing preventable childhood illnesses, primarily through immunizations. Enormous advances have been realized in measles, neonatal tetanus, and polio reduction; wild-type smallpox was eradicated in 1978. Although there are advocates for providing primary care interventions (e.g., vaccinations) in the ED, the role of the PEM practitioner in this area of prevention has been limited.

Injuries

Injuries are a leading cause of childhood morbidity and mortality. Unintentional injuries constitute 90% of injury mortality to children 5-19 yr old and are the cause of 9% of the world's mortality (see Chapter 13). Intentional injuries, which remain underrecognized and underreported, make a smaller but significant contribution. Unintentional injuries cause more than 2,000 childhood deaths daily, or 950,000 annually worldwide. The burden of these deaths is borne disproportionately by children in middle- and lower-income countries, where >95% of all injury deaths occur. For each of these deaths, many more children are permanently disabled, and an even larger number are treated and released without permanent sequelae.

The World Health Organization (WHO) and United Nations Children's Fund (UNICEF) have outlined several proven injury prevention strategies, of which child health practitioners in the global community must be aware. The top 3 causes of injury mortality are traffic-related injuries, burns, and drowning. There are 7 specific effective strategies for reducing **traffic-related injuries** : a minimum drinking age, appropriate child restraints and seatbelts, helmets for motorcycle and bicycle riders, reduced vehicle speeds around schools and residential areas, running lights on motorcycles, graduated licensing for drivers, and separation of different types of road users. There is insufficient evidence to demonstrate that school-based programs on drunk driving, increased pedestrian visibility, or designated driver programs are effective. Although these strategies have proved effective, the data are based on U.S. research and may not be generalizable to other countries. It may be difficult to reduce vehicle speeds around schools when there is insufficient infrastructure for street signs. Alternatively, lack of separation of car and bus traffic from bicyclists and pedestrians contributes to unsafe and dangerous road conditions. This is more of a problem in lower- and middle-income countries, where bicycles and motorized 2-wheel vehicles are used to carry children as well as goods, while the drivers negotiate among rapidly moving vehicles. With rising income, these countries have seen increases in both the number of cars and the number of 2-wheeled vehicles, with a corresponding increase in the number of related injuries.

For reducing **drowning deaths** , strategies that have proven effective focus on creating barriers between children and water hazards, such as covering wells, buckets, and other standing sources of water, and placing high fences around pools (see Chapter 91). **Burns** have been addressed by advocating for installation of smoke detectors and lowering the temperature of water from water heaters (see Chapter 92).

Out-of-Hospital Care

Out-of-hospital care comprises access to emergency services, prehospital care, and interfacility transport of patients. Morbidity and mortality arise from delayed or limited access to emergency care, lack of prehospital care, transport without proper monitoring or trained personnel, or delayed transport to a higher level of care. *Safe transport of seriously ill children* is a neglected global health issue. An emergency response system must address the following links in the patient's care: a communication system with prompt activation of EMS, the correct assessment and initial treatment of the patient, and the rapid transport to definitive care.

Access to Care

When a child is injured or ill, a parent or caretaker must be able to access help and activate EMS. Many countries worldwide have dedicated emergency numbers to rapidly dispatch medical, police, or fire services. The simple 112 emergency number has been adopted and is being phased in throughout the European Union (EU) member states, to access medical, fire, and police services, in addition to secondary regional emergency access numbers. The universal U.S. emergency number system 911 today covers the large majority of the country (98%) and has enhanced features of automatically linking the phone number to an address. However, there remain limitations to universal access resulting from absence of phones in some households, unclear addresses in rural areas, and insufficient reach of the emergency system.

In the majority of low- and middle-income countries, no such universal emergency numbers have been established, requiring access by direct dialing to an ambulance, if such private services exist. In most low- and middle-income countries, the family must bring the ill or injured child to the health facility for stabilization and treatment. For this to occur, families must overcome financial and geographic barriers, which can result in delayed presentation for care. This delay predictably increases the acuity of the illness or injury and associated complications and decreases the likelihood of full recovery and survival.

Prehospital Care

In regions with maturing EMS systems, there must be adequately trained personnel to stabilize and transport the child to a medical facility. The quality and level of training of such prehospital personnel vary tremendously among countries and within regions of the same country. In urban areas, there is a greater concentration of medical care and therefore a greater opportunity to have strong prehospital training. In most of Asia and sub-Saharan Africa, trained personnel are used primarily to transfer patients between health facilities, not from the initial site of illness or injury. In most high-income countries, medical services are dispatched to the patient.

In the French model, Service d'Aide Médicale Urgente (SAMU), a physician, often an emergency medicine specialist, will review calls for acuity and can dispatch a physician-led team by ambulance to go to the patient's home to assess, stabilize, and initiate treatment. This Franco-German system is used in other countries, including many in Latin America and Europe. There are no clear data on the cost-effectiveness and patient outcomes associated with delivery of patients to the nearest facility vs bringing hospital resources to the patient.

Around the world, the effort to establish standardized approaches to prehospital care exists primarily in the form of courses to educate EMS and hospital personnel in the emergency management of patients. For trauma care, the WHO manuals *Prehospital Trauma Care Systems* and *Guidelines for Essential Trauma Care* both focus on guidelines for prehospital and trauma care systems that are affordable and sustainable. The AAP course Pediatric Education for Prehospital Professionals is a dynamic, modularized teaching tool designed to provide specific pediatric prehospital education that can be adapted to any EMS system. Table 79.6 describes additional prehospital resources.

Table 79.6

Pediatric Emergency Care Resources

Prehospital

Advanced Medical Life Support (AMLS)

Newest course developed by the National Association of Emergency Medical Technicians (NAEMT) to provide more clinical teaching and reasoning around emergent medical problems. Course is open to physicians, nurses EMTs and paramedics.

www.naemt.org/education/amls/amls.aspx

Prehospital Trauma Life Support

Available in 33 countries, PHTLS is the leading continuing education program for prehospital emergency trauma care.

www.phtls.org

International Trauma Life Support

Training course for prehospital trauma care.

www.itrauma.org

Pediatric Education for Prehospital Professionals (PEPP)

Curriculum designed specifically to teach prehospital professionals how to assess and manage ill or injured children.

www.peppsite.org

Hospital Care

Pocket Book of Hospital Care for Children

WHO publication providing guidelines for the management of common illnesses with limited resources; incorporates both the Emergency Triage Assessment and Treatment (ETAT) and Integrated Management of Childhood Illness (IMCI) guidelines.

www.who.int/maternal_child_adolescent/documents/9241546700/en/index.

AFEM Handbook of Acute and Emergency Care

Management strategies based on available resources. It leads providers through a rapid, systematic, and integrated approach to stabilization and resuscitation of patients stratified to 3 resource levels: where there are no available resources, where there are minimal resources, and where there are full resources.

Available for purchase online.

Where There Is No Doctor: A Village Health Handbook

Healthcare manual for health workers, clinicians, and others involved in primary healthcare delivery and health promotion programs around the world. Available for purchase or as a free download.

United Nations Children's Fund (UNICEF)
Organization dedicated to providing lifesaving assistance to children affected by disasters and to protecting their rights in any circumstances; formerly United Nations International Children's Emergency Fund.
www.unicef.org
Safe Kids Worldwide
The first and only international nonprofit organization dedicated solely to preventing unintentional childhood injury.
www.safekids.org

Although most middle- and high-income countries have a system of trained EMS workers, low-income countries lack this advanced tier of emergency care. In these countries, commercial drivers, volunteers, and willing bystanders provide the first line of care. Training a cadre of first responders can rely on existing networks of aid or can be drawn from specific populations, such as students, soldiers, or public servants. Training needs to emphasize basic lifesaving and limb-saving interventions, including how to stop bleeding and support breathing, access advanced care, and splint broken limbs. In Ghana, for example, taxi drivers participated in a first-aid course that relied heavily on demonstration and practice rather than knowledge transfer through didactic sessions. Taxi drivers were selected because they already provided much of the transport for injured patients, either voluntarily or for pay by the family. Two years after the course, external evaluators favorably rated the quality of their care compared with untrained drivers. In rural areas, such first responders become vital in providing emergency interventions when more definitive care is distant. Thus a system of trained first responders forms the foundation of an effective prehospital system.

Methods of Transport

In many low-income countries, there is no means of transport other than the family's motorized or other type of transport. Health centers may only have 1 vehicle for transport to a higher-level facility. This vehicle may also be used for outreach primary care services, such as offering immunizations and collecting drugs and equipment from a central supply location, and sometimes, improperly for personal reasons by local officials or politicians. In large cities, taxis and auto rickshaws are frequently used because they are rapidly available, well disseminated, and able to pass around traffic jams. Where organized prehospital systems exist, different types of vehicles are adapted for emergency transportation, from fully equipped ambulances to basic transport with trained personnel. The WHO recommends identifying transport vehicles in advance, choosing vehicles that can be repaired and maintained locally, and equipping the vehicles according to recognized standards. Therefore the provision of available and appropriately staffed and equipped transport vehicles is crucial to the realization of recommended emergency care plans.

Hospital-Based Care

Once a child has reached a medical facility for the care of an injury or illness, adequate emergency services must be available. In many countries the ED serves only as a triage area where patients are distinguished by their likely disease process and directed for admission to the corresponding unit within the hospital. Strengthening emergency services includes seeing the ED as a unit where definitive treatment can be provided to the ill and injured child. Critically ill children must receive not only prompt care but also correct care. Such expedience and accuracy are ensured by implementation of an effective triage system, moving the sickest patients to immediate care and standardizing the initial care of emergency conditions.

Triage

Children requiring emergency care frequently are not promptly recognized. Too often, children presenting to EDs are treated on a first-come first-served basis, in an approach that creates long waiting times for critically ill children, a contributor to unnecessary mortality. Medical facilities need to adopt an efficient and effective triage system to respond rapidly to the needs of patients and to assign the appropriate amount of resources. To this end, WHO has developed a course entitled **Emergency Triage Assessment and Treatment (ETAT)** . This course teaches to triage patients on arrival as having emergency, priority, or nonurgent signs and to provide emergency treatment for life-threatening conditions. ETAT emphasizes the evaluation of a patient's **ABCD status** to identify emergency situations—the patency of the airway (A), the quality of breathing (B), the quality of circulation and presence of coma or convulsions (C), and the presence of severe dehydration (D).

One of the benefits of the ETAT guidelines is that they can be adapted to centers with limited resources and are applicable to areas with high morbidity and mortality from meningitis, dehydration, malaria, respiratory illness, and malnutrition. Another benefit is that the care algorithms are based on limited diagnostic studies, that is, hemoglobin measurement, blood smear for malaria, and bedside blood glucose testing. Widely accepted triage assessment guidelines are teachable to emergency care staff, and their adoption can provide better organization within a healthcare center. At the Queen Elizabeth Central Hospital in Blantyre, Malawi, for example, the institution of triage and rapid treatment in its emergency care center led to a 50% decrease in the mortality of children within 24 hr of presentation to the hospital, with a further 50% decrease as implementation and practice of triaging patients have continued.

Beyond triage, education on overall emergency center organization is a low-resource intervention that can obviate some of the obstacles to quality care delivery. Additionally, the arrangement of short-stay areas (hydration and infusion rooms) can lessen the burden on inpatient units.

Pediatric-Specific Emergency Centers

Anecdotally, most countries have developed at least 1 pediatric-capable center, usually as part of an academic medical center. The emergency services in these centers are variable, but certainly can be a starting point from which to build overall improvement in pediatric emergency care.

Practitioners

Throughout the world, nurses, paramedics, and nonspecialist physicians provide most of the care to acutely ill or injured children. The majority of sick children attend local clinics or district or central hospitals, where financial and human resources are not always matched to the potential acuity of presenting patient complaints. Nominal supervision is provided to staff attending these patients. Pediatric EDs located in tertiary hospitals are often staffed by training physicians with little or no supervision from faculty, who themselves may have limited exposure to or training in PEM. General hospitals lack dedicated pediatric staff; guidelines as to which patients should be moved to a higher level of care are often not standardized and depend on local influences and/or cultural beliefs about health and illness.

Clinical Guidelines

The **Integrated Management of Childhood Illnesses (IMCI)** guidelines were developed by the WHO and UNICEF to provide assistance in the initial triage and management of the presenting signs and symptoms of the major killers of children <5 yr old in first-level health facilities (e.g., clinics, health centers, outpatient departments of hospitals). The flow charts within each chapter of the IMCI manuals allow easy accessibility to materials that can enhance education and outreach to less experienced health workers.

Evaluations in various countries of the implementation of IMCI guidelines have shown improvements in health worker performance and quality of care, as well as decreases in delay in treatment and mortality of the under-5 population. These guidelines also dramatically reduce the cost of healthcare. The WHO website provides all the necessary implementation tools, including course manuals and evaluation tools.

The International Federation of Emergency Medicine developed standards to improve emergency care globally. These standards are not just aimed at dedicated EDs, but at any setting where emergency care takes place, regardless of the providers or the resources available. At the same time, however, the existence of the standards allows sites to advocate for improved resources dedicated to expertise in the various aspects of providing quality emergency care for children. The standards address design of care spaces, child- and family-centered care, assessment of ill and injured children, staff training and competencies, quality and safety, and disaster response.

Trauma

Morbidity and mortality from trauma are among the most prevalent problems for children worldwide. Trauma care presents the challenge of sequential, often simple, interventions that must be performed in a timely manner to limit the severity of the outcome. However, with lack of specific training, signs and symptoms of pediatric trauma may go unrecognized or may be underappreciated.

Trauma courses such as Advanced Trauma Life Support (ATLS) are educational tools that can be disseminated to improve the quality of care at emergency centers worldwide. For low-resource settings, WHO has developed the Integrated Management for Emergency and Essential Surgical Care toolkit, which provides clear directions and reasoning for the initial care of injured patients. Not expressly addressed in the ATLS course is specific concern about **child abuse** as the cause of trauma. This is an area of pediatric care that many countries do not yet address comprehensively in their medical training, their law enforcement, or their judicial systems. The epidemiologic need for reliable trauma registries is great, as is the need to identify personnel with trauma management skill sets and dedicated trauma centers to serve as higher-level referral sites.

Equipment

Pediatric emergency equipment guidelines are available for a variety of settings where acutely ill and injured children would present. Although these equipment guidelines may represent minimum supplies to treat the widest variety of pediatric emergencies, the roles of substitution and improvisation often provide for equivalent function of recommended supplies.

Inpatient Services

After the initial stabilization, children requiring ongoing care are admitted to the hospital. The quality of inpatient services varies greatly depending on institutional and provider experience, comfort with pediatric conditions, and the resources available to treat them. WHO has produced the *Pocket Book of Hospital Care for Children*, which is based on IMCI guidelines and focuses on inpatient management of high-morbidity/high-mortality illnesses common in developing countries.

Humanitarian Disasters

Children are a vulnerable population who experience disproportionate suffering during humanitarian emergencies, either natural (earthquakes, tsunamis, hurricanes, floods, droughts) or manmade (armed conflicts, terrorist attacks). The under-5 population is especially susceptible to infectious diseases, malnutrition, and trauma following disasters. The **Rainbow Center for Global**

Child Health at the Case Western Reserve University School of Medicine offers a training course, *Management of Humanitarian Emergencies: Focus on Children and Families*, to educate and train health professionals, relief workers, and policymakers to recognize and address the unique needs of children affected by manmade and natural disasters worldwide. AAP also maintains a CHILD disaster Network, which acts as an electronic database of child health professionals with education and experience in humanitarian emergencies. Nongovernmental organizations can access the database to solicit practitioners to aid in disaster response.

The WHO *Manual for the Health Care of Children in Humanitarian Emergencies* is based on IMCI guidelines and addresses the emergency care of children in disaster situations where hospital facilities and resources are not immediately available. It goes beyond the IMCI guidelines by discussing initial assessment and management of trauma, burns, and poisonings. Preexisting IMCI guidelines assumed a functioning health system that facilitated the referral of children, which may not be available in all emergency situations. This manual also includes the initial management of severe conditions, such as injuries, burns, neonatal illness, and psychosocial problems, which are considered high priority in acute care settings.

Exchange and Dissemination of Information

The WHO established the **HINARI** (Health InterNetwork Access to Research Initiative) program to allow free or reduced-cost access to more than 6,200 journal publications. This internet access is made available to the 108 countries with gross national income per capita <$3,500. For middle-income countries not meeting the financial eligibility, internet access continues to be a barrier, and resources may be limited to out-of-date textbooks and journals.

Another valuable tool is the website pemdatabase.org . This nonproprietary site was started as an online resource for PEM practitioners. It contains links to PEM abstracts and articles, evidence-based reviews, pediatric resuscitation websites, and relevant journals, as well as PEM conferences and professional organizations.

CHAPTER 80

Triage of the Acutely Ill Child

Anna K. Weiss, Frances B. Balamuth

Identifying the acutely ill child in the ambulatory setting is a challenge. Children presenting to pediatricians' offices, urgent care practices, and emergency departments (EDs) may have a range of illnesses from simple viral infections to life-threatening emergencies. Although most children in this setting will have a benign course of illness, it is incumbent on the pediatric practitioner to quickly and accurately discern which children are likely to deteriorate from potentially serious or life-threatening disease. When assessing an acutely ill child, practitioners must remember that the early signs of severe illness may be subtle.

Assessment of Vital Signs

Assessment of vital signs is critical in all pediatric visits for acute illness, including temperature, heart rate, respiratory rate, and blood pressure. Normal vital signs vary with age. Although there have been increasing efforts to build evidence-based vital sign cutoffs for different age-groups, most institutions use nonempirically derived cutoffs such as those in Pediatric Advanced Life Support (PALS). **Tachycardia** is common in children presenting for acute care and can result from benign (fever, pain, dehydration) to life-threatening (septic shock, hemorrhage) conditions. An abnormal heart rate should prompt a full history and physical examination, as described later, and careful *reassessment* (often multiple times) after the presumed cause is identified and treated. The vast majority of children will improve after initiation of simple interventions such as antipyretics or analgesia. Tachycardia that persists after fever, pain, and dehydration have been treated *must* be evaluated further, particularly if the child appears ill or has deficit in perfusion or altered mental state.

Tachypnea is also common and has many causes, including fever, respiratory conditions (bronchiolitis, asthma, pneumonia), cardiac disease (e.g., heart failure), and metabolic acidosis (shock, poisoning, diabetic ketoacidosis). Similar to tachycardia, tachypnea often resolves with antipyretics in febrile children, and should be reassessed to ensure resolution once fever has been managed. In cases where bronchiolitis and asthma have been ruled out, persistent tachypnea and fever can be a sign of pneumonia, even in the absence of focal lung findings on examination. Consider evaluation for metabolic acidosis in cases of significant tachypnea without apparent pulmonary or cardiac causes. **Apnea** is a sign of respiratory failure and should be *treated emergently with bag-valve-mask ventilation and immediate ED evaluation.*

Hypotension is rare in children, and when present, it is a sign of critical illness. Children with hypotension should be evaluated in an ED. Hypotension is evidence of decompensated circulatory shock and can result from severe dehydration, sepsis, hemorrhage, neurogenic spinal shock, or cardiogenic shock.

Pulse oximetry (oxygen-hemoglobin saturation, Spo_2) should be assessed in children with respiratory or cardiac illness/compromise and also in children with underlying abnormalities of oxygenation. Healthy children have Spo_2 >95%. The practitioner should consider evaluating for any underlying respiratory or cardiac causes in children with Spo_2 <93–95%. For children with underlying abnormalities, the child's baseline Spo_2 should be assessed and alterations from that baseline should be investigated further.

The combination of bradycardia, hypertension, and altered breathing known as **Cushing triad** can be a sign of life-threatening increased intracranial pressure (ICP) and should be evaluated in an ED. Anisocoria and a 6th cranial nerve palsy are other signs of increased ICP. **Toxidromes** should also be considered in children with abnormal combinations of vital signs (see Chapter 77).

History

A thorough history is paramount to identifying patients whose condition will require prompt intervention. Obtaining an accurate history from young patients is challenging, particularly with preverbal or very anxious children who are unable or unwilling to localize the source of their discomfort. In such instances, parents or caretakers often provide the most important information, and their perceptions of the child's course of illness must be carefully considered. Pediatricians should be guided by the patient's chief complaint to ask *open-*

ended questions that help distinguish between benign and potentially life-threatening disease entities. The most common complaints leading to acute care visits among children include fever, headache and altered mental status, trauma, abdominal pain and vomiting, respiratory distress, and chest pain. Table 80.1 describes signs and symptoms that should prompt immediate transfer to an ED or, if already in the ED, initiation of rapid intervention.

Table 80.1

History and Examination Findings That Should Prompt Immediate Intervention and/or Transfer to Emergency Department

HISTORY AND EXAM FINDINGS	**RISK FACTORS**
RED FLAGS FOR RESPIRATORY FAILURE	
Tachycardia Tachypnea Cyanosis Apnea Brief resolved unexplained event (BRUE) with cyanosis or change in tone Suspected button-battery ingestion Foreign body aspiration with respiratory distress Respiratory distress with hypoxemia and/or altered mental status	Tracheostomy Ventilator dependence History of critical airway
RED FLAGS FOR CIRCULATORY FAILURE	
Tachycardia Tachypnea Cyanosis Apnea Petechial or purpuric rashes Erythroderma Peritonitis Bilious emesis Posttonsillectomy or postadenoidectomy with bleeding Extremity trauma with neurovascular deficits	Oncology (or other immunosuppressed) patients Bone marrow or solid-organ transplants Sickle cell (or otherwise asplenic) patients Infants <56 days old Cardiac patient with change from baseline pulse oximetry Bleeding disorder with trauma
RED FLAGS FOR NEUROLOGIC FAILURE	
Tachycardia Bradycardia-hypertension Double vision Unequal pupils Apnea Frequent or prolonged seizure(s) Focal neurologic deficit(s) Acute onset of severe headache Suicidal or homicidal ideation, psychosis	Ventriculoperitoneal shunt Diabetes or metabolic disease with altered mental status Hypoxic-ischemic encephalopathy Clotting disorder with neurologic change(s)

Adapted from Farah MM, Tay Y, Lavelle J. A general approach to ill and injured children. In Shaw KN, Bachur RG, editors: *Fleischer and Ludwig's textbook of pediatric emergency medicine,* Philadelphia, 2015, LWW.

Fever is the most common reason for a sick-child visit. Most cases of fever are the result of self-limited viral infection. However, pediatricians need to be aware of the age-dependent potential for serious bacterial infections, such as urinary tract infection (UTI), sepsis, meningitis, pneumonia, acute abdominal infection, and osteoarticular infection.

During the 1st 2 mo of life, the neonate is at risk for sepsis caused by pathogens that are uncommon in older children. These organisms include group B streptococcus, *Escherichia coli* , *Listeria monocytogenes* , and herpes simplex virus (HSV). In neonates, the history must include untreated maternal obstetric information and the patient's birth history. Risk factors for sepsis include untreated maternal group B streptococcus colonization, prematurity, chorioamnionitis, and prolonged rupture of membranes. If there is a maternal history of sexually transmitted infections (STIs) during the pregnancy, the differential diagnosis must be expanded to include those pathogens. Septic infants can present with lethargy, poor feeding, grunting respirations, and cool or mottled extremities, in addition to fever (or hypothermia). Febrile infants in the 1st 1-2 mo of life should be evaluated broadly for infection, including sampling blood, urine, and cerebrospinal fluid (CSF).

When the infant matures beyond 2 mo of age and receives their 1st set of vaccinations, serious bacterial infections become less common. Evaluation to rule out serious infection is an important part of treating the febrile older child. Children with fever should have a full set of vital signs, history, and physical examination to ensure that critical illness is absent and to identify any focal source. Red flags for **septic shock** include hypotension, poor perfusion, altered mental status, or the presence of purpuric or erythrodermic rash. Red flags for **meningitis** include severe headache, meningismus, and altered mental state. The presence of any of these signs should prompt emergency evaluation in the ED or rapid treatment if the patient is already in the ED.

Additional focal findings to consider include evaluation for acute otitis media, pharyngitis, pneumonia, abdominal infections (bacterial enteritis, appendicitis), skin and soft tissue infections, septic arthritis, and osteomyelitis. Occult UTI should be considered if 3 of the following risk factors are present: age <1 yr, fever >39°C, fever >48 hr, and no focal source of fever. Pneumonia should be considered in the presence of tachypnea, hypoxia, or focal findings on chest examination. Bacteremia is rare in the post–pneumococcal and *Haemophilus influenzae* vaccine era but should be considered if staphylococcal infection or meningococcemia is suspected, as well as in unvaccinated children or children with signs of septic shock. In addition to infection, inflammatory conditions to consider include juvenile idiopathic arthritis and Kawasaki disease. The diagnosis of **Kawasaki disease** should be considered if the patient meets the diagnostic criteria for this illness although some patients may have an atypical or incomplete presentation (see Chapter 191).

For patients presenting in an **altered mental state** , the pediatrician should inquire about any symptoms, such as fever or headache. Screening questions should explore feeding changes, medications in the household, ill contacts, and the possibility of trauma. Parents will often describe a febrile child as lethargic, but further questioning will reveal a tired-appearing child who interacts appropriately when no longer febrile. The child who appears ill only when febrile must be differentiated from the lethargic patient who presents with suspected sepsis or meningitis, and from the child whose altered behavior is secondary to an intracranial emergency or seizure. Infants with meningitis, sepsis, or cardiac defects may have a history of irritability, being inconsolable, poor feeders, grunting breathing, seizures, poor urine output, and/or color changes such as pallor, mottling, or cyanosis. Patients with poisoning or inborn error of metabolism can also present with lethargy, poor feeding, unusual odors, seizures, and vomiting. Nonaccidental **trauma** should always be considered in a lethargic infant, particularly in the absence of additional signs or symptoms. In infants and young toddlers, rapidly growing head circumference or bulging anterior fontanel may signal increased ICP. Older children may present with altered mental state as a result of meningitis/encephalitis, trauma, or ingestions. School-age children and adolescents with meningitis may have a history of fever and neck pain; other associated symptoms may include rash, headache, photophobia, or vomiting. Children with ingestions can present with other abnormal neurologic symptoms, such as ataxia, slurred speech, and seizures, or with characteristic constellations of vital sign changes and other physical findings consistent with certain toxidromes.

In patients with **headache** , ask questions about the chronicity of the headache and any accompanying symptoms. Headaches that occur on arising in the morning, are worse when lying flat, or are accompanied by vomiting are concerning for increased ICP. Similarly, headache accompanied by focal neurologic deficit should be referred to an ED for urgent head imaging. While migraine headaches in teenagers are similar in presentation to those in adults (unilateral, throbbing, accompanied by an aura), pediatric practitioners should be aware that migraines in prepubertal children may have a nonclassic presentation and may be bilateral and not accompanied by aura, photophobia, or phonophobia.

Parents may interpret a variety of symptoms as **respiratory distress** , and care must be taken to distinguish normal and benign respiratory patterns from true respiratory distress. Tachypnea secondary to fever is a common source of parental anxiety, and parents of newborn infants are sometimes alarmed by the presence of periodic breathing. Parents should be questioned about their child's other symptoms, such as fever, limitation of neck movement, drooling, choking, and the presence of stridor or wheezing. A history of apnea or cyanosis warrants further investigation. Practitioners should also remember that tachypnea in a child without evidence of true respiratory distress may be evidence of compensation for shock or metabolic acidosis, both of which will require rapid treatment. Although wheezing is often secondary to bronchospasm, it can also be caused by cardiac disease or congenital airway anomalies such as vascular rings. Parents may interpret true **stridor** as noisy breathing or wheezing. Stridor is most frequently caused by upper airway obstruction such as croup. However, anatomic abnormalities such as laryngeal webs, laryngomalacia, subglottic stenosis, and paralyzed vocal cords also cause stridor. Toddlers who present with breathing difficulty after a coughing or choking episode should be evaluated for **foreign body aspiration** . In these cases, practitioners must ask about the possibility of button-battery ingestion, as this constitutes a true medical emergency that warrants immediate endoscopic removal or transfer to a facility that can perform the procedure. In toxic-appearing children with stridor, the pediatrician should consider epiglottitis, bacterial tracheitis, or a rapidly expanding retropharyngeal abscess. The incidence of epiglottitis has greatly declined with the advent of the *H. influenzae* type b (Hib) vaccine, but it remains a possibility in the unimmunized or partially immunized patient. Children with retropharyngeal abscesses may also present with drooling and limitation of neck movement (especially hyperextension) after a recent upper respiratory infection or penetrating mouth injury.

Abdominal pain is a very common complaint in the ambulatory setting and can herald either acute intraabdominal or pelvic pathology, or it can be a subtler sign of systemic illness. Both relatively benign (e.g., streptococcal infection, UTI, pneumonia) and severe abdominal (e.g., appendicitis) or systemic (e.g., diabetic ketoacidosis) illness can present with abdominal pain, and questions to the patient and parent should include whether there is an extraabdominal source of discomfort. Questions should include details about pain onset and location; presence of accompanying symptoms, such as fever, abdominal distention; and changes in feeding, urination, and stooling patterns. Care should be taken to elicit a history of peritonitis or obstruction, including worsening pain with abrupt movements and persistent or bilious vomiting.

In neonates, a tender abdomen with or without bilious emesis should raise concern for the presence of a small bowel obstruction (volvulus). These infants appear ill and may have a history of decreased stooling. Pediatricians should be wary of neonates with abdominal tenderness and bloody stools, because 10% of cases of necrotizing enterocolitis occur in term infants. Infants with milk protein intolerance can also present with bloody stools, but these infants appear well and do not have abdominal tenderness. In older patients the differential diagnosis for emergency causes of abdominal pain expands to include intussusception and appendicitis. Patients with intussusception present in a variety of ways, ranging from colicky abdominal pain but otherwise well between episodes to being lethargic or in shock. The diagnosis of appendicitis in the child younger than 3 yr is extremely difficult because children in this age-group cannot localize pain well. In adolescent females with abdominal pain, practitioners must obtain a menstrual and sexual history, because acute lower abdominal pain may be caused by adnexal pathology, including ovarian torsion or ectopic pregnancy.

For patients with **vomiting** , pediatricians should ask if they have experienced bilious or blood-stained emesis, abdominal distention or constipation, weight changes, and diarrhea or bloody stools. An infant with bilious emesis and abdominal distention may have intestinal obstruction (as with midgut volvulus or Hirschsprung disease), whereas an infant who appears immediately hungry after nonbilious projectile vomiting may have pyloric stenosis. In an older child, vomiting may be caused by peritonitis or obstruction, as well as by systemic illnesses, including diabetic ketoacidosis, ingestion, or trauma. Patients with headache and vomiting raise the concern for increased ICP and should be questioned about neurologic changes, meningismus, and fever.

Practitioners should also obtain a thorough account of the child's **past medical history** . It is important to be aware of any underlying chronic problems that might predispose the child to recurring infections or a serious acute illness. Children with sickle cell anemia, indwelling central venous access devices, or immune compromise are at increased risk for bacteremia and sepsis. Similarly, children with prior surgery, including ventriculoperitoneal shunt placement or intraabdominal procedures, can develop complications from their previous surgeries.

Physical Examination

Observation is important when evaluating the acutely ill child. Most observational data that the pediatrician gathers should focus on assessing the child's response to stimuli. Does the child awaken easily? Does the child smile and interact with the parent, or with the examiner? Evaluating these responses requires knowledge of normal child development and an understanding of the manner in which normal responses are elicited, depending on the child's age.

During the physical examination, the pediatric practitioner seeks evidence of illness. The portions of the exam that require the child to be most cooperative are completed first. Initially, it is best to seat the child on the parent's lap; the older child may be seated on the examination table. It is also important to assess the child's willingness to move, as well as ease of movement. It is reassuring to see the child moving about on the parent's lap with ease and without discomfort. *Vital signs are often overlooked but are invaluable in assessing ill children.* The presence of tachycardia out of proportion to fever and the presence of tachypnea and blood pressure abnormalities raise the suspicion for more serious illness. The respiratory evaluation includes determining respiratory rate, noting the presence or absence of hypoxia by SpO_2, and noting any evidence of inspiratory stridor, expiratory wheezing, grunting, coughing, or increased work of breathing (e.g., retractions, nasal flaring, accessory muscle use). The **skin** should be carefully examined for rashes. Frequently, viral infections cause an exanthem, and many of these eruptions are diagnostic, such as the reticulated rash and slapped-cheek appearance of parvovirus infections and the stereotypical appearance of hand-foot-and-mouth disease caused by coxsackieviruses, as well as measles, chickenpox, and roseola. The skin examination may also yield evidence of more serious infections, including petechiae and purpura associated with bacteremia and erythroderma associated with a toxin-producing systemic infection. Cutaneous perfusion should be assessed by warmth and capillary refill time. The extremities may then be evaluated not only for ease of movement but also for the presence of swelling, warmth, tenderness, or alterations in perfusion. Such abnormalities may indicate focal infections (e.g., cellulitis, bone/joint infection) or vascular changes (e.g., arterial or venous thromboembolus).

When an infant is seated and is least perturbed, the examiner should assess the anterior fontanel to determine whether it is depressed, flat, or bulging. While the child is calm and cooperative, the **eyes** should be examined to identify features that might indicate an infectious or neurologic process. Often, viral infections result in watery discharge or redness of the bulbar conjunctivae. Bacterial infection, if superficial, results in purulent drainage; if the infection is more deep-seated, tenderness, swelling, and redness of the tissues surrounding the eye may be present, as well as proptosis, altered visual acuity, and impaired extraocular movement. Abnormalities in pupillary response or extraocular movements may also be indicators of cranial nerve abnormalities and if new, are indications for head imaging.

During this initial portion of the physical examination, when the child is most comfortable (and therefore most likely to be quiet), the **heart and lungs** are auscultated. It is important to assess the adequacy of air entry into the lungs, the equality of breath sounds, and any evidence of adventitial breath sounds, especially wheezes, rales, or rhonchi. The coarse sound of air moving through a congested nasal passage is frequently transmitted to the lungs. The examiner can become attuned to these coarse sounds by placing the stethoscope near the child's nose and then compensating for this sound as the chest is auscultated. The cardiac examination is next; findings such as pericardial friction rubs, loud murmurs, and distant heart sounds may indicate cardiac inflammation or infection. In the neonate, murmurs may herald congenital heart disease, especially in the presence of cyanosis, unequal extremity pulses, or a differential in upper- vs lower-extremity blood pressures. A complete cardiac exam should also look for displacement of the PMI (point of maximal impulse) and the presence of jugular venous distention or facial plethora.

The components of the physical examination that are more bothersome to the child are completed last. This is best done with the patient on the examination table. Initially, the **neck** is examined to assess for areas of swelling, redness, or tenderness, as may be seen in cervical adenitis. Resistance to neck movement should prompt evaluation for signs of meningeal irritation or retropharyngeal abscess. During examination of the **abdomen** , the diaper, if present, is removed. The abdomen is inspected for distention. Auscultation is performed to assess adequacy of bowel sounds, followed by palpation. Every attempt should be made to quiet a fussing child during this part of the exam; if this is not possible, practitioners should note that increased crying as the abdomen is palpated may indicate tenderness, especially if this finding is focally reproducible. In addition to focal tenderness, palpation may elicit involuntary guarding or rebound tenderness (including tenderness to percussion); these findings indicate peritoneal irritation, as seen in appendicitis. During palpation of the abdomen, practitioners should look for signs of hepatomegaly or splenomegaly. When palpating the bottom-most edge of the liver or spleen, examiners should begin in the pelvis and work upward toward the ribs, because severe organomegaly can be missed if the examiner begins palpating in the mid-abdomen. The **inguinal area and genitals** are then examined. One should assess the inguinal area for hernias. Care should be taken to examine the testicles of boys with abdominal pain; testicular trauma, testicular torsion, and epididymitis all may present with abdominal discomfort. A unilateral swollen or painful testicle with an absent cremasteric reflex on the affected side is concerning for testicular torsion and should be referred for emergent ultrasound and urologic consultation. After the genital exam, the child is then placed in the prone position, and abnormalities of the **back** are sought. The spine and costovertebral angle areas are percussed to elicit any tenderness; such findings may be indicative of vertebral osteomyelitis or diskitis and pyelonephritis, respectively.

Examining the **ears and throat** completes the physical examination. These are usually the most bothersome parts of the examination for the child, and parents frequently can be helpful in minimizing head movement. During the oropharyngeal examination, it is important to document the presence of enanthemas; these may be seen in many infectious processes, such as stomatitis caused by herpes or enteroviruses. This portion of the examination is also important in documenting inflammation or exudates on the tonsils, which may indicate viral or bacterial infection. Findings such as trismus or unilateral tonsillar swelling are concerning for peritonsillar abscess and for infections in the para- and retropharyngeal spaces; such cases should be referred for specialist ear, nose, and throat evaluation and imaging of the neck.

Repeating portions of the assessment may be indicated. If the child cried continuously during the initial clinical evaluation, the examiner may not be certain whether the crying was caused by the high fever, stranger anxiety, or pain, or is indicative of a serious or localizing illness. Constant crying also makes portions of the physical examination, such as auscultation of the chest, more difficult. Before a repeat assessment is performed, efforts to make the child as comfortable as possible are indicated. In young infants, **persistent irritability** , even when the examiner is absent from the room, is concerning for meningitis, encephalitis, or other causes of meningeal irritation (e.g., intracranial injury from nonaccidental trauma). When faced with a truly inconsolable infant, practitioners should have a low threshold to obtain head imaging and/or perform lumbar puncture, as the clinical scenario dictates.

Management

Most patients who present to the pediatrician's office with an acute illness will not require acute stabilization. However, the pediatrician needs to be prepared to evaluate and begin resuscitation for the seriously ill or unstable child. Outpatient pediatric offices and urgent care facilities should be stocked with appropriate equipment necessary to stabilize an acutely ill child. Maintenance of that equipment and ongoing training of the office staff in its use is required, and every effort should be made to ensure that pediatric clinicians are PALS certified (see Chapter 81).

The evaluation of the potentially unstable child must begin with assessment of the ABCs—airway, breathing, and circulation. When assessing the **airway** , chest rise should be evaluated and evidence of increased work of breathing sought. The examiner should ensure that the trachea is midline and should listen carefully for evidence of air exchange at the level of the extrathoracic airway. If the airway is patent and no signs of obstruction are present, the patient is allowed to assume a position of comfort. If the child shows signs of airway obstruction, repositioning of the head with the chin-lift maneuver may alleviate the obstruction. An oral or nasal airway may be necessary in patients in whom airway patency cannot be maintained. These devices are not well tolerated in conscious patients because they may induce gagging or vomiting; instead, they are most often used to facilitate effective bag-valve-mask ventilation in semiconscious or unconscious children. Once airway patency has been established, the adequacy of **breathing** should be evaluated. Slow respiratory rates or cyanosis may signal impending respiratory failure. If the airway is patent but the child's respiratory effort is inadequate, positive pressure ventilation via bag-valve-mask support should be initiated. Oxygen should be administered to all seriously ill or hypoxic children via nasal cannula or face mask. Auscultation of the lung fields should assess for air entry, symmetry of breath sounds, and presence of adventitious breath sounds such as crackles or wheezes. Bronchodilator therapy can be initiated to alleviate bronchospasm. Racemic epinephrine is indicated for stridor at rest in a patient with croup. Once airway and breathing have been addressed, **circulation** must be evaluated. Symptoms of *shock* include tachycardia, cool extremities, delayed capillary refill time, mottled or pale skin, and effortless tachypnea. In children, hypotension is a late finding in shock and indicates that significant decompensation has already taken place. Vascular access is necessary for volume resuscitation in patients with impaired circulation, and an intraosseous line should be considered early if there is any difficulty in obtaining vascular access for a patient requiring resuscitation. Each time an intervention is performed, the clinician should **reassess the patient** to determine whether interventions have been successful and whether additional care is needed.

Disposition

The majority of children evaluated in the office or urgent care setting for an acute illness can be managed as an **outpatient** . These patients should have a reassuring physical examination, stable vital signs, and an adequate follow-up plan before being sent home. A mildly dehydrated patient can be discharged home for a trial of oral rehydration. Patients with respiratory illness who exhibit signs of mild respiratory distress may be monitored at home, with a repeat examination scheduled the next day. Depending on the child's condition, the comfort of the parents, and the relationship of the family with the physician, telephone follow-up may be all that is necessary. When no specific diagnosis has been established at the first outpatient visit, a follow-up examination may yield the diagnosis and can provide reassurance for both the caregiver and the practitioner that a child's severity of illness has not progressed.

However, if it is deemed that the child needs a higher level of care, it is the pediatrician's responsibility to decide what method of transfer is appropriate. Physicians may be reluctant to call for help because of a misperception that emergency 911 services should be activated only for ongoing resuscitation. Emergency medical services (EMS) transport should be initiated for any child who is physiologically unstable (e.g., with severe respiratory distress, hypoxia, signs of shock, or altered mental state). If the family's ability to comply promptly with recommendation for ED evaluation is in question, this patient also should be transported by EMS. Some physicians and families may defer calling EMS because of the perception that a parent can reach the hospital faster by private motor vehicle. Although rapidity of transport should be considered, the need for further interventions during transport and the risk of clinical decompensation are other important factors in the decision to activate EMS. Ultimately, the legal responsibility for choosing an appropriate level of transport for a patient lies with the referring physician, until responsibility of care is officially transferred to another medical provider.

CHAPTER 81

Pediatric Emergencies and Resuscitation

Mary E. Hartman, Ira M. Cheifetz

Injuries are the leading cause of death in American children and young adults and account for more childhood deaths than all other causes combined (see Chapter 13). Rapid, effective bystander cardiopulmonary resuscitation (CPR) for children is associated with survival rates as high as 70%, with good neurologic outcome. However, bystander CPR is still provided for <50% of children who experience cardiac arrest outside medical settings. This failing has led to long-term survival rates of <40%, often with a poor neurologic outcome.

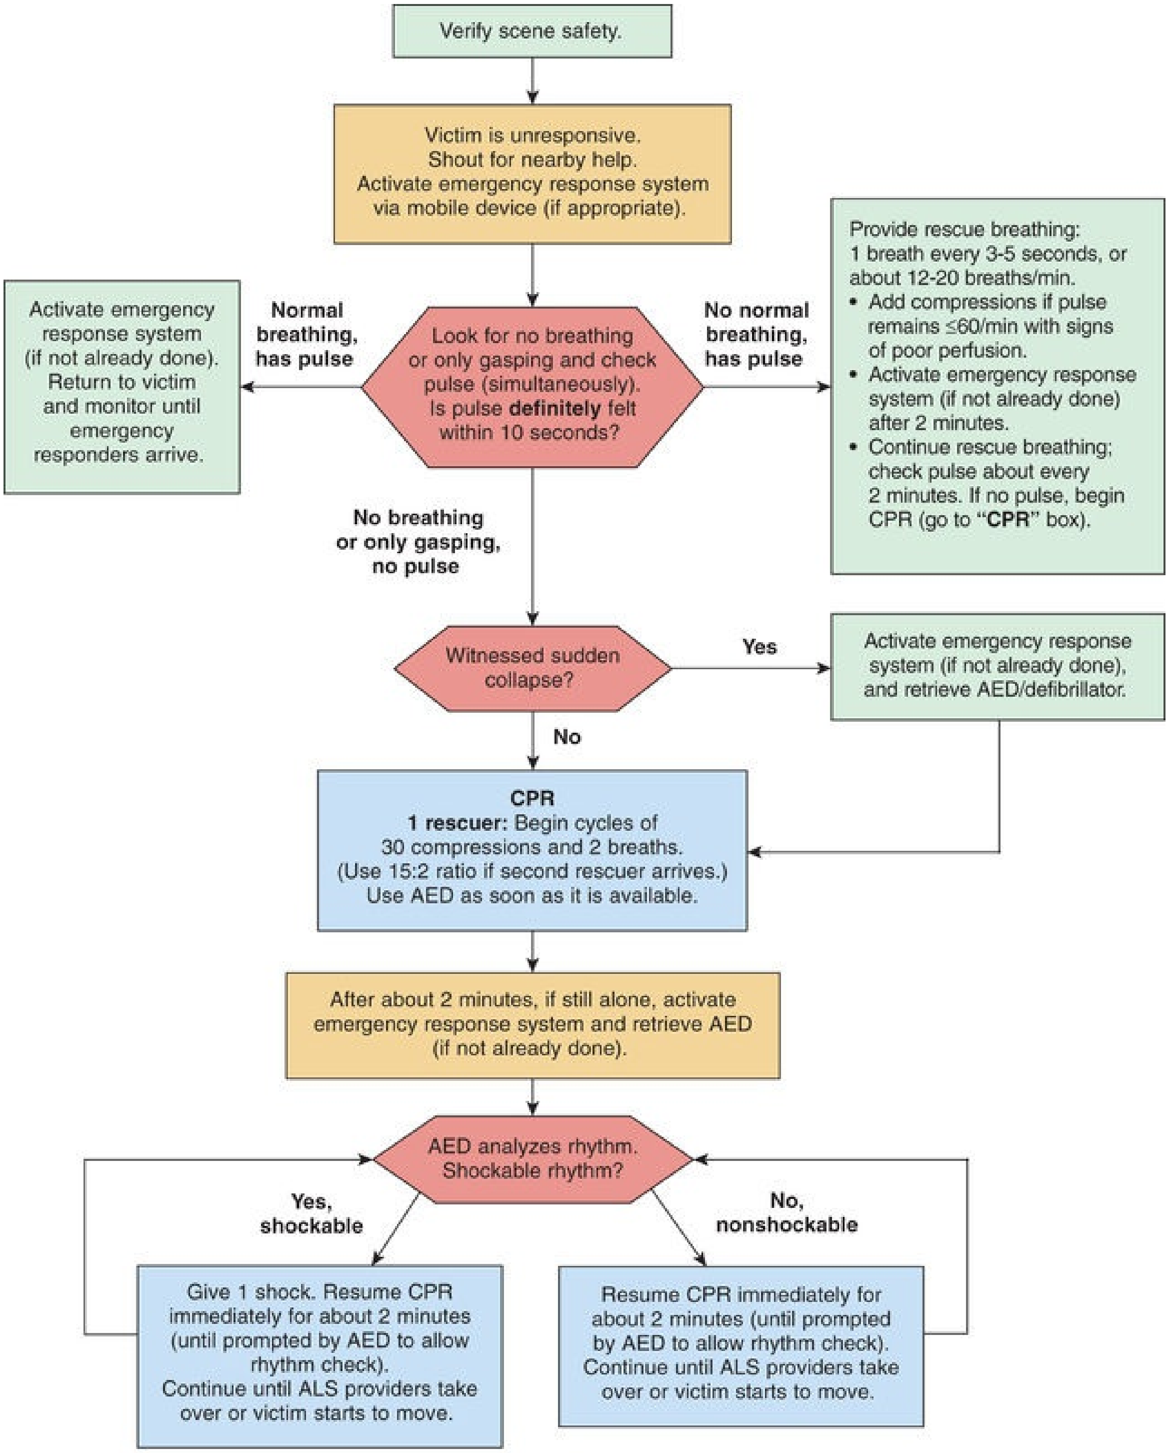
Approach to the Emergency Evaluation of a Child

The first response to a pediatric emergency of any cause is a systematic, rapid **general assessment** of the scene and the child to identify immediate threats to the child, care providers, or others. If an emergency is identified, the emergency response system (emergency medical services, EMS) should be activated immediately. Care providers should then proceed through **primary** , **secondary** , and **tertiary** assessments as allowed by the child's condition, safety of the scene, and resources available. This standardized approach provides organization to what might otherwise be a confusing or chaotic situation and reinforces an organized thought process for care providers. If at any point in these assessments the caregiver identifies a life-threatening problem, the assessment is halted and lifesaving interventions are initiated. Further assessment and intervention should be delayed until other caregivers arrive or the condition is successfully treated or stabilized.

General Assessment

On arrival at the scene of a compromised child, a caregiver's first task is a quick survey of the scene itself. Is the rescuer or child in imminent danger because of circumstances at the scene (e.g., fire, high-voltage electricity)? If so, can the child be safely extricated to a safe location for assessment and treatment? Can the child be safely moved with the appropriate precautions (i.e., cervical spine protection), if indicated? A rescuer is expected to proceed only if these important safety conditions have been met.

Once the caregiver and patient's safety has been ensured, the caregiver performs a rapid **visual survey** of the child, assessing the child's **general appearance** and **cardiopulmonary function** . This action should be only a few seconds and include assessment of (1) general appearance, determining color, tone, alertness, and responsiveness; (2) adequacy of breathing, distinguishing between normal, comfortable respirations and respiratory distress or apnea; and (3) adequacy of circulation, identifying cyanosis, pallor, or mottling. A child found unresponsive from an *unwitnessed* collapse should be approached with a gentle touch and the verbal question, “Are you OK?” If there is no response, the caregiver should immediately shout for help and send someone to activate the emergency response system and locate an **automated external defibrillator (AED)** . Figs. 81.1 and 81.2 present basic life support (BLS) pediatric cardiac arrest algorithms for 1 rescuer and 2 or more rescuers, respectively. The provider should then determine whether the child is breathing and, if not, provide 2 rescue breaths. If the child is breathing adequately, the circulation is quickly assessed. Any child with heart rate <60 beats/min or without a pulse requires immediate CPR. If the caregiver *witnesses* the sudden collapse of a child, the caregiver should have a higher suspicion for a sudden cardiac event. In this case, rapid deployment of an AED is crucial. Any interruptions in care of the child to activate EMS and locate the nearest AED should be very brief. If >1 caregiver is present, someone should always remain with the child and provide initial care or stabilization (see Fig. 81.2).



Verify scene safety.
Victim is unresponsive. Shout for nearby help. Activate emergency response system via mobile device (if appropriate).
Look for no breathing or only gasping and check pulse (simultaneously). Is pulse **definitely** felt within 10 seconds?
Normal breathing, has pulse
Activate emergency response system (if not already done). Return to victim and monitor until emergency responders arrive.
No normal breathing, has pulse
Provide rescue breathing: 1 breath every 3-5 seconds, or about 12-20 breaths/min.
• Add compressions if pulse remains ≤60/min with signs of poor perfusion.
• Activate emergency response system (if not already done) after 2 minutes.
• Continue rescue breathing; check pulse about every 2 minutes. If no pulse, begin CPR (go to "**CPR**" box).
No breathing or only gasping, no pulse
Witnessed sudden collapse?
Yes
Activate emergency response system (if not already done), and retrieve AED/defibrillator.
No
CPR
1 rescuer: Begin cycles of 30 compressions and 2 breaths. (Use 15:2 ratio if second rescuer arrives.) Use AED as soon as it is available.
After about 2 minutes, if still alone, activate emergency response system and retrieve AED (if not already done).
AED analyzes rhythm. Shockable rhythm?
Yes, shockable
Give 1 shock. Resume CPR immediately for about 2 minutes (until prompted by AED to allow rhythm check). Continue until ALS providers take over or victim starts to move.
No, nonshockable
Resume CPR immediately for about 2 minutes (until prompted by AED to allow rhythm check). Continue until ALS providers take over or victim starts to move.

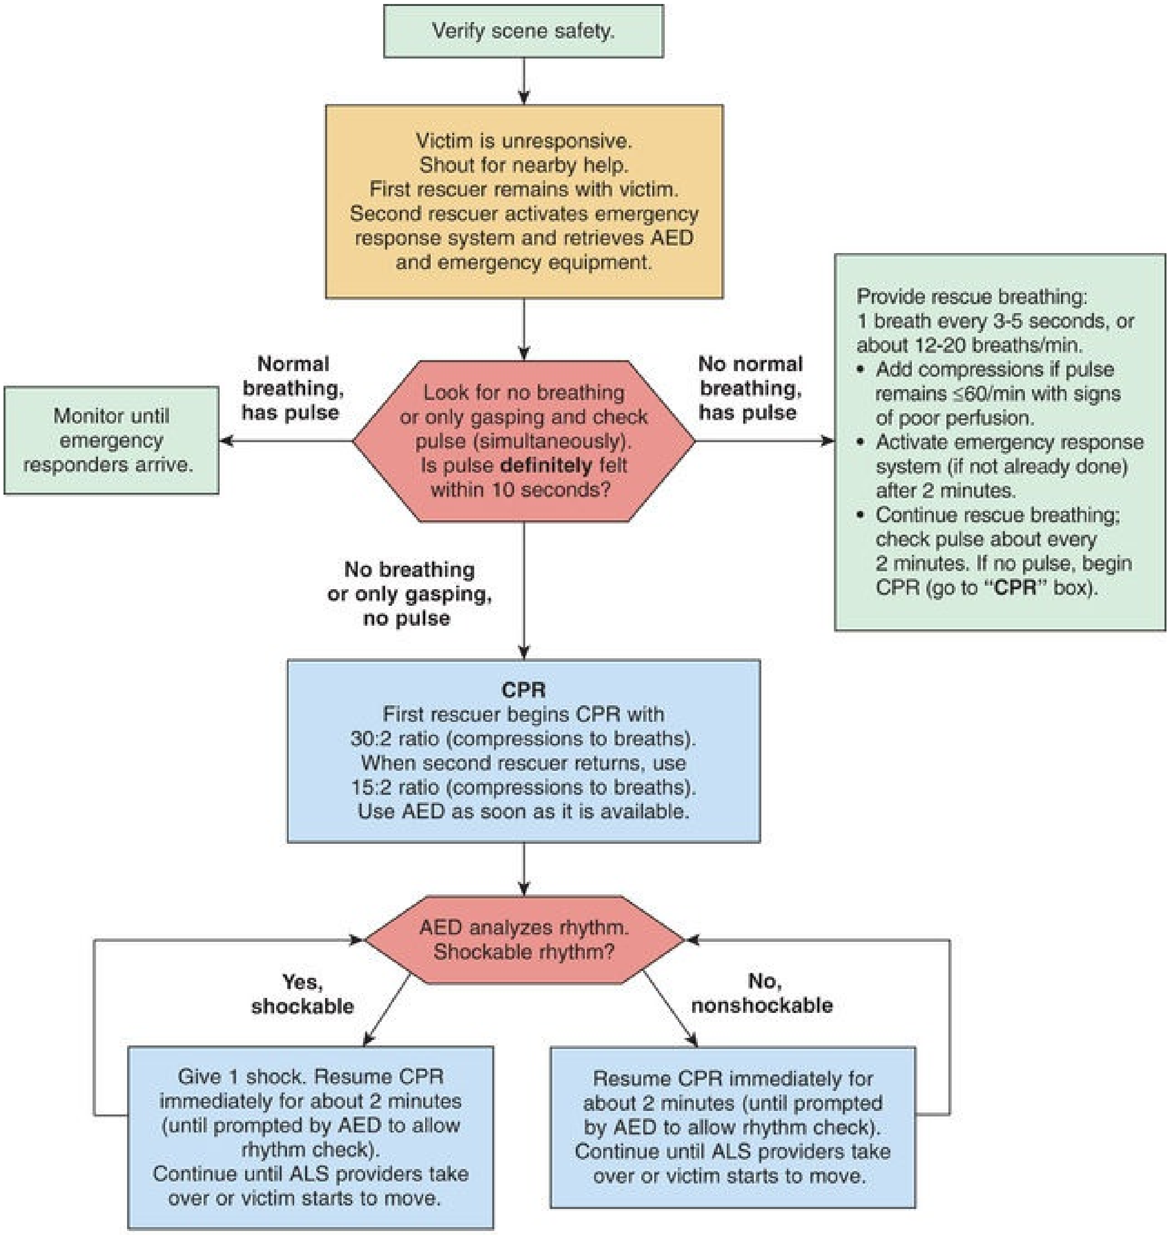
AED, Automated external defibrillator; ALS, advanced life support; CPR, cardiopulmonary resuscitation. (From Atkins DL, Berger S, Duff JP, et al: Part 11. Pediatric basic life support and cardiopulmonary resuscitation quality: 2015 American Heart Association guidelines update for cardiopulmonary resuscitation and emergency cardiovascular care, Circulation 132[Suppl 2]:S519–S525, 2015, Fig 1, p S521.)



Verify scene safety.

Victim is unresponsive.
Shout for nearby help.
First rescuer remains with victim.
Second rescuer activates emergency response system and retrieves AED and emergency equipment.

Look for no breathing or only gasping and check pulse (simultaneously).
Is pulse **definitely** felt within 10 seconds?

Normal breathing, has pulse

Monitor until emergency responders arrive.

No normal breathing, has pulse

Provide rescue breathing:
1 breath every 3-5 seconds, or about 12-20 breaths/min.
- Add compressions if pulse remains ≤60/min with signs of poor perfusion.
- Activate emergency response system (if not already done) after 2 minutes.
- Continue rescue breathing; check pulse about every 2 minutes. If no pulse, begin CPR (go to "**CPR**" box).

No breathing or only gasping, no pulse

CPR
First rescuer begins CPR with 30:2 ratio (compressions to breaths).
When second rescuer returns, use 15:2 ratio (compressions to breaths).
Use AED as soon as it is available.

AED analyzes rhythm.
Shockable rhythm?

Yes, shockable

Give 1 shock. Resume CPR immediately for about 2 minutes (until prompted by AED to allow rhythm check).
Continue until ALS providers take over or victim starts to move.

No, nonshockable

Resume CPR immediately for about 2 minutes (until prompted by AED to allow rhythm check).
Continue until ALS providers take over or victim starts to move.

FIG. 81.2 Basic life support (BLS) healthcare provider pediatric cardiac arrest algorithm for 2 or more rescuers—2015 update. AED, Automated external defibrillator; ALS, advanced life support; CPR, cardiopulmonary resuscitation. (From Atkins DL, Berger S, Duff JP, et al: Part 11. Pediatric basic life support and cardiopulmonary resuscitation quality: 2015 American Heart Association guidelines update for cardiopulmonary resuscitation and emergency cardiovascular care, Circulation 132[Suppl 2]:S519–S525, 2015, Fig 2, p S522.)

Primary Assessment

Once the emergency response system has been activated and the child is determined not to need CPR, the caregiver should proceed with a primary assessment that includes a brief, **hands-on assessment** of cardiopulmonary and neurologic function and stability. This assessment includes a limited physical examination, evaluation of vital signs, and measurement of pulse oximetry if available. The American Heart Association, in its Pediatric Advanced Life Support (PALS) curriculum, supports the structured format of **airway, breathing, circulation, disability, exposure (ABCDE)** . The goal of the primary assessment is to obtain a focused, systems-based assessment of the child's injuries or abnormalities, so that resuscitative efforts can be directed to these areas; if the caregiver identifies a life-threatening abnormality, further evaluation is postponed until appropriate corrective action has been taken.

The exam and vital sign data can be interpreted only if the caregiver has a thorough understanding of normal values. In pediatrics, normal respiratory rate, heart rate, and blood pressure have age-specific norms (Table 81.1). These ranges can be difficult to remember, especially if used infrequently. However, several standard principals apply: (1) a child's respiratory rate should not be >60 breaths/min for a sustained period; (2) normal heart rate is 2-3 times normal respiratory rate for age; and (3) a simple guide for pediatric blood pressure is that the lower limit of systolic blood pressure should be ≥60 mm Hg for neonates; ≥70 mm Hg for 1 mo-1 yr olds; ≥70 mm Hg + (2 × age) for 1-10 yr olds; and ≥90 mm Hg for any child older than 10 yr.

Table 81.1

Normal Vital Signs According to Age

AGE	HEART RATE (beats/min)	BLOOD PRESSURE (mm Hg)	RESPIRATORY RATE (breaths/min)
Premature	120-170[*]	55-75/35-45[†]	40-70[‡]
0-3 mo	100-150[*]	65-85/45-55	35-55
3-6 mo	90-120	70-90/50-65	30-45
6-12 mo	80-120	80-100/55-65	25-40
1-3 yr	70-110	90-105/55-70	20-30
3-6 yr	65-110	95-110/60-75	20-25
6-12 yr	60-95	100-120/60-75	14-22
12+ yr	55-85	110-135/65-85	12-18

[*] In sleep, infant heart rates may drop significantly lower, but if perfusion is maintained, no intervention is required.

[†] A blood pressure cuff should cover approximately two thirds of the arm; too small a cuff yields

spuriously high pressure readings, and too large a cuff yields spuriously low pressure readings. Values are systolic/diastolic.

‡ Many premature infants require mechanical ventilatory support, making their spontaneous respiratory rate less relevant.

Airway and Breathing

The most common precipitating event for cardiac instability in infants and children is respiratory insufficiency . Therefore, rapid assessment of respiratory failure and immediate restoration of adequate ventilation and oxygenation remain the first priority in the resuscitation of a child. Using a systematic approach, the caregiver should first assess whether the child's airway is patent and maintainable. A healthy, **patent** airway is unobstructed, allowing normal respiration without noise or effort. A **maintainable** airway is one that is either already patent or can be made patent with a simple maneuver. To assess airway patency, the provider should look for breathing movements in the child's chest and abdomen, listen for breath sounds, and feel the movement of air at the child's mouth and nose. Abnormal breathing sounds (e.g., snoring or stridor), increased work of breathing, and apnea are all findings potentially consistent with airway obstruction. If there is evidence of airway obstruction, maneuvers to relieve the obstruction should be instituted before the caregiver proceeds to evaluate the child's breathing.

Assessment of breathing includes evaluation of the child's respiratory rate, respiratory effort, abnormal sounds, and pulse oximetry. Normal breathing appears comfortable, is quiet, and occurs at an age-appropriate rate. Abnormal respiratory rates include apnea and rates that are either too slow (bradypnea) or too fast (tachypnea). *Bradypnea and irregular respiratory patterns require urgent attention because they are often signs of impending respiratory failure and/or apnea.* Signs of increased respiratory effort include nasal flaring, grunting, chest or neck muscle retractions, head bobbing, and seesaw respirations. Hemoglobin oxygen desaturation, as measured by pulse oximetry, often accompanies parenchymal lung disease apnea or airway obstruction. However, providers should keep in mind that adequate perfusion is required to produce a reliable oxygen saturation (SO_2) measurement. A child with low SO_2 is a child in distress. **Central cyanosis** is a sign of severe hypoxia and indicates an emergent need for oxygen supplementation and respiratory support.

Circulation

Cardiovascular function is assessed by evaluation of skin color and temperature, heart rate, heart rhythm, pulses, capillary refill time, and blood pressure. In nonhospital settings, much of the important information can be obtained without measuring the blood pressure; lack of blood pressure data should not prevent the provider for determining adequacy of circulation or implementing a lifesaving response. Mottling, pallor, delayed capillary refill, cyanosis, poor pulses, and cool extremities are all signs of diminished perfusion and compromised cardiac output. **Tachycardia** is the earliest and most reliable sign of shock but is itself fairly nonspecific and should be correlated with other components of the exam, such as weakness, threadiness, and absence of pulses. An age-specific approach to pulse assessment will yield best results.

Disability

In the setting of a pediatric emergency, *disability* refers to a child's neurologic function in terms of the level of consciousness and cortical function. Standard evaluation of a child's neurologic condition can be done quickly with an assessment of pupillary response to light (if one is available) and use of either of the standard scores used in pediatrics: the Alert, Verbal, Pain, Unresponsive (AVPU) Pediatric Response Scale and the Glasgow Coma Scale (GCS). The causes of decreased level of consciousness in children are numerous and include conditions as diverse as respiratory failure with hypoxia or hypercarbia, hypoglycemia, poisonings or drug overdose, trauma, seizures, infection, and shock. *Most often, an ill or injured child has an altered level of consciousness because of respiratory compromise, circulatory compromise, or both.* Any child with a depressed level of consciousness should be immediately assessed for abnormalities in cardiorespiratory status.

Alert, Verbal, Pain, Unresponsive Pediatric Response Scale.

The AVPU scoring system is used to determine a child's level of consciousness and cerebral cortex function (Table 81.2). Unlike the GCS, the AVPU scale is not developmentally dependent—a child does not have to understand spoken language or follow commands, merely respond to a stimulus. The child is scored according to the amount of stimulus required to obtain a response, from *alert* (no stimulus, the child is already awake and interactive) to *unresponsive* (child does not respond to any stimulus).

Table 81.2

AVPU Neurologic Assessment

A	The child is awake, alert, and interactive with parents and care providers.
V	The child responds only if the care provider or parents call the child's name or speak loudly.
P	The child responds only to painful stimuli, such as pinching the nail bed of a toe or finger.
U	The child is unresponsive to all stimuli.

A, Alert; V, verbal, P, pain, U, unresponsive.

From Ralston M, Hazinski MF, Zaritsky AL, et al, editors: *Pediatric advanced life support course guide and PALS provider manual: provider manual,* Dallas, 2007, American Heart Association.

Glasgow Coma Scale.

Although it has not been systematically validated as a prognostic scoring system for infants and young children as it has in adults, GCS is frequently used in the assessment of pediatric patients with an altered level of consciousness. The GCS is the most widely used method of evaluating a child's neurologic function and has 3 components. Individual scores for eye opening, verbal response, and motor response are added together, with a maximum of 15 points (Table 81.3). Patients with a GCS score ≤8 require aggressive management, generally including stabilization of the airway and breathing with endotracheal intubation and mechanical ventilation, respectively, and if indicated, placement of an intracranial pressure monitoring device. The **Full Outline of Unresponsiveness** (FOUR) score is another useful assessment and monitoring tool (see Table 85.1).

Exposure

Exposure is the final component of the pediatric primary assessment. This component of the exam is reached only after the child's airway, breathing, and circulation have been assessed and determined to be stable or have been stabilized through simple interventions. In this setting, *exposure* stands for the dual responsibility of the provider to both expose the child to assess for previously unidentified injures and consider prolonged exposure in a cold environment as a possible cause of hypothermia and cardiopulmonary instability. The provider should undress the child (as is feasible and reasonable) to perform a focused physical exam, assessing for burns, bruising, bleeding, joint laxity, and fractures. If possible, the provider should assess the child's temperature. All maneuvers should be performed with careful maintenance of cervical spine precautions.

Secondary Assessment

For healthcare providers in community or outpatient settings, transfer of care of a child to emergency or hospital personnel may occur before a full secondary assessment is possible. However, before the child is removed from the scene and separated from witnesses or family, a brief history should be obtained for medical providers at the accepting facility. The components of a secondary assessment include a **focused history** and **focused physical examination.**

The history should be targeted to information that could explain cardiorespiratory or neurologic dysfunction and should take the form of a **SAMPLE history** : signs/symptoms, allergies, medications, past medical history, timing of last meal, and events leading to this situation. Medical personnel not engaged in resuscitative efforts can be dispatched to elicit history from witnesses or relatives. The physical examination during the secondary assessment is a thorough head-to-toe exam, although the severity of the child's illness or injury could necessitate curtailing portions of the exam or postponing nonessential elements until a later time.

Tertiary Assessment

The tertiary assessment occurs in a hospital setting, where ancillary laboratory and radiographic assessments contribute to a thorough understanding of the child's condition. A basic blood chemistry profile, complete blood count, liver function tests, coagulation studies, and arterial blood gas analyses give fairly broad (but somewhat nonspecific) estimates of renal function, acid-base balance, cardiorespiratory function, and presence or absence of shock. Chest radiographs can be useful to evaluate both the heart and lungs, although more detailed estimates of heart function and cardiac output can be made with **echocardiography** . Arterial and central venous catheters can be placed to monitor arterial and central venous pressure.

Recognition and Treatment of Respiratory Distress and Failure

The goals of initial management of respiratory distress or failure are to rapidly stabilize the child's airway and breathing and to identify the cause of the problem so that further therapeutic efforts can be appropriately directed.

Airway Obstruction

Children <5 yr old are particularly susceptible to foreign body aspiration and choking. Liquids are the most common cause of choking in infants, whereas small objects and food (e.g., grapes, nuts, hot dogs, candy) are the most common source of foreign bodies in the airways of toddlers and older children. A history consistent with foreign body aspiration is considered diagnostic. Any child in the proper setting with the sudden onset of choking, stridor, or wheezing has foreign body aspiration until proven otherwise.

Airway obstruction is treated with a sequential approach, starting with the head-tilt/chin-lift maneuver to open and support the airway, followed by inspection for a foreign body, and finger-sweep clearance or suctioning if one is visualized (Fig. 81.3). *Blind suctioning or finger sweeps of the mouth are not recommended.* A nasopharyngeal airway or oropharyngeal airway can be inserted for airway support, if indicated. A conscious child suspected of having a partial foreign body obstruction should be permitted to cough spontaneously until coughing is no longer effective, respiratory distress and stridor increase, or the child becomes unconscious.

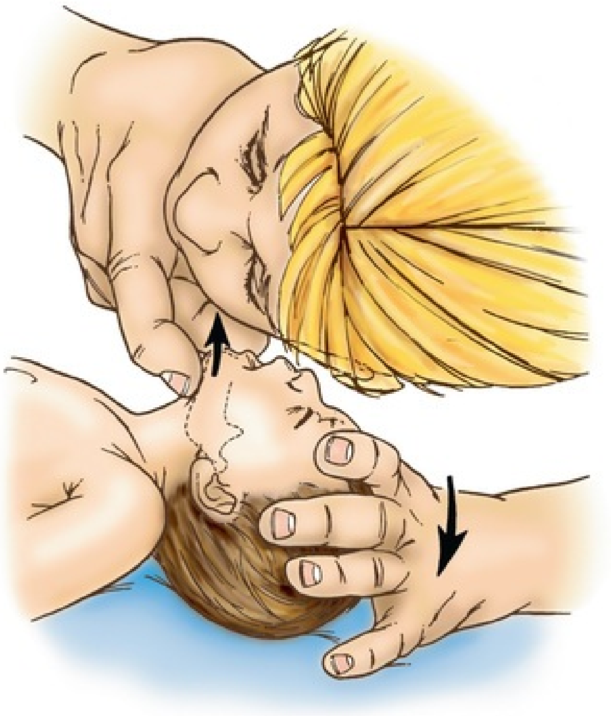

FIG. 81.3 **Opening the airway with the head-tilt/chin-lift maneuver. One hand is used to tilt the head, extending the neck. The index finger of the rescuer's other hand lifts the mandible outward by lifting the chin. Head-tilt should not be performed if a cervical spine injury is suspected. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, *JAMA* 268:2251–2261, 1992.)**

If the child becomes unconscious, the child should be gently placed on the ground, supine. The provider should then open the airway with the head-tilt/chin-lift maneuver and attempt mouth-to-mouth ventilation (Figs. 81.4 and 81.5). If ventilation is unsuccessful, the airway is repositioned and ventilation attempted again. If there is still no chest rise, attempts to remove a foreign body are indicated. In an infant <1 yr old, a combination of 5 back blows and 5 chest thrusts is administered (Fig. 81.6). After each cycle of back blows and chest thrusts, the child's mouth should be visually inspected for the presence of the foreign body. If identified within finger's reach, it should be removed with a gentle finger sweep. If no foreign body is visual, ventilation is again attempted. If this is unsuccessful, the head is repositioned and ventilation attempted again. If there is still no chest rise, the series of back blows and chest thrusts is repeated.

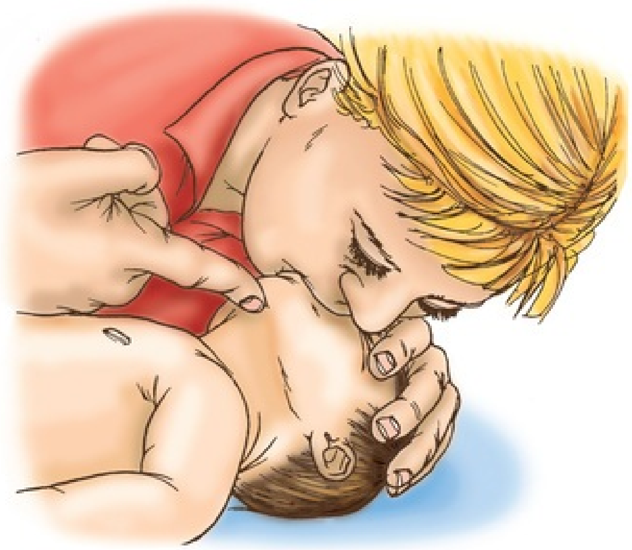

FIG. 81.4 **Rescue breathing in an infant. The rescuer's mouth covers the infant's nose and mouth, creating a seal. One hand performs the head-tilt while the other hand lifts the infant's jaw. Avoid head-tilt if the infant has sustained head or neck trauma. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, *JAMA* 268:2251–2261, 1992.)**

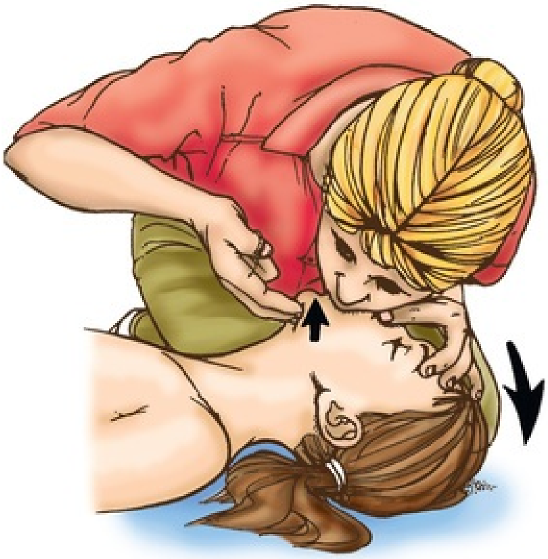

FIG. 81.5 Rescue breathing in a child. The rescuer's mouth covers the child's mouth, creating a mouth-to-mouth seal. One hand maintains the head-tilt; the thumb and forefinger of the same hand are used to pinch the child's nose. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, *JAMA* 268:2251–2261, 1992.)

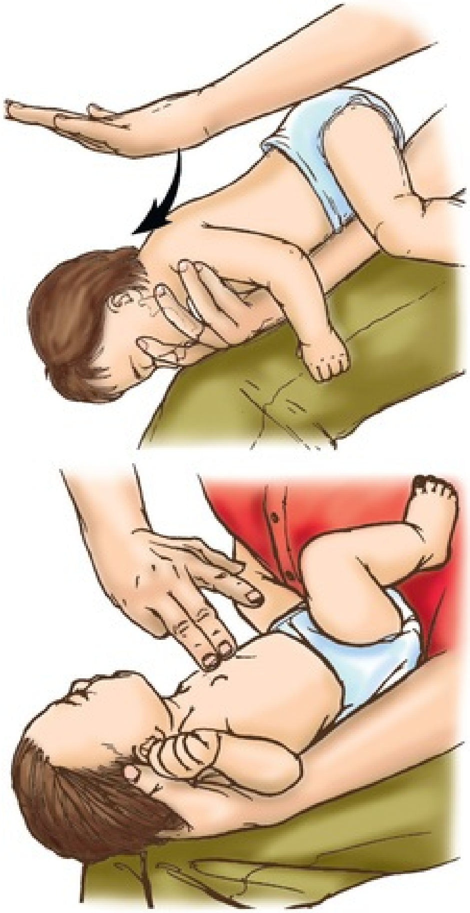

FIG. 81.6 Back blows *(top)* and chest thrusts *(bottom)* to relieve foreign body airway obstruction in the infant. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, *JAMA* 268:2251–2261, 1992.)

For a conscious child >1 yr old, providers should give a series of 5 abdominal thrusts (**Heimlich maneuver**) with the child standing or sitting (Fig. 81.7); this should occur with the child lying down if unconscious (Fig. 81.8). After the abdominal thrusts, the airway is examined for a foreign body, which should be removed if visualized. If no foreign body is seen, the head is repositioned and ventilation attempted. If unsuccessful, the head is repositioned and ventilation attempted again. If these efforts are unsuccessful, the Heimlich sequence is repeated.

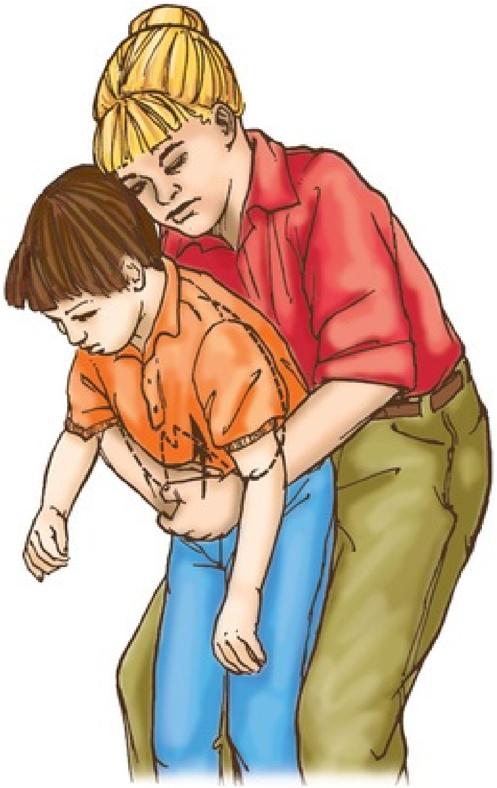

FIG. 81.7 Abdominal thrusts with the victim standing or sitting (conscious). (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, *JAMA* 268:2251–2261, 1992.)

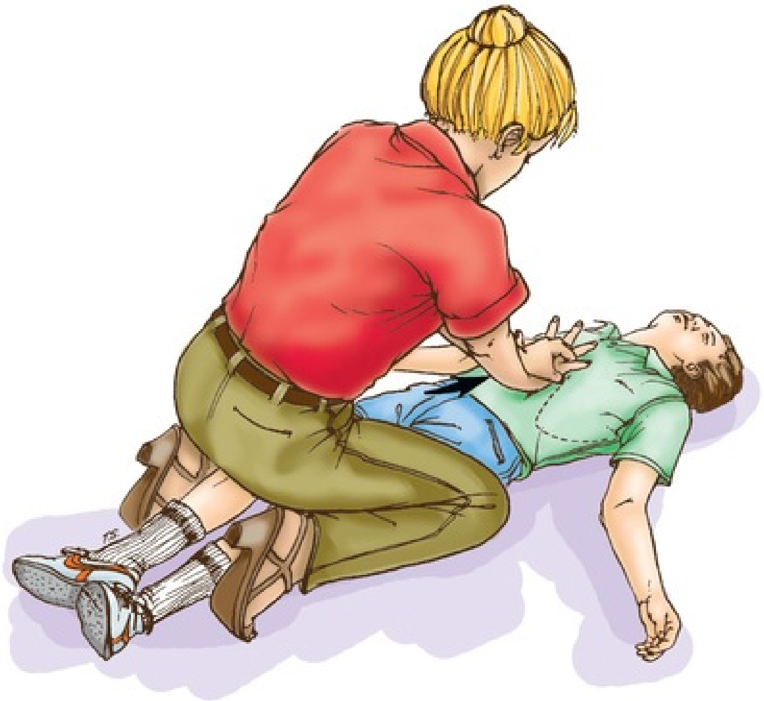

FIG. 81.8 Abdominal thrusts with victim lying (conscious or unconscious). (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, *JAMA* 268:2251–2261, 1992.)

Airway Narrowing

Airway obstruction can also be caused by airway narrowing, in both the upper and lower airways. *Upper airway obstruction* refers to narrowing of the extrathoracic portion of the airway, including the oropharynx, larynx, and trachea. In the upper airways, narrowing is most often caused by airway **edema** (e.g., croup or anaphylaxis). Lower airway disease affects all intrathoracic airways, notably the bronchi and bronchioles. In the lower airways, **bronchiolitis** and acute **asthma** exacerbations are the major contributors to intrathoracic airway obstruction in children, causing airway narrowing through a combination of airway swelling, mucus production, and circumferential smooth muscle constriction of smaller airways.

Airway support for these processes is dictated by both the underlying condition and the clinical severity of the problem. In cases of mild upper airway obstruction, the child has minimally elevated work of breathing (evidenced by tachypnea and few to mild retractions). Stridor, if present at all, should be audible with only coughing or activity. Children with these findings can be supported with supplemental oxygen as needed. In cases with moderate obstruction, in which the child has a higher work of breathing and more pronounced stridor, nebulized racemic **epinephrine** and oral or intravenous (IV) **dexamethasone** can be added. **Heliox** (combined helium-oxygen therapy) administration may also be considered. Children with severe upper airway obstruction have marked intercostal retractions, prominent stridor, and decreased air entry on auscultation of the lung fields. Most children with significant airway obstruction are also hypoxic, and many appear dyspneic and agitated. A child in severe distress needs to be closely observed because the signs of impending respiratory failure may be initially confused with improvement. Stridor becomes quieter and intercostal retractions less prominent when a child's respiratory effort begins to diminish. The child in respiratory failure can be distinguished from one who is improving by evidence of poor air movement on auscultation and lethargy or decreased level of consciousness from hypercarbia, hypoxia, or both. When **anaphylaxis** is suspected as the cause for upper airway edema, providers should administer an intramuscular (IM) or IV dose of epinephrine as needed (see Chapter 174). No matter the cause, any child in impending respiratory failure should be prepared for endotracheal intubation and respiratory support. Prompt notification of providers trained in airway management is essential.

In cases of *lower airway obstruction* , therapies are targeted to both relieving the obstruction and reducing the child's work of breathing. Inhaled **bronchodilators** , such as albuterol, augmented by oral or IV corticosteroids, remain the mainstay of therapy in settings of mild to moderate acute distress caused by lower airway obstruction (e.g., **asthma**). Children with more significant obstruction appear dyspneic, with tachypnea, retractions, and easily audible wheezing. In these cases, the addition of an anticholinergic agent, such as nebulized ipratropium bromide, or a smooth muscle relaxant, such as magnesium sulfate, may provide further relief, although the evidence for these measures remains controversial (see Chapter 169). Supplemental oxygen and IV fluid hydration can also be useful adjuncts. As in cases of upper airway obstruction, impending respiratory failure in children with lower airway obstruction can be insidious. When diagnosed early in a school-age child who is cooperative, respiratory failure can be averted through judicious use of noninvasive support, including heated, high-flow nasal cannula (HFNC) therapy, continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), or heliox therapy. Endotracheal intubation should be performed only by skilled providers, preferably in a hospital setting, because there is a high risk of cardiorespiratory compromise in patients with lower airway obstruction during the procedure.

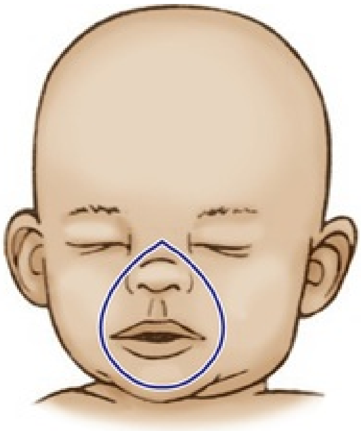
Parenchymal Lung Disease

Parenchymal lung disease includes a heterogeneous list of conditions, such as pneumonia, acute respiratory distress syndrome (ARDS), pneumonitis, bronchiolitis, bronchopulmonary dysplasia, cystic fibrosis, and pulmonary edema. The commonalities of these conditions are their effects on the small airways and alveoli, including inflammation and exudation leading to consolidation of lung tissue, decreased gas exchange, and increased work of breathing. Clinical management of these conditions includes specific treatment as indicated (e.g., antibiotics for bacterial pneumonia) and supportive care in the form of supplemental oxygen, noninvasive respiratory support (with HFNC, CPAP, or BiPAP), or invasive mechanical ventilation.

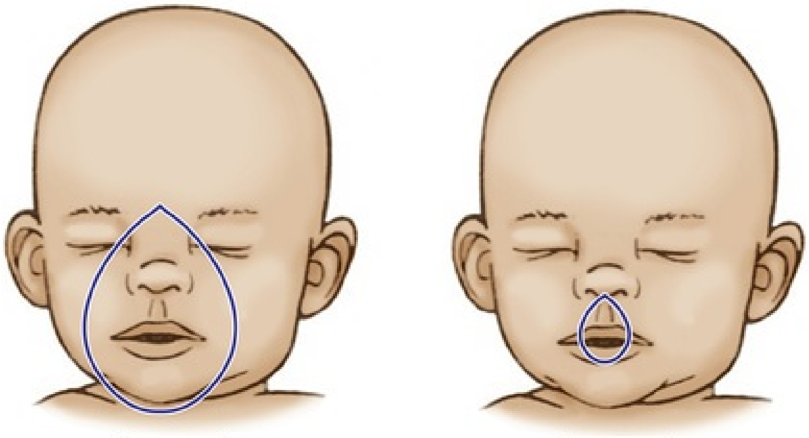
Advanced Airway Management Techniques

Bag-Valve-Mask Positive Pressure Ventilation

Rescue breathing with a bag-valve-mask apparatus can be as effective as endotracheal intubation and safer when the provider is inexperienced with intubation. Bag-valve-mask ventilation itself requires training to ensure that the provider is competent to select the correct mask size, open the child's airway, form a tight seal between the mask and the child's face, deliver effective ventilation, and assess the effectiveness of the ventilation. An appropriately sized mask is one that fits over the child's mouth and nose but does not extend below the chin or over the eyes (Fig. 81.9). An adequate seal is best achieved through a combination “C-E” grip on the mask, in which the thumb and index finger form the letter “C” on top of the mask, pressing the mask downward onto the child's face, and the remaining 3 fingers form an “E” grip under the child's mandible, holding the jaw forward and extending the head up toward the mask. Using this method, the care provider can secure the mask to the child's face with one hand and use the other hand to compress the ventilation bag (Fig. 81.10).



Correct
Covers mouth, nose, and chin but not eyes



Incorrect
Too large: covers eyes and extends over chin

Incorrect
Too small: does not cover nose and mouth well

FIG. 81.9 Appropriate sizing technique for pediatric bag-valve-mask apparatus. (From American Academy of Pediatrics and the American Heart Association; Kattwinkel J (ed): *Textbook of Neonatal Resuscitation,* ed 6. Elk Grove, IL: American Academy of Pediatrics, 2011. Fig 3-17.)

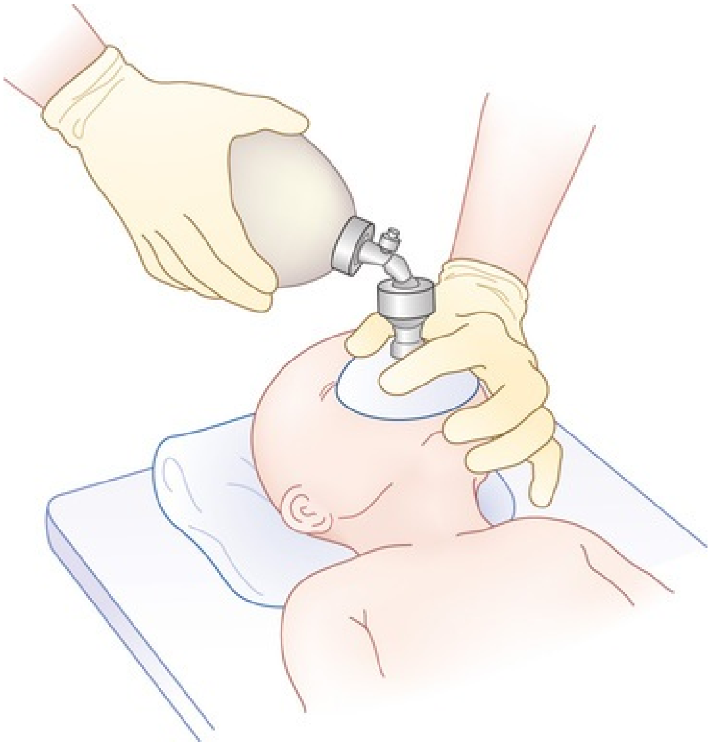


FIG. 81.10 “C-E” grip to secure bag-valve-mask to a child's face with appropriate seal.

The provider may have to move the head and neck through a range of positions to find the one that best maintains airway patency and allows maximal ventilation. In infants and young children, optimal ventilation is often provided when the child's head is in the neutral sniffing position without hyperextension of the head (Fig. 81.11). Poor chest rise and persistently low S_{O_2} values indicate inadequate ventilation. In this setting the care provider should recheck the mask's seal on the child's face, reposition the child's head, and consider suctioning the airway, if indicated. If these maneuvers do not restore ventilation, the provider should consider noninvasive or invasive respiratory support (i.e., endotracheal intubation) as clinically indicated.

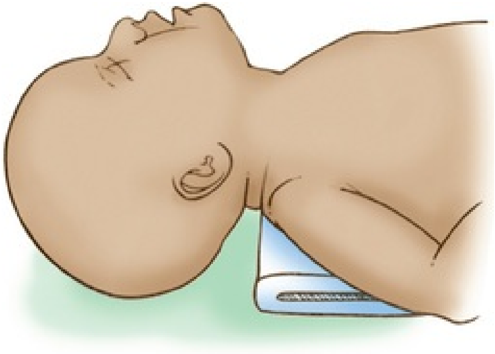

FIG. 81.11 Appropriate head position for bag-valve-mask ventilation. (From American Academy of Pediatrics and the American Heart Association; Kattwinkel J (ed): *Textbook of Neonatal Resuscitation,* ed 6. Elk Grove, IL: American Academy of Pediatrics, 2011. Fig 3-19.)

Endotracheal Intubation

A child generally requires intubation when at least one of these conditions exists: (1) the child is unable to maintain airway patency or protect the airway against aspiration (as occurs in settings of neurologic compromise); (2) the child is failing to maintain adequate oxygenation; (3) the child is failing to control blood carbon dioxide levels and maintain safe acid-base balance; (4) sedation and/or paralysis is required for a procedure; and (5) care providers anticipate a deteriorating course that will eventually lead to any of the first 4 conditions. It should be noted that in centers *experienced in noninvasive respiratory support* , a trial of HFNC, CPAP, and/or BiPAP may be indicated based on the specific clinical scenario.

There are few *absolute contraindications* to tracheal intubation, but experts generally agree that in settings of known complete airway obstruction, endotracheal intubation should be avoided, and emergency cricothyroidotomy performed instead. Another important consideration is to ensure that caregivers provide appropriate cervical spine (C-spine) protection during the intubation procedure when neck or spinal cord injury is suspected.

The most important phase of the intubation procedure is the preprocedural preparation, when the provider ensures all the equipment and staff needed for safe intubation are present and functioning. An easy pneumonic for this is **SOAP MM** : *suction* (Yankauer suction catheter attached to wall suction); *oxygen* (both preoxygenation of the patient and devices needed to deliver oxygen, such as a bag-valve-mask); *airway* (appropriately sized endotracheal tube and laryngoscope); *people* (all those needed during and immediately after the procedure, including respiratory therapists and nurses); *monitor* (SO_2, heart rate, blood pressure, capnography); and *medications* (sedation and often neuromuscular blockade to allow the provider(s) to control the airway). A simple formula for selecting the appropriately sized endotracheal tube (ETT) is:

$$\text{Uncuffed ETT size (in mm)} = \left(\frac{\text{age in years}}{4}\right) + 4$$

Cuffed ETTs should generally be 0.5 mm smaller. Providers should always have a range of ETTs available given the heterogeneity of patients and airway size.

Analgesia is recommended to reduce metabolic stress, discomfort, and anxiety during intubation. Pretreatment with a sedative, an analgesic, and possibly a muscle relaxant is recommended unless the situation is emergent (i.e., apnea, asystole, unresponsiveness) and the administration of drugs would cause an unacceptable delay.

Because many intubations in critically ill children are emergency procedures, caregivers should be prepared for **rapid sequence intubation** (RSI) (Fig. 81.12 and Table 81.4). The goals of RSI are to induce anesthesia and paralysis and to complete intubation quickly. This approach minimizes elevations of intracranial pressure and blood pressure that may accompany intubation in awake or lightly sedated patients. Because the stomach generally cannot be emptied before RSI, the **Sellick maneuver** (downward pressure on the cricoid cartilage to compress the esophagus against the vertebral column) should be used to prevent aspiration of gastric contents.

Table 81.4

Rapid Sequence Intubation

STEP	PROCEDURE	COMMENT/EXPLANATION
1	Obtain a brief history and perform an	Rule out drug allergies; examine the airway anatomy (e.g., micrognathia, cleft palate).

	assessment.	
2	Assemble equipment, medications, etc.	ETT: select the proper size for the age and weight of the child. Laryngoscope blades: a variety of Miller and the Macintosh blades.
3	Preoxygenate the patient.	With bag/mask, nasal cannula, hood or blow-by.
4	Position the patient.	Patient supine; neck is extended moderately to the “sniffing” position.
5	Premedicate the patient with lidocaine, atropine.	Lidocaine minimizes the ICP rise with intubation and can be applied topically to the airway mucosa for local anesthesia.
		Atropine helps blunt the bradycardia associated with upper airway manipulation and reduces airway secretions.
6	Perform a Sellick maneuver.	Pressure on the cricoid cartilage, to occlude the esophagus and prevent regurgitation or aspiration.
7	Induce sedation and analgesia.	**Sedatives**
		Midazolam (0.1 mg/kg): onset ~1 min; elimination in 30-40 min.
		Ketamine (2 mg/kg, may repeat as clinically indicated): onset 1-2 min; elimination in 30-40 min. May cause hallucinations if used alone; can cause higher ICP, mucous secretions, increased vital signs, and bronchodilation.
		Analgesics
		Fentanyl (3-5 µg/kg, may repeat as clinically indicated): onset ~1 min; elimination in 20-30 min. Rapid administration risks “tight chest” response, with no effective ventilation. Effects wear off in 20-30 min.
		Morphine (0.05-0.1 mg/kg dose): may last 30-60 min; may lead to hypotension in hypovolemic patients.
8	Administer muscle relaxants.	**Option 1:** Rocuronium (1 mg/kg): rapid onset and short duration. Other nondepolarizing agents include vecuronium and pancuronium, both dosed at 0.1 mg/kg.
		Option 2: Succinylcholine dose is 1-2 mg/kg; causes initial contraction of muscles, then relaxation. This depolarization can, however, increase ICP and blood pressure. Onset of paralysis in 30-40 sec; duration is 5-10 min. Pretreat with a small dose of a nondepolarizing paralytic agent, with intent of diminishing the depolarizing effect of succinylcholine.
9	Perform endotracheal intubation.	Performed by trained personnel.
10	Secure the tube, and verify position with radiograph.	ETT secured with tape to the cheeks and upper lip or to an adhesive patch applied to the skin near the mouth.
11	Begin mechanical ventilation.	Verify tube placement before ventilating with positive pressure; if an ETT is in 1 bronchus, barotraumas may occur.

ETT, Endotracheal tube; ICP, intracranial pressure.

Once the patient is intubated, proper ETT placement should be assessed by auscultation of breath sounds, evidence of symmetric chest rise, and analysis of exhaled carbon dioxide (CO_2) by a colorimetric device placed within the respiratory tubing near the ETT or a device that directly measures CO_2 elimination (capnogram or capnograph). Chest radiography is necessary to confirm appropriate tube position.

Recognition and Management of Shock

In simple terms, shock occurs when oxygen and nutrient delivery to the tissues is inadequate to meet metabolic demands (see Chapter 88). The definition of shock *does not* include hypotension, and it is important for care providers to understand that **shock does not begin when blood pressure drops; it merely worsens and becomes more difficult (refractory) to treat once blood pressure is abnormal.**

Early *compensated* shock, whereby oxygen delivery is mostly preserved through compensatory mechanisms, is defined by the presence of normal blood pressure. When compensatory mechanisms fail, the shock progresses to *decompensated* shock, as defined by hypotension and organ dysfunction. In *irreversible* shock, organ failure progresses and death ensues.

Shock is also often described according to the underlying pathophysiology, which dictates the appropriate therapeutic response. **Hypovolemic shock** is the most common type of shock in children worldwide, usually related to fluid losses from severe diarrhea. Hemorrhage is a cause of hypovolemic shock after trauma or intestinal hemorrhage. When hypovolemia occurs because of third spacing of intravascular fluids into the extravascular compartment, the shock is described as **distributive shock** . The most common causes of distributive shock are sepsis, anaphylaxis, and burn injuries, in which release of inflammatory cytokines causes massive capillary leak of fluid and proteins, leading to low oncotic pressure and intravascular volume. In settings of profound myocardial dysfunction, a child has tissue hypoperfusion from **cardiogenic shock** . The most common causes of cardiogenic shock are myocarditis, cardiomyopathy, and congenital heart disease, generally in the postoperative setting. **Obstructive shock** occurs when cardiac output is lowered by obstruction of blood flow to the body, as occurs when a ductus arteriosus closes in a child with ductus-dependent systemic blood flow, pericardial tamponade, tension pneumothorax, or massive pulmonary embolism.

The evaluation of a child in shock should proceed as described in the preceding sections on primary, secondary, and tertiary assessments. If the child presents in a hospital setting, providers should generally place a central venous line to provide secure venous access and an arterial line to permit continuous blood pressure monitoring and a more thorough laboratory assessment of organ systems, including studies of renal and liver function, acid-base balance and presence of lactic acidosis, hypoxemia and/or hypercapnia, and evidence of coagulopathy or disseminated intravascular coagulation. Chest radiography and echocardiography may also be useful. Respiratory and cardiovascular support should be provided as clinically indicated.

The treatment of shock focuses on the modifiable determinants of oxygen delivery while reducing the imbalance between oxygen supply and demand. A multipronged approach is recommended consisting of optimizing the arterial oxygen content of the blood, improving the volume and distribution of cardiac output, correcting metabolic derangements, and reducing oxygen demand. Blood oxygen content is maximized when hemoglobin values are normal and 100% of available hemoglobin is saturated with oxygen. Transfusion may be considered in the presence of hemorrhagic or distributive shock, in which crystalloid volume resuscitation has led to hemodilution and anemia. Appropriate SO_2 may be achieved by simple maneuvers, such as oxygen administration by nasal cannula or face mask; supportive measures (e.g., HFNC, CPAP, BiPAP) or invasive mechanical ventilation may be necessary. Therapies to increase cardiac output should be selected on the basis of the underlying pathophysiology. For hypovolemic and distributive shock, aggressive volume resuscitation, guided by arterial and central venous pressures, is the mainstay of therapy. In obstructive shock, relief of the obstruction is critical. The ductus arteriosus can often be reopened with prostaglandin administration and tamponade physiology relieved with appropriate drainage.

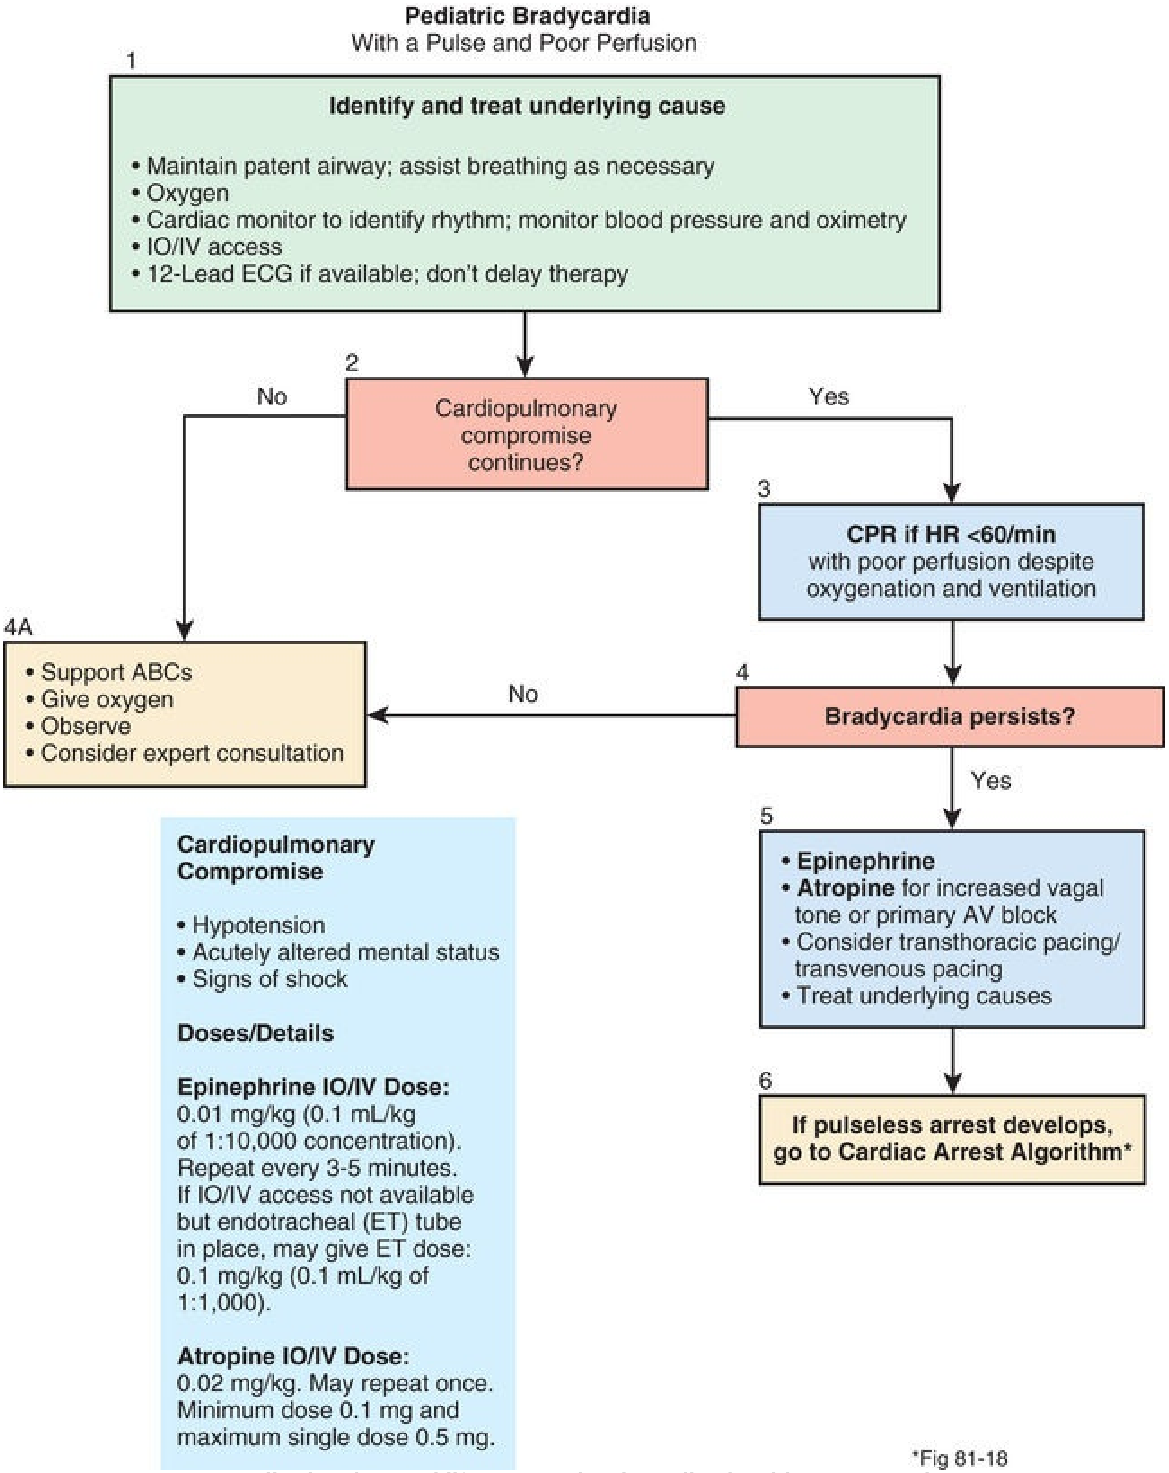
Recognition of Bradyarrhythmias and Tachyarrhythmias

In the advanced life support (ALS) setting, arrhythmias are most usefully classified according to the observed heart rate (i.e., slow or fast) and its effect on perfusion (i.e., adequate or poor). If, in the primary survey, a caregiver finds a child with an abnormal heart rate plus poor perfusion and/or altered mental status, the rhythm is inadequate no matter its rate. In those settings the child is diagnosed with shock, and further evaluation is generally halted until appropriate resuscitation has been initiated.

Bradyarrhythmias

By definition, a child is *bradycardic* when the heart rate is slower than the normal range for age (see Table 81.1). Sinus bradycardia can be a harmless incidental finding in an otherwise healthy person and not usually associated with cardiac compromise. A relative bradycardia occurs when the heart rate is too slow for a child's activity level or metabolic needs. A clinically significant bradycardia occurs when the heart rate is slow and there are signs of systemic hypoperfusion (i.e., pallor, altered mental status, hypotension, acidosis). Symptomatic bradycardia occurs most often in the setting of hypoxia but can also be caused by hypoglycemia, hypocalcemia, other electrolyte abnormalities, hypothermia, heart block, and intracranial hypertension. Bradyarrhythmias are often the most common *prearrest* rhythms in young children.

Initial management of symptomatic bradycardia includes support or opening of the airway and confirming or establishing adequate So_2 and ventilation (Fig. 81.13). After breathing has been secured, the child should be reassessed for continued bradycardia and poor perfusion. If cardiac compromise was solely the result of respiratory insufficiency, support of the child's airway and breathing may have been sufficient to restore normal hemodynamics. If respiratory support does not correct the perfusion abnormalities, further care is based on the quality of perfusion and degree of bradycardia. *A heart rate <60 beats/min with poor perfusion is an indication to begin chest compressions.* If the bradycardia persists, vascular access should be obtained; resuscitative epinephrine should be administered, and it should be repeated every 3-5 min for persistent symptomatic bradycardia. If increased vagal tone (e.g., in the setting of head injury with increased intracranial pressure) or primary atrioventricular block is suspected, atropine can also be given. For cases of refractory bradycardia, cardiac pacing should be considered. During the resuscitation of a child with bradycardia, providers should assess and treat factors known to cause bradycardia, referred to collectively as the **6 Hs** —hypoxia, hypovolemia, hydrogen ions (acidosis), hypokalemia or hyperkalemia, hypoglycemia, and hypothermia—and **5 Ts** —toxins, tamponade, tension pneumothorax, thrombosis (in either the pulmonary or cardiac circulations), and trauma (causing hypovolemia, intracranial hypertension, cardiac compromise or tamponade) (Table 81.5).



Pediatric Bradycardia
With a Pulse and Poor Perfusion
1
Identify and treat underlying cause
• Maintain patent airway; assist breathing as necessary
• Oxygen
• Cardiac monitor to identify rhythm; monitor blood pressure and oximetry
• IO/IV access
• 12-Lead ECG if available; don't delay therapy
2
Cardiopulmonary compromise continues?
No
Yes
3
CPR if HR <60/min
with poor perfusion despite oxygenation and ventilation
4A
• Support ABCs
• Give oxygen
• Observe
• Consider expert consultation
No
4
Bradycardia persists?
Yes
5
• Epinephrine
• Atropine for increased vagal tone or primary AV block
• Consider transthoracic pacing/ transvenous pacing
• Treat underlying causes
6
If pulseless arrest develops, go to Cardiac Arrest Algorithm*
Cardiopulmonary Compromise
• Hypotension
• Acutely altered mental status
• Signs of shock
Doses/Details
Epinephrine IO/IV Dose:
0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration). Repeat every 3-5 minutes. If IO/IV access not available but endotracheal (ET) tube in place, may give ET dose: 0.1 mg/kg (0.1 mL/kg of 1:1,000).
Atropine IO/IV Dose:
0.02 mg/kg. May repeat once. Minimum dose 0.1 mg and maximum single dose 0.5 mg.
*Fig 81-18

FIG. 81.13 Pediatric advanced life support bradycardia algorithm. ABCs, Airway, breathing, and circulation; AV, atrioventricular (conductor); ECG, electrocardiogram; HR, heart rate; IO/IV, intraosseous/intravenous. (From Kleinman ME, Chameides L, Schexnayder SM, et al: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care, part 14, *Circulation* 122[Suppl 3]:S876–S908, 2010, Fig. 2, p. S887.)

Table 81.5

Potentially Treatable Conditions Associated With Cardiac Arrest

CONDITION	COMMON CLINICAL SETTINGS	CORRECTIVE ACTIONS
Acidosis	Preexisting acidosis, diabetes, diarrhea, drugs and toxins, prolonged resuscitation, renal disease, and shock	Reassess the adequacy of cardiopulmonary resuscitation, oxygenation, and ventilation; reconfirm endotracheal tube placement. Hyperventilate. Consider intravenous bicarbonate if pH <7.2 after above actions have been taken.
Cardiac tamponade	Hemorrhagic diathesis, cancer, pericarditis, trauma, after cardiac surgery, and after myocardial infarction	Administer fluids; obtain bedside echocardiogram, if available. Perform pericardiocentesis; immediate surgical intervention is appropriate if pericardiocentesis is unhelpful but cardiac tamponade is known or highly suspected.
Hypothermia	Alcohol abuse, burns, central nervous system disease, debilitated patient, drowning, drugs and toxins, endocrine disease, history of exposure, homelessness, extensive skin disease, spinal cord disease, and trauma	If hypothermia is severe (temperature <30°C [86°F]), limit initial shocks for ventricular fibrillation or pulseless ventricular tachycardia to 3; initiate active internal rewarming and cardiopulmonary support. If hypothermia is moderate (temperature 30-34°C [86-93.2°F]), proceed with resuscitation (space medications at longer intervals than usual), passively rewarm child, and actively rewarm truncal body areas.
Hypovolemia, hemorrhage, anemia	Major burns, diabetes, gastrointestinal losses, hemorrhage, hemorrhagic diathesis, cancer, pregnancy, shock, and trauma	Administer fluids. Transfuse packed red blood cells if hemorrhage or profound anemia is present. Thoracotomy is appropriate when a patient has cardiac arrest from penetrating trauma and a cardiac rhythm and the duration of cardiopulmonary resuscitation before thoracotomy is <10 min.
Hypoxia	Consider in all patients with cardiac arrest.	Reassess the technical quality of cardiopulmonary resuscitation, oxygenation, and ventilation; reconfirm endotracheal tube placement.
Hypomagnesemia	Alcohol abuse, burns, diabetic ketoacidosis, severe diarrhea, diuretics, and drugs (e.g., cisplatin, cyclosporine, pentamidine)	Administer 1-2 g magnesium sulfate intravenously over 2 min.
Poisoning	Alcohol abuse, bizarre or puzzling behavioral or metabolic presentation, classic toxicologic syndrome, occupational or industrial exposure, and psychiatric disease	Consult a toxicologist for emergency advice on resuscitation and definitive care, including an appropriate antidote. Prolonged resuscitation efforts may be appropriate; immediate cardiopulmonary bypass should be considered, if available.
Hyperkalemia	Metabolic acidosis, excessive administration of potassium, drugs and toxins, vigorous exercise, hemolysis, renal disease, rhabdomyolysis, tumor lysis syndrome, and	If hyperkalemia is identified or strongly suspected, treat* with all the following: 10% calcium chloride (5-10 mL by slow IV push; do not use if hyperkalemia is secondary to digitalis poisoning), glucose and insulin (50 mL of 50% dextrose in water and 10 units of regular insulin IV), sodium bicarbonate (50 mmol IV; most effective if concomitant

	clinically significant tissue injury	metabolic acidosis is present), and albuterol (15-20 mg nebulized or 0.5 mg by IV infusion).
Hypokalemia	Alcohol abuse, diabetes, use of diuretics, drugs and toxins, profound gastrointestinal losses, hypomagnesemia	If profound hypokalemia (<2.0-2.5 mmol of potassium) is accompanied by cardiac arrest, initiate urgent IV replacement (2 mmol/min IV for 10-15 mmol);* then reassess.
Pulmonary embolism	Hospitalized patient, recent surgical procedure, peripartum, known risk factors for venous thromboembolism, history of venous thromboembolism, or prearrest presentation consistent with a diagnosis of acute pulmonary embolism	Administer fluids; augment with vasopressors as necessary. Confirm the diagnosis, if possible; consider immediate cardiopulmonary bypass to maintain patient's viability. Consider definitive care (e.g., thrombolytic therapy, embolectomy by interventional radiology or surgery).
Tension pneumothorax	Placement of a central catheter, mechanical ventilation, pulmonary disease (including asthma, chronic obstructive pulmonary disease, and necrotizing pneumonia), thoracentesis, and trauma	Needle decompression, followed by chest tube insertion.

* Adult dose. Adjust for size of child. See Table 81.6 .

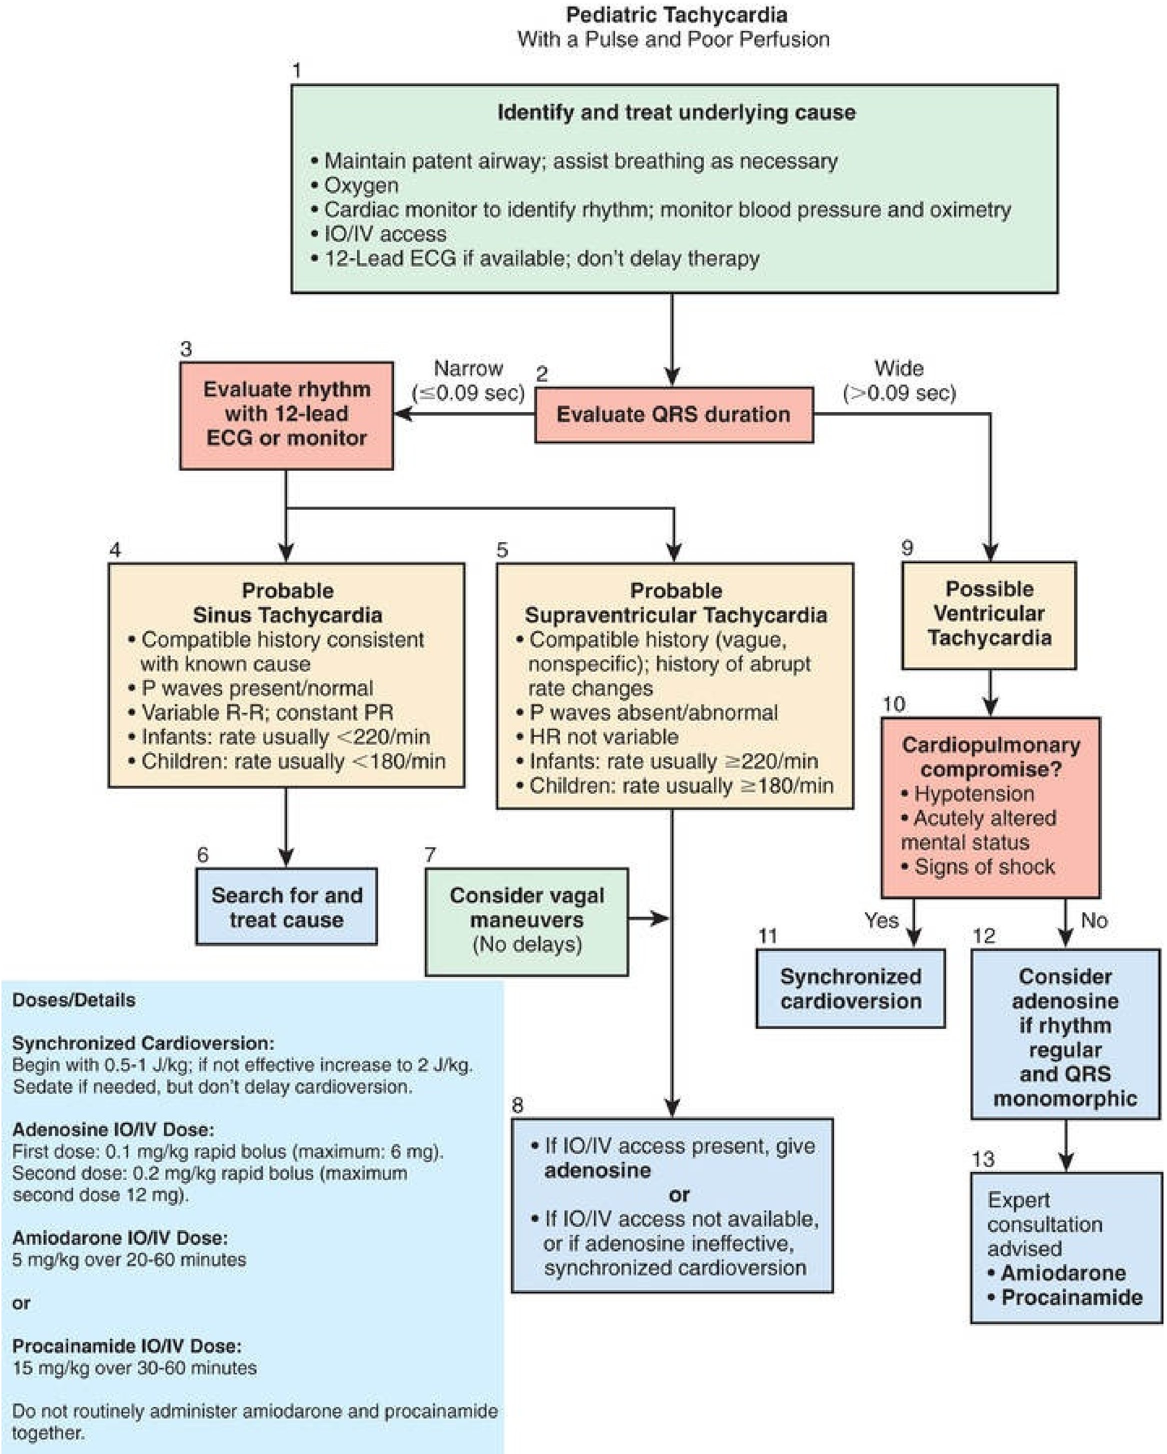
Tachyarrhythmias

Tachyarrhythmias represent a wide variety of rhythm disturbances of atrial and ventricular origin (see Chapter 462). Sinus tachycardia is a normal physiologic response to the body's need for increased cardiac output or oxygen delivery, as occurs with fever, exercise, or stress. It can also occur in more pathologic states, such as hypovolemia, anemia, pain, anxiety, and metabolic stress. Tachyarrhythmias that do not originate in the sinus node are often categorized as *narrow complex rhythms* (i.e., originating in the atrium, such as atrial flutter or supraventricular tachycardia, SVT) and *wide complex rhythms* (i.e., rhythms of ventricular origin, such as ventricular tachycardia).

The initial management of tachycardia includes confirmation that the child has an adequate airway and life-sustaining breathing and circulation (Fig. 81.14). For children with persistent symptoms, further treatment is based on whether the QRS complex of the electrocardiogram (ECG) is narrow (≤0.09 sec) or wide (>0.09 sec). For narrow complex tachycardia, providers must distinguish between sinus tachycardia and SVT. In **sinus tachycardia** , (a) the history and onset are consistent with a known cause of tachycardia, such as fever or dehydration, and (b) P waves are consistently present, are of normal morphology, and occur at a rate that varies somewhat. In **supraventricular tachycardia** , (a) onset is often abrupt without prodrome, and (b) P waves are absent or polymorphic, and when present, their rate is often fairly steady at or above 220 beats/min. For children with SVT and good perfusion, vagal maneuvers can be attempted. When SVT is associated with poor perfusion, providers should rapidly move to convert the child's heart rhythm back to sinus rhythm. If the child already has IV access, adenosine can be given via IV access with rapid push. Adenosine has an extremely short half-life, so a proximal IV line is best, and the adenosine should be set up with a 3-way stopcock so it can be given and immediately flushed into the circulation. If the child does not have IV access, or adenosine does not successfully convert the heart rhythm back to sinus rhythm, then **synchronized cardioversion** , using 0.5-1.0 joule (J)/kg, should be performed. In cases of wide complex tachycardia, providers should generally move immediately to cardioversion and increase the dose to 2 J/kg if 1 J/kg is not effective. As with cases of bradycardia, providers should review the 6 Hs and 5 Ts to identify factors that might be contributing to the tachycardia (see Table 81.5).



Pediatric Tachycardia
With a Pulse and Poor Perfusion
1
Identify and treat underlying cause
• Maintain patent airway; assist breathing as necessary
• Oxygen
• Cardiac monitor to identify rhythm; monitor blood pressure and oximetry
• IO/IV access
• 12-Lead ECG if available; don't delay therapy
2
Evaluate QRS duration
Narrow (≤0.09 sec)
Wide (>0.09 sec)
3
Evaluate rhythm with 12-lead ECG or monitor
4
Probable Sinus Tachycardia
• Compatible history consistent with known cause
• P waves present/normal
• Variable R-R; constant PR
• Infants: rate usually <220/min
• Children: rate usually <180/min
5
Probable Supraventricular Tachycardia
• Compatible history (vague, nonspecific); history of abrupt rate changes
• P waves absent/abnormal
• HR not variable
• Infants: rate usually ≥220/min
• Children: rate usually ≥180/min
9
Possible Ventricular Tachycardia
10
Cardiopulmonary compromise?
• Hypotension
• Acutely altered mental status
• Signs of shock
Yes
No
6
Search for and treat cause
7
Consider vagal maneuvers (No delays)
11
Synchronized cardioversion
12
Consider adenosine if rhythm regular and QRS monomorphic
8
• If IO/IV access present, give adenosine
or
• If IO/IV access not available, or if adenosine ineffective, synchronized cardioversion
13
Expert consultation advised
• Amiodarone
• Procainamide
Doses/Details
Synchronized Cardioversion:
Begin with 0.5-1 J/kg; if not effective increase to 2 J/kg. Sedate if needed, but don't delay cardioversion.
Adenosine IO/IV Dose:
First dose: 0.1 mg/kg rapid bolus (maximum: 6 mg).
Second dose: 0.2 mg/kg rapid bolus (maximum second dose 12 mg).
Amiodarone IO/IV Dose:
5 mg/kg over 20-60 minutes
or
Procainamide IO/IV Dose:
15 mg/kg over 30-60 minutes
Do not routinely administer amiodarone and procainamide together.

FIG. 81.14 Pediatric advanced life support tachycardia algorithm. AV, Atrioventricular (conductor); ECG, electrocardiogram; HR, heart rate; IO/IV, intraosseous/intravenous. (From Kleinman ME, Chameides L, Schexnayder SM, et al: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. Part 14, *Circulation* 122[Suppl 3]:S876–S908, 2010, Fig 3, p S888.)

Recognition and Management of Cardiac Arrest

Cardiac arrest occurs when the heart fails as an effective pump and blood flow ceases. Outwardly, the patient in cardiac arrest presents as unresponsive and apneic with no palpable pulse. Internally, the cessation of nutrient flow causes progressive tissue ischemia and organ dysfunction. If not rapidly reversed, cardiac arrest leads to progressive deterioration in brain, heart, and other organ function, such that resuscitation and recovery are no longer possible.

Pediatric cardiac arrest is rarely caused by a sudden coronary event or arrhythmia. Instead, cardiac arrest in children is most often the end result of progressive organ and tissue ischemia, caused by tissue hypoxia, acidosis, and nutrient depletion at the end stages of respiratory deterioration, shock, or heart failure. Therefore, **the most important treatment of cardiac arrest is anticipation and prevention. Intervening when a child manifests respiratory distress or early stages of shock can prevent deterioration to full arrest** . When sudden cardiac arrest does occur, it is often associated with an arrhythmia, specifically ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT). In sudden events such as these, the key to successful resuscitation is early recognition of the arrhythmia and prompt treatment with high-quality CPR *and* defibrillation.

The principle behind high-quality CPR is that adequate chest compressions—those that circulate blood around the body with a good pulse pressure—are the most important component of CPR. The caregiver providing chest compressions should **push hard, push fast, allow for complete chest recoil, and minimize interruptions** . Ideally, chest compressions should be interrupted only for a rhythm check or delivery of a defibrillating shock. Providers should refer to the most recent American Heart Association (AHA) guidelines for pediatric BLS and ALS (eccguidelines.heart.org).

Cardiac arrest is recognized from general and primary survey findings consistent with a pale or cyanotic child who is unresponsive, apneic, and pulseless. Even experienced providers have a relatively high error rate when asked to determine presence or absence of pulse in a child. Therefore, any child found unresponsive and apneic can be presumed to be in cardiac arrest, and a rescuer should respond accordingly. **A lone rescuer for an *unwitnessed* pediatric cardiac arrest in an outpatient setting should treat the arrest as**

asphyxial in nature, immediately initiate CPR, and activate the emergency response system via a mobile phone (if available). If a mobile phone is not immediately available, the rescuer should perform initial rescue breaths and 2 min of chest compressions and ventilations before leaving the child to activate the emergency response system. For an in-hospital arrest, the provider should call for help and have a team member activate the emergency response system while beginning CPR. **A lone rescuer in an outpatient setting who *witnesses* a child's sudden collapse should treat the arrest as a primary arrhythmia, should immediately activate the EMS system, and obtain an AED.** On returning to the child, the rescuer should confirm pulselessness, turn on the AED, place the leads on the child's chest, and follow the defibrillator's voice commands.

The initial step in CPR for a child of any age is to restore ventilation and oxygenation as quickly as possible. On confirmation of unresponsiveness, apnea, and/or pulselessness, resuscitation should follow current AHA Basic Life Support (BLS), (or Advanced Cardiac Life Support, ACLS) guidelines, as appropriate (eccguidelines.heart.org).

If a person is pulseless, chest compressions should be initiated. Chest compressions in infants <1 yr old may be performed by placing 2 thumbs on the midsternum with the hands encircling the thorax or by placing 2 fingers over the midsternum and compressing (Figs. 81.15 and 81.16). For children >1 yr old, the care provider should perform chest compressions over the lower half of the sternum with the heel of 1 hand, or with 2 hands as used for adult resuscitation (Fig. 81.17). In all cases, care should be taken to avoid compression of the xiphoid and the ribs. When feasible, a cardiac resuscitation board should be placed under the child's back to maximize the efficiency of compressions. CPR and rescue breathing should be performed based on current AHA BLS/ACLS guidelines.

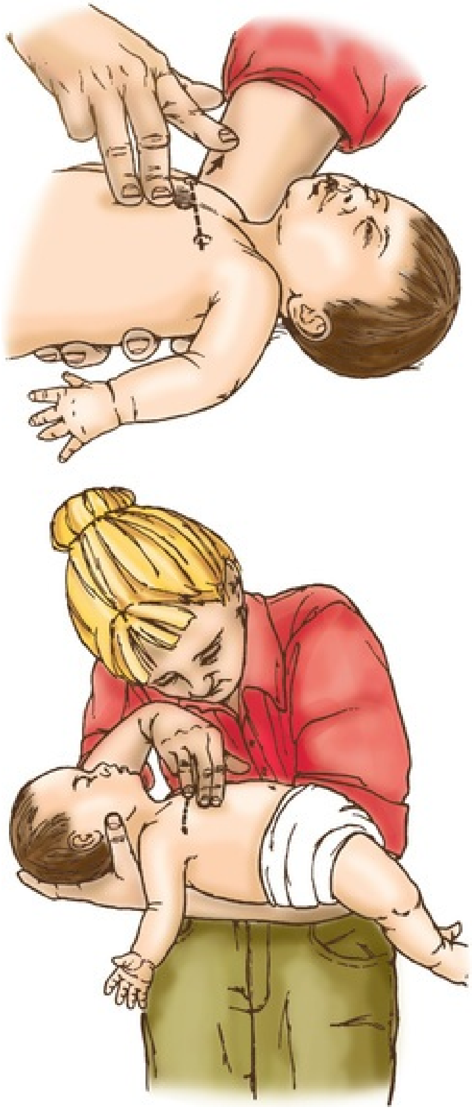


FIG. 81.15 Cardiac compressions. *Top,* The infant is supine on the palm of the rescuer's hand. *Bottom,* Performing CPR while carrying an infant or small child. Note that the head is kept level with the torso. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, *JAMA* 268:2251–2261, 1992.)

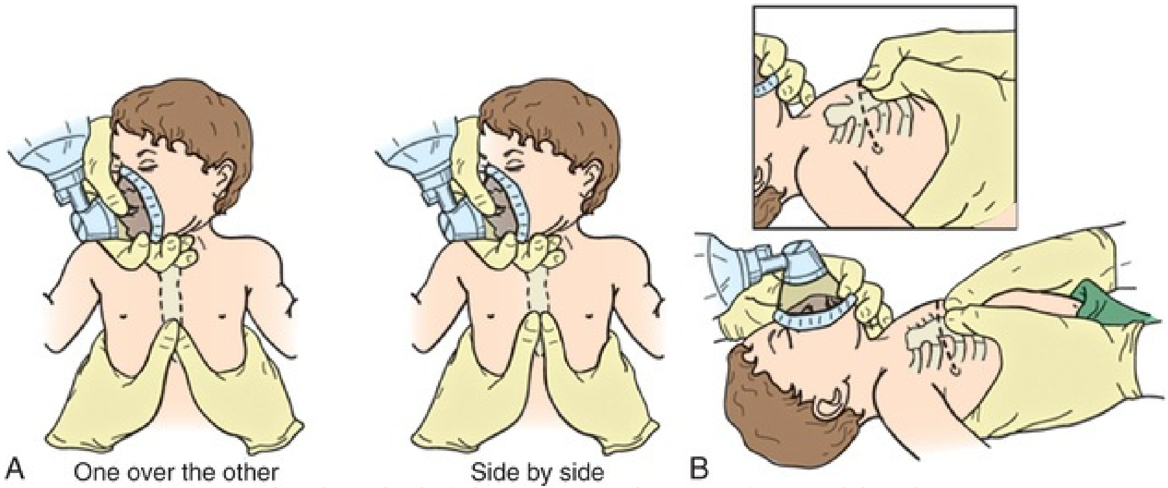

FIG. 81.16 Thumb method of chest compressions. A, Infant receiving chest compressions with thumb 1 fingerbreadth below the nipple line and hands encircling chest. B, Hand position for chest encirclement technique for external chest compressions in neonates. Thumbs are side by side over the lower third of the sternum. In the small newborn, thumbs may need to be superimposed *(inset)* . Gloves should be worn during resuscitation. (From Fleisher GR, Ludwig S, editors: *Textbook of pediatric emergency medicine,* Philadelphia, 2010, Wolters Kluwer/Lippincott Williams & Wilkins Health, Fig 2.2.)

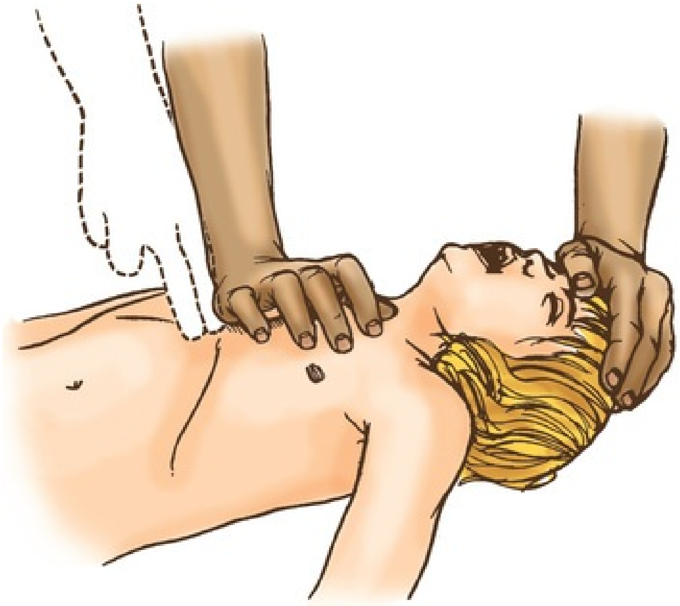

FIG. 81.17 Locating the hand position for chest compression in a child. Note that the rescuer's other hand is used to maintain the head position to facilitate ventilation. (From Guidelines for cardiopulmonary resuscitation and emergency cardiac care. Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Part V. Pediatric basic life support, *JAMA* 268:2251–2261, 1992.)

The goal of CPR is to reestablish spontaneous circulation at a level that is compatible with survival. If resuscitative efforts do not succeed in reestablishing life-sustaining breathing and circulation, the medical team must decide whether continued efforts are warranted or whether the resuscitation should be stopped. If EMS care is en route, bringing the potential for further escalation in care, such as endotracheal intubation, vascular access, and medications, CPR should be continued as long as possible or deemed reasonable by the rescuers.

In the in-hospital setting, the ECG should dictate further resuscitative efforts. For children without a pulse and in asystole or electromechanical dissociation (**pulseless electrical activity** , PEA), providers should continue rescue breathing and CPR, obtain vascular access, and administer emergency IV epinephrine (Fig. 81.18). For continued asystole or PEA, epinephrine can be repeated every 3-5 min. Patient history, physical exam findings, and laboratory evaluation should be used to elicit correctable causes of arrest (e.g., 6 Hs, 5 Ts; see Table 81.5). CPR should be continued after epinephrine administration, to circulate the drug through the body. After 5 cycles of CPR, providers should reassess the child for the presence of a pulse or a change in the ECG rhythm that would necessitate a different response.

Doses/Details

CPR Quality

- Push hard ≥ 1/3 of anterior-posterior diameter of chest) and fast (at least 100/min) and allow complete chest recoil
- Minimize interruptions in compressions
- Avoid excessive ventilation
- Rotate compressor every 2 minutes
- If no advanced airway, 15:2 compression-ventilation ratio. If advanced airway, 8-10 breaths per minute with continuous chest compressions

Shock Energy for Defibrillation

First shock 2 J/kg, second shock 4 J/kg, subsequent shocks ≥ 4 J/kg, maximum 10 J/kg or adult dose.

Drug Therapy

- **Epinephrine IO/IV Dose:** 0.01 mg/kg (0.1 mL/kg of 1:10,000 concentration). Repeat every 3-5 minutes.
  If no IO/IV access, may give endotracheal dose: 0.1 mg/kg (0.1 mL/kg of 1:1,000 concentration).
- **Amiodarone IO/IV Dose:** 5 mg/kg bolus during cardiac arrest May repeat up to 2 times for refractory VF/pulseless VT.

Advanced Airway

- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement.
- Once advanced airway in place give 1 breath every 6-8 seconds (8-10 breaths per minute)

Return of Spontaneous Circulation (ROSC)

- Pulse and blood pressure
- Spontaneous arterial pressure waves with intra-arterial monitoring

Reversible Causes

- Hypovolemia
- Hypoxia
- Hydrogen ion (acidosis)
- Hypoglycemia
- Hypo-/hyperkalemia
- Hypothermia
- Tension pneumothorax
- Tamponade cardiac
- Toxins
- Thrombosis, pulmonary
- Thrombosis, coronary

FIG. 81.18 Pediatric advanced life support pulseless arrest algorithm. CPR, Cardiopulmonary resuscitation; IO/IV, intraosseous/intravenous; PEA, pulseless electrical activity; VF/VT, ventricular fibrillation/tachycardia. (From Kleinman ME, Chameides L, Schexnayder SM, et al: 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care. Part 14, *Circulation* 122[Suppl 3]:S876–S908, 2010, Fig 1, p S885.)

For those children with pulseless VT or VF, emergency defibrillation is indicated (Fig. 81.18). Providers should apply the pads to the child's bare chest and back and follow the verbal instructions given by the AED. For younger children, a defibrillator (if available) set to the dose of 2 J/kg should be used. Ideally, the AED used in a child ≤8 yr of age should be equipped with an attenuated adult dose or should be designed for children; if neither device is available, a standard adult AED should be used. CPR should be immediately restarted after defibrillation. Emergency dose epinephrine can also be administered with another 5 cycles of CPR to ensure its circulation throughout the child's body. If the ECG rhythm continues to show VF or VT, defibrillation can be alternated with epinephrine. For refractory VF or VT, an IV antiarrhythmic, such as lidocaine or amiodarone, can be given (Tables 81.6 and 81.7). Some adult studies have suggested that a combination of epinephrine, vasopressin, and methylprednisolone improves intact survival after CPR.

Table 81.6

Medications for Pediatric Resuscitation and Arrhythmias

MEDICATION	DOSE	REMARKS
Adenosine	0.1 mg/kg (max: 6 mg)	Monitor ECG.
	Repeat: 0.2 mg/kg (max: 12 mg)	Rapid IV/IO bolus.
Amiodarone	5 mg/kg IV/IO; repeat up to 15 mg/kg	Monitor ECG and blood pressure.
	Max: 300 mg	Adjust administration rate to urgency (give more slowly when perfusing rhythm is present).
		Use caution when administering with other drugs that prolong QT interval (consider expert consultation).
Atropine	0.02 mg/kg IV/IO	Higher doses may be used with organophosphate poisoning.
	0.03 mg/kg ETT*	
	Repeat once if needed	
	Minimum dose: 0.1 mg	
	Minimum single dose:	
	Child, 0.5 mg	
	Adolescent, 1 mg	
Calcium chloride (10%)	20 mg/kg IV/IO (0.2 mL/kg)	Slowly
		Adult dose: 5-10 mL

Epinephrine	0.01 mg/kg (0.1 mL/kg 1 : 10,000) IV/IO 0.1 mg/kg (0.1 mL/kg 1 : 1,000) ETT* Max dose: 1 mg IV/IO; 10 mg ET	May repeat every 3-5 min
Glucose	0.5-1 g/kg IV/IO	D10W: 5-10 mL/kg D25W: 2-4 mL/kg D50W: 1-2 mL/kg
Lidocaine	Bolus: 1 mg/kg IV/IO Max dose: 100 mg Infusion: 20-50 µg/kg/min ETT* : 2-3 mg	
Magnesium sulfate	25-50 mg/kg IV/IO over 10-20 min; faster in torsades de pointes Max dose: 2 g	
Naloxone	<5 yr or ≤20 kg: 0.1 mg/kg IV/IO/ETT* ≥5 yr or >20 kg: 2 mg IV/IO/ETT*	Use lower doses to reverse respiratory depression associated with therapeutic opioid administration (1-15 µg/kg).
Procainamide	15 mg/kg IV/IO over 30-60 min	Monitor EGG and blood pressure.
	Adult dose: 20 mg/min IV infusion up to total max dose of 17 mg/kg	Use caution when administering with other drugs that prolong QT interval (consider expert consultation).
Sodium bicarbonate	1 mEq/kg/dose IV/IO slowly	After adequate ventilation

* Flush with 5 mL of normal saline and follow with 5 ventilations.

ECG, Electrocardiogram; ETT, endotracheal tube; IO, intraosseous; IV, intravenous.

Table 81.7

Medications to Maintain Cardiac Output and for Postresuscitation Stabilization*

MEDICATION	DOSE RANGE	COMMENT
Inamrinone	0.75-1 mg/kg IV/IO over 5 min; may repeat 2×; then: 2-20 µg/kg/min	Inodilator
Dobutamine	2-20 µg/kg/min IV/IO	Inotrope; vasodilator
Dopamine	2-20 µg/kg/min IV/IO in low doses; pressor in higher doses	Inotrope; chronotrope; renal and splanchnic vasodilator
Epinephrine	0.1-1 µg/kg/min IV/IO	Inotrope; chronotrope; vasodilator in low doses; vasopressor in higher doses
Milrinone	50-75 µg/kg IV/IO over 10-60 min then 0.5-0.75 µg/kg/min	Inodilator
Norepinephrine	0.1-2 µg/kg/min	Inotrope; vasopressor
Sodium nitroprusside	1-8 µg/kg/min	Vasodilator; prepare only in D5W

* Alternative formula for calculating an infusion: Infusion rate (mL/hr) = [weight (kg) × dose (µg/kg/min) × 60 (min/hr)]/concentration µg/mL).

D5W, 5% Dextrose in water; IO, intraosseous; IV, intravenous.

From ECC Committee, Subcommittees and Task Forces of the American Heart Association: 2005 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care, *Circulation* 112:IV1–IV203, 2005.

Traditionally, continuing CPR >20 min in children with in-hospital cardiac arrest has been considered futile. With current practice for CPR, survival for in-hospital cardiac arrest is approximately 40% for CPR duration <15 min, compared with approximately 12% for CPR lasting >35 min. Survivors had a favorable neurologic outcome in 70% with a CPR duration <15 min, compared with 60% for those requiring resuscitation for >35 min.

Vascular Access

Venous Access

Veins suitable for cannulation are numerous, but there is considerable anatomic variation from patient to patient. In the upper extremities, the *median antecubital vein* , located in the antecubital fossa, is often the largest and easiest to access (Fig. 81.19). Many veins on the dorsum of the hand are also suitable for cannulation because they are often large and easily located, and their cannulation is generally well tolerated. The *cephalic vein* is usually cannulated at the wrist, along the forearm, or at the elbow. The *median vein* of the forearm is also suitable as it lies along a flat surface of the forearm. In the lower extremity, the *great saphenous vein* , located just anterior to the medial malleolus, is accessible in most patients. The dorsum of the foot usually has a large vein in the midline, passing across the ankle joint, but catheters are difficult to maintain in this vein because dorsiflexion tends to dislodge them. A 2nd large vein on the lateral side of the foot, running in the horizontal plane, usually 1-2 cm dorsal to the lower margin of the foot, is preferable (Fig. 81.20). The most notable scalp veins are the *superficial temporal* (just anterior to the ear) and *posterior auricular* (just behind the ear).

Dorsal vein

FIG. 81.20 Veins of the lower extremity. (From Roberts JR, Hedges JR, editors: *Clinical procedures in emergency medicine,* ed 4, Philadelphia, 2004, Saunders.)

Deeper and larger central veins can provide more reliable, larger-bore access for medications, nutritive solutions, and blood sampling than peripheral venous lines. They may be reached by percutaneous cannulation or surgical exposure. In infants and young children, the *femoral vein* is often the easiest to access and cannulate, but the *internal jugular* and *subclavian* veins may also be used (Figs. 81.21 and 81.22). Because of its proximity to the median nerve, the brachial vein is not often recommended for cannulation.

(From Mathers LW, Smith DW, Frankel L: Anatomic considerations in placement of central venous catheters, *Clin Anat* 5:89, 1992. Reprinted by permission of Wiley-Liss.)

Intraosseous Access

Intraosseous (IO) needles (for intramedullary venous plexus access) are special rigid, large-bore needles. IO cannulation is recommended for patients in whom IV access proves difficult or unattainable, even in older children. If venous access is not available within approximately 1 min in a child with cardiopulmonary arrest, an IO needle should be placed in the anterior proximal tibia (with care taken to avoid traversing the epiphyseal plate). The needle should penetrate the anterior layer of compact bone, and its tip is advanced into the spongy interior of the bone (Fig. 81.23). Commercially available IO kits frequently include drills that obviate the complications of needle placement associated with manual placement. All medications, blood products, and fluids may be administered through the IO route, including medications required for emergency resuscitation. Complications are uncommon but may include osteomyelitis with prolonged infusions and tibial fracture.

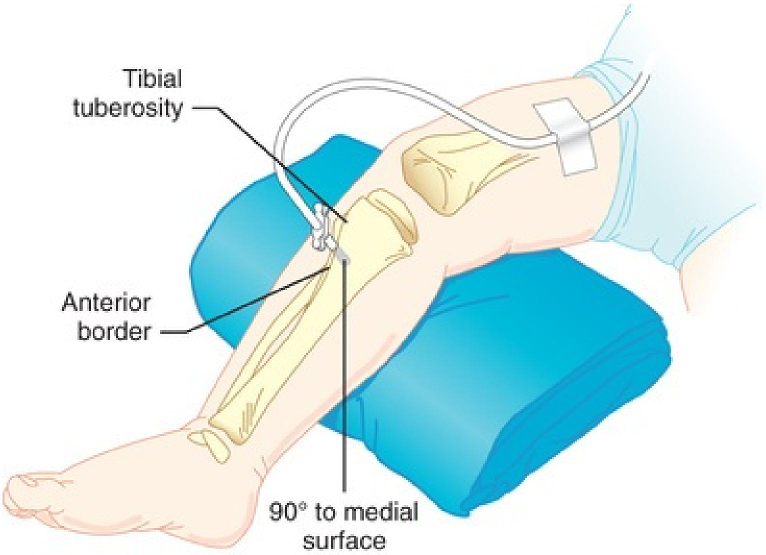

FIG. 81.23 Intraosseous cannulation technique. (From Zwass MS, Gregory GA: Pediatric and neonatal intensive care. In Miller RD, Eriksson LI, Fleisher LA, et al, editors: *Miller's anesthesia,* ed 7, Philadelphia, 2009, Churchill Livingstone, Fig 84-1.)

If IV and IO routes are unavailable in an intubated patient, medication can be given through the ETT (epinephrine, atropine, naloxone, vasopressin).

Arterial Access

Arterial access is indicated when care providers need frequent blood sampling, particularly to assess adequacy of oxygenation, ventilation, or acid-base balance, and/or continuous blood pressure monitoring. The *radial artery* , the most commonly cannulated artery, lies on the lateral side of the anterior wrist, just medial to the styloid process of the radius (Fig. 81.24). The ulnar artery, just lateral to the tendon of the flexor carpi ulnaris, is used less often because of its proximity to the ulnar nerve. Useful sites in the lower extremity, particularly in neonates and infants, are the *dorsalis pedis artery* , on the dorsum of the foot between the tendons of the tibialis anterior and the extensor hallucis longus, and the *posterior tibial artery* , posterior to the medial malleolus. Arterial catheters require special care for insertion and subsequent management.

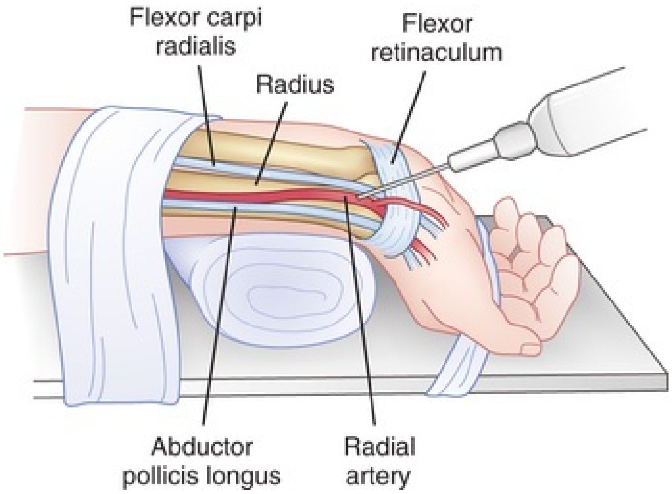

FIG. 81.24 Radial artery anatomy and cannulation.

Nonvascular Emergency Procedures

Thoracentesis and Chest Tube Placement

Thoracentesis is the placement of a needle or catheter into the pleural space to evacuate fluid, blood, or air. Most insertions are performed in one of the intercostal spaces between the 4th and 9th ribs in the plane of the midaxillary line. After appropriate systemic and local anesthesia/sedation is performed as clinically indicated, a skin incision is made, and dissection through the chest wall is accomplished in layers with use of blunt dissection techniques. The needle (and later the chest tube) that enters the pleural space should penetrate the intercostal space by passing over the superior edge of the lower rib, because there are larger vessels along the inferior edge of the rib. Ideally, the chest tube should lie *anterior* in the pleural space for air accumulation and *posterior* for fluid accumulation. A radiograph must be obtained to verify chest tube placement and evacuation of the pleural space.

Pericardiocentesis

When fluid, blood, or gas accumulates in the pericardial sac, the heart may become compressed and may be unable to fill/empty with normal volumes of blood, leading to diminished cardiac output. The cardinal signs of such a restrictive pericardial effusion are tachycardia, hypotension generally with a narrowed pulse pressure, and decreased So_2. Pericardiocentesis includes needle aspiration of the pericardial sac, often followed by the placement of a catheter for continuous drainage. As with thoracentesis, chest radiography should be done to confirm catheter location as well as evaluate for any complications, such as pneumothorax or hemothorax. Pericardiocentesis may be performed with echocardiography.

Postresuscitation Care

After successful resuscitation, close observation in an intensive care unit, where the child can receive ongoing multiorgan system assessments and support, is critical. Optimal postresuscitation care includes ongoing support of cardiovascular and respiratory system function as needed and the identification and treatment of other organ system dysfunction that may have contributed to (or resulted from) the child's cardiopulmonary instability. Good postresuscitation intensive care also includes supportive services for the child's parents, siblings, family, and friends.

Induced hypothermia (32-34°C [89.6-91.4°F] versus targeted temperature 36.8°C (98.2°F) (range, 36-37.5°C [96.8-99.5°F]) for about 48 hr) has *not* been shown to improve survival and neurologic function in pediatric survivors of CPR. However, *hyperthermia must be avoided.* **Hypoxic-ischemic encephalopathy** with subsequent development of seizures, intellectual impairment, and spasticity, is a serious and common complication of cardiac arrest. In addition, *hyperglycemia and hypoglycemia should be avoided.*

Postresuscitation management generally has 2 phases. First, the providers must assess the child's airway and breathing and support oxygenation and ventilation as indicated. If the child has ongoing respiratory failure and has been supported with bag-valve-mask ventilation until this time, the providers should now move forward with intubation. Once the child is intubated, mechanical ventilation must be established and respiratory assessments performed, such as chest radiography and arterial blood gas analysis. The child's circulatory system must also be assessed and supported as needed. Continuous arterial blood pressure monitoring can help the provider determine the need for, and response to, inotropic and chronotropic medications (see Table 81.7). Once the ABCs have been managed, providers can move on to full organ system assessments. A systematic approach should be used, with a full physical exam and laboratory evaluation to reveal the child's respiratory, cardiovascular, neurologic, gastrointestinal, renal, and hematologic system function.

Communication with the patients' family is an essential element of postresuscitation care. The family should be thoroughly briefed on the elements of the resuscitation performed, the child's condition, and ongoing medical concerns, uncertainties, or issues by the *most senior provider available* . This provider should be available to answer the family's questions, clarify information, and provide comfort. Other support staff, including social workers and chaplains, should be contacted, as the family wishes, to provide additional support and comfort. For situations in which the resuscitation is ongoing and the child is not expected to survive, it is recommended that the provider make every effort possible to have the family present at the bedside, if they wish. Family presence during CPR or other emergency resuscitative efforts, even if the child dies, is associated with a more positive medical experience than if they are excluded. In situations where the child is critically ill but stable, the family should be brought to the bedside as soon as the healthcare team deems it safe and appropriate (see Chapter 7).

CHAPTER 82

Acute Care of Multiple Trauma

Cindy Ganis Roskind, Howard I. Pryor II, Bruce L. Klein

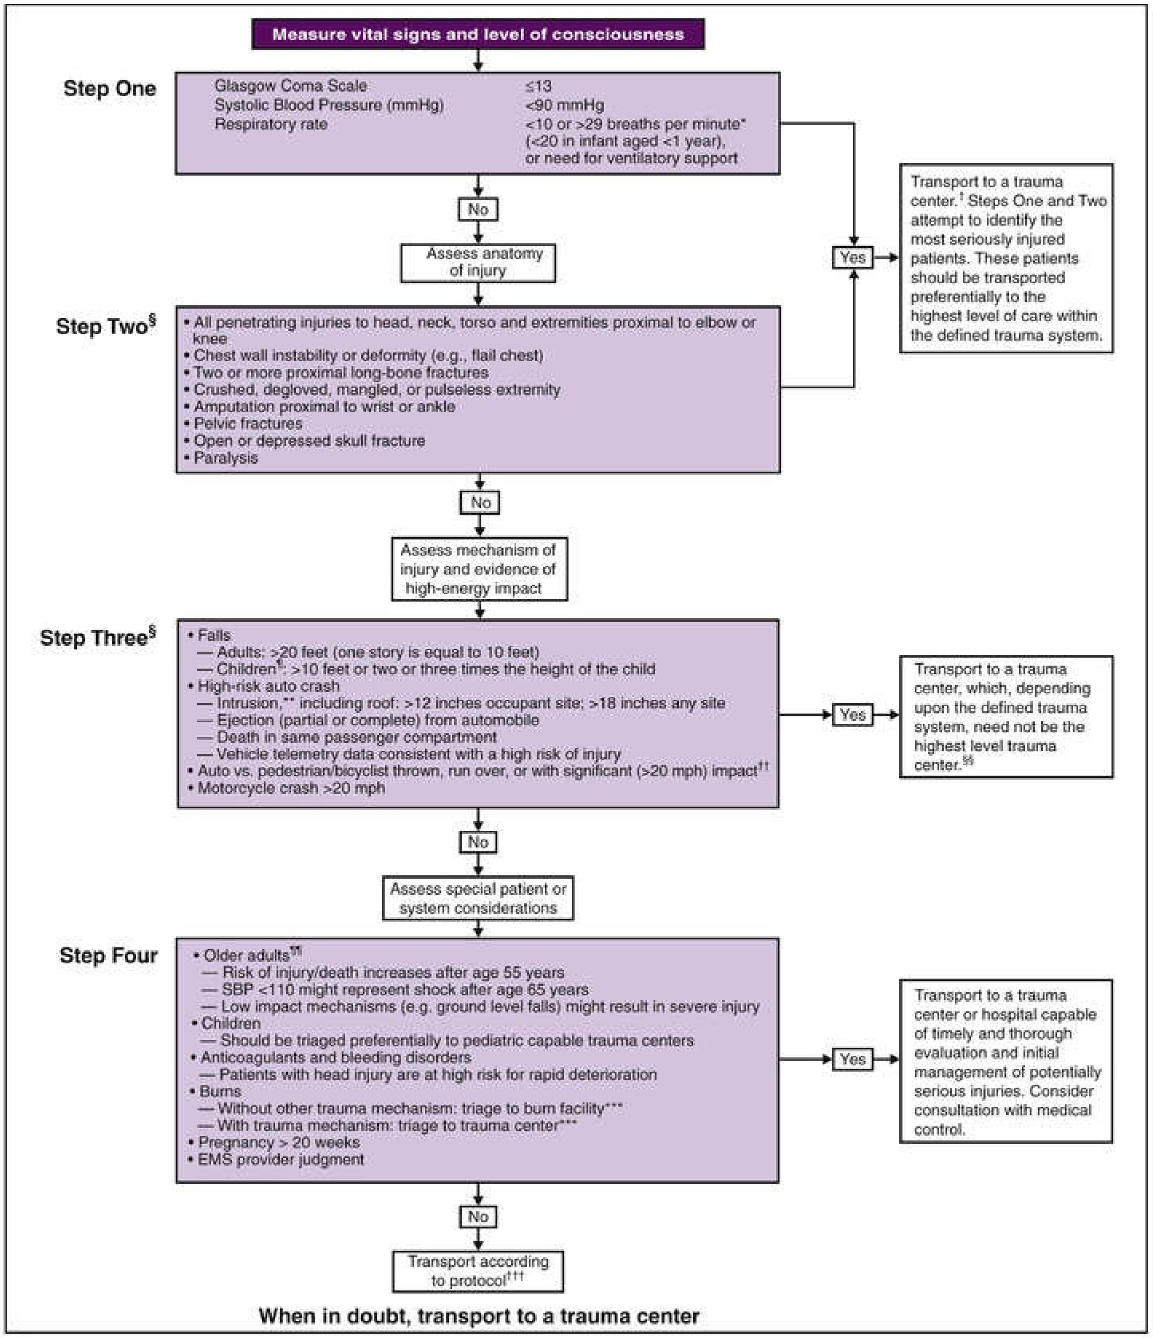
Epidemiology

Injury is a leading cause of death and disability in children throughout the world (see Chapter 13). Deaths represent only a small fraction of the total trauma burden. Approximately 140,000 children were treated in U.S. trauma centers in 2016 for serious injury. Many survivors of trauma have permanent or temporary functional limitations. Motor vehicle–related injuries and falls rank among the top 15 causes of disability-adjusted life years in children worldwide.

Trauma is frequently classified according to the number of significantly injured body parts (≥1), the severity of injury (mild, moderate, or severe), and the mechanism of injury (blunt or penetrating). In childhood, blunt trauma predominates, accounting for the majority of injuries. In adolescence, penetrating trauma increases in frequency, accounting for approximately 15% of injuries, and penetrating trauma secondary to a firearm is associated with a high case fatality rate of 11%.

Regionalization and Trauma Teams

Mortality and morbidity rates have decreased in geographic regions with comprehensive, coordinated trauma systems. Treatment at designated trauma centers is associated with decreased mortality. At the scene of injury, paramedics should administer necessary advanced life support and perform **triage** (Fig. 82.1). It is usually preferable to bypass local hospitals and rapidly transport a seriously injured child directly to a pediatric trauma center (or a trauma center with pediatric commitment). *Children have lower mortality rates, lower complication rates, and less operative interventions after severe blunt trauma* *when they are treated in designated pediatric trauma centers or in hospitals with pediatric intensive care units.*



Measure vital signs and level of consciousness
Step One
Glasgow Coma Scale ≤13
Systolic Blood Pressure (mmHg) <90 mmHg
Respiratory rate <10 or >29 breaths per minute* (<20 in infant aged <1 year), or need for ventilatory support
No
Assess anatomy of injury
Step Two§
• All penetrating injuries to head, neck, torso and extremities proximal to elbow or knee
• Chest wall instability or deformity (e.g., flail chest)
• Two or more proximal long-bone fractures
• Crushed, degloved, mangled, or pulseless extremity
• Amputation proximal to wrist or ankle
• Pelvic fractures
• Open or depressed skull fracture
• Paralysis
Yes
Transport to a trauma center.† Steps One and Two attempt to identify the most seriously injured patients. These patients should be transported preferentially to the highest level of care within the defined trauma system.
No
Assess mechanism of injury and evidence of high-energy impact
Step Three§
• Falls
— Adults: >20 feet (one story is equal to 10 feet)
— Children¶: >10 feet or two or three times the height of the child
• High-risk auto crash
— Intrusion,** including roof: >12 inches occupant site; >18 inches any site
— Ejection (partial or complete) from automobile
— Death in same passenger compartment
— Vehicle telemetry data consistent with a high risk of injury
• Auto vs. pedestrian/bicyclist thrown, run over, or with significant (>20 mph) impact††
• Motorcycle crash >20 mph
Yes
Transport to a trauma center, which, depending upon the defined trauma system, need not be the highest level trauma center.§§
No
Assess special patient or system considerations
Step Four
• Older adults¶¶
— Risk of injury/death increases after age 55 years
— SBP <110 might represent shock after age 65 years
— Low impact mechanisms (e.g. ground level falls) might result in severe injury
• Children
— Should be triaged preferentially to pediatric capable trauma centers
• Anticoagulants and bleeding disorders
— Patients with head injury are at high risk for rapid deterioration
• Burns
— Without other trauma mechanism: triage to burn facility***
— With trauma mechanism: triage to trauma center***
• Pregnancy > 20 weeks
• EMS provider judgment
Yes
Transport to a trauma center or hospital capable of timely and thorough evaluation and initial management of potentially serious injuries. Consider consultation with medical control.
No
Transport according to protocol†††
When in doubt, transport to a trauma center

---

[*] The upper limit of respiratory rate in infants is >29 breaths per minute to maintain a higher level of overtriage for infants.

[†] Trauma centers are designated Level I-IV. A Level I center has the greatest amount of resources and personnel for care of the injured patient and provides regional leadership in education, research, and prevention programs. A Level II facility offers similar resources to a Level I facility, possibly differing only in continuous availability of certain subspecialties or sufficient prevention, education, and research activities for Level I designation; Level II facilities are not required to be resident or fellow education centers. A Level III center is capable of assessment, resuscitation, and emergency surgery, with severely injured patients being transferred to a Level I or II facility. A Level IV trauma center is capable of providing 24-hour physician coverage, resuscitation, and stabilization to injured patients before transfer to a facility that provides a higher level of trauma care.

[§] Any injury noted in Step Two or mechanism identified in Step Three triggers a "yes" response.

[¶] Age <15 years.

[**] Intrusion refers to interior compartment intrusion, as opposed to deformation which refers to exterior damage.

[††] Includes pedestrians or bicyclists thrown or run over by a motor vehicle or those with estimated impact >20 mph with a motor vehicle.

[§§] Local or regional protocols should be used to determine the most appropriate level of trauma center within the defined trauma system; need not be the highest-level trauma center.

[¶¶] Age >55 years.

[***] Patients with both burns and concomitant trauma for whom the burn injury poses the greatest risk for morbidity and mortality should be transferred to a burn center. If the nonburn trauma presents a greater immediate risk, the patient may be stabilized in a trauma center and then transferred to a burn center.

[†††] Patients who do not meet any of the triage criteria in Steps One through Four should be transported to the most appropriate medical facility as outlined in local EMS protocols.

FIG. 82.1 Guidelines for field triage of injured patients—United States, 2011. (From Guidelines for field triage of injured patients: recommendations of the National Expert Panel on Field Triage, *MMWR* 61:6, 2012.)

When the receiving emergency department (ED) is notified before the child's arrival, the trauma team should also be mobilized in advance. Each member has defined tasks. A senior surgeon (surgical coordinator) or, sometimes initially, an emergency physician leads the team. Team compositions vary somewhat from hospital to hospital; Fig. 82.2 shows the model used at The Johns Hopkins Hospital Bloomberg Children's Center (Baltimore, MD). Consultants, especially neurosurgeons and orthopedic surgeons, must be promptly available; and the operating room staff should be alerted.

Physiologic status, anatomic locations, and/or mechanism of injury are used for field triage as well as to determine whether to activate the trauma team. More importance should be placed on physiologic compromise and less on mechanism of injury. Scoring scales such as the Abbreviated Injury Scale (AIS), Injury Severity Score (ISS), Pediatric Trauma Score (Table 82.1), and Revised Trauma

Score use these parameters to predict patient outcome. The AIS and ISS are used together. First, the AIS is used numerically to score injuries—as 1 minor, 2 moderate, 3 serious, 4 severe, 5 critical, or 6 probably lethal—in each of 6 ISS body regions: head/neck, face, thorax, abdomen and pelvic contents, extremities and bony pelvis, and external. The ISS is the sum of the squares of the highest 3 AIS region scores.

Table 82.1

Pediatric Trauma Score*

COMPONENT	**+2**	**+1**	**−1**
Size	≥20 kg	10-20 kg	<10 kg
Airway	Normal	Maintainable	Unmaintainable
Systolic BP	≥90 mm Hg	50-90 mm Hg	<50 mm Hg
CNS	Awake	Obtunded/LOC	Coma/decerebrate
Open wound	None	Minor	Major/penetrating
Skeletal	None	Closed fracture	Open/multiple fractures
Sum total points			

[*] Children with a Pediatric Trauma Score ≤6 are at increased risk of mortality as well as morbidity.

BP, Blood pressure; CNS, central nervous system; LOC, loss of consciousness.

From Tepas JJ 3rd, Mollitt DL, Talbert JL, et al: The Pediatric Trauma Score as a predictor of injury severity in the injured child, *J Pediatr Surg* 22:14–18, 1987 (Table 1, p 15).

Primary Survey

During the primary survey, the physician quickly assesses and treats any life-threatening injuries. The principal causes of death shortly after trauma are airway obstruction, respiratory insufficiency, shock from hemorrhage, and central nervous system (CNS) injury. The primary survey addresses the **ABCDEs** : Airway, Breathing, Circulation, neurologic Deficit, and Exposure of the patient and control of the Environment.

Airway/Cervical Spine

Optimizing oxygenation and ventilation, while protecting the cervical spine (C-spine) from potential further injury, is of paramount importance. Initially, C-spine injury should be suspected in any child sustaining multiple, blunt trauma. Although C-spine injuries occur less often in children than adults, children are at risk for such injuries because of their relatively large heads in proportion to the rest of their body, which augment flexion-extension forces, and weak neck muscles, which predispose them to ligament injuries. To prevent additional spinal injury, paramedics have traditionally been taught to immobilize the cervical (and thoracic and lumbar) spine in neutral position with a stiff collar, head blocks, tape or cloth placed across the forehead, torso, and thighs to restrain the child, and a rigid backboard.

Airway obstruction manifests as snoring, gurgling, hoarseness, stridor, and/or diminished breath sounds (even with apparently good respiratory effort). Children are more likely than adults to have airway obstruction because of their smaller oral and nasal cavities, proportionately larger tongues and more tonsillar and adenoidal tissue, higher and more anterior glottic opening, and narrower larynx and trachea. Obstruction is common in patients with severe head injuries, partly because of decreased muscle tone, which allows the tongue to fall posteriorly and occlude the airway. With trauma, obstruction can also result from fractures of the mandible or facial bones, secretions such as blood or vomit, crush injuries of the larynx or trachea, and foreign body aspiration.

If it is necessary to open the airway, a jaw thrust without head tilt is recommended. This procedure minimizes cervical spine motion. In an unconscious child, an oropharyngeal airway may be inserted to prevent posterior displacement of the mandibular tissues. A semiconscious child will gag with an oropharyngeal airway but may tolerate a nasopharyngeal airway. A nasopharyngeal airway is contraindicated when there is a possibility of cribriform plate fracture. If these maneuvers plus suctioning do not clear the airway, oral endotracheal intubation is indicated. When endotracheal intubation proves difficult, a laryngeal mask airway can be used as a temporary alternative. A laryngeal mask airway consists of a tube with an inflatable cuff that rests above the larynx and thus does not require placement of the tube into the trachea. Video-assisted laryngoscopy or the use of a bougie can also be helpful in the management of a difficult airway. Emergency cricothyrotomy is needed in <1% of trauma victims.

Breathing

The physician assesses breathing by counting the respiratory rate; visualizing chest wall motion for symmetry, expansion, and accessory muscle use; and auscultating breath sounds in both axillae. Continuous waveform capnography monitoring should also be used as an adjunct; however, it is less reliable in patients with shock. In addition to looking visually for cyanosis, pulse oximetry is standard. If ventilation is inadequate, bag-valve-mask ventilation with 100% oxygen must be initiated immediately, followed by endotracheal intubation. End-expiratory carbon dioxide (CO_2) detectors or capnography help verify accurate tube placement.

Head trauma is the most common cause of respiratory insufficiency. An unconscious child with severe head injury may have a variety of breathing abnormalities, including Cheyne-Stokes respiration, slow irregular breaths, and apnea.

Although less common than a pulmonary contusion, tension pneumothorax and massive hemothorax are immediately life threatening (Tables 82.2 and 82.3). **Tension pneumothorax** occurs when air accumulates under pressure in the pleural space. The adjacent lung is compacted, the mediastinum is pushed toward the opposite hemithorax, and the heart, great vessels, and contralateral lung are compressed or kinked (see Chapter 439). Both ventilation and cardiac output are impaired. Characteristic findings include cyanosis, tachypnea, retractions, asymmetric chest rise, contralateral tracheal deviation, diminished breath sounds on the ipsilateral (more than contralateral) side, and signs of shock. Needle thoracentesis, followed by thoracostomy tube insertion, is diagnostic and lifesaving. **Hemothorax** results from injury to the intercostal vessels, lungs, heart, or great vessels. When ventilation is adequate, fluid resuscitation should begin before evacuation, because a large amount of blood may drain through the chest tube, resulting in shock.

Table 82.2

Differential Diagnosis of Immediately Life-Threatening Cardiopulmonary Injuries

	TENSION PNEUMOTHORAX	MASSIVE HEMOTHORAX	CARDIAC TAMPONADE
Breath sounds	Ipsilaterally decreased more than contralaterally	Ipsilaterally decreased	Normal
Percussion note	Hyperresonant	Dull	Normal
Tracheal location	Contralaterally shifted	Midline or shifted	Midline
Neck veins	Distended	Flat	Distended
Heart tones	Normal	Normal	Muffled

Modified from Cooper A, Foltin GL: Thoracic trauma. In Barkin RM, editor: *Pediatric emergency medicine* , ed 2, St Louis, 1997, Mosby, p 325.

Table 82.3

Life-Threatening Chest Injuries

Tension Pneumothorax

- One-way valve leak from the lung parenchyma or tracheobronchial tree
- Lung collapse with mediastinal and tracheal shift to the side opposite the leak
- Compromises venous return and decreases ventilation of the other lung
- Clinically, manifests as respiratory distress, unilateral absence of breath sounds, tracheal deviation, distended neck veins, tympany to percussion of the involved side, and cyanosis
- Relieve first with needle aspiration, then with chest tube drainage

Open Pneumothorax (Sucking Chest Wound)

- Effect on ventilation depends on size

Major Flail Chest

- Usually caused by blunt injury resulting in multiple rib fractures
- Loss of bone stability of the thoracic cage
- Major disruption of synchronous chest wall motion
- Mechanical ventilation and positive end-expiratory pressure required

Massive Hemothorax

- Must be drained with a large-bore tube
- Initiate drainage only with concurrent vascular volume replacement

Cardiac Tamponade

Beck's triad:

1. Decreased or muffled heart sounds
2. Jugular venous distention
3. Hypotension (with narrow pulse pressure)

Must be drained

Modified from Krug SE: The acutely ill or injured child. In Behrman RE, Kliegman RM, editors: *Nelson essentials of pediatrics* , ed 4, Philadelphia, 2002, Saunders, p 97.

Circulation

Signs of **shock** include tachycardia; weak pulse; delayed capillary refill; cool, mottled, pale skin; and altered mental state (see Chapter 88). The most common type of shock in trauma is *hypovolemic* shock caused by hemorrhage. *Cardiac tamponade*, which is a form of obstructive shock, may be suspected clinically or diagnosed by **focused assessment with sonography in trauma (FAST)** examination or echocardiography. Cardiac tamponade is best managed by thoracotomy or pericardial window, although pericardiocentesis may be necessary as a temporizing maneuver (see Table 82.3).

Early in shock, blood pressure remains normal because of compensatory increases in heart rate and peripheral vascular resistance (Table 82.4). Some individuals can lose up to 30% of blood volume before blood pressure declines. It is important to note that 25% of blood volume equals 20 mL/kg, which is only 200 mL in a 10 kg child. Losses >40% of blood volume cause severe hypotension that, if prolonged, may become irreversible. Direct pressure should be applied to control external hemorrhage. When direct pressure does not control hemorrhage, a tourniquet should be applied to a proximal pressure point. Blind clamping of bleeding vessels, which risks damaging adjacent structures, is not advisable.

Table 82.4

Systemic Responses to Blood Loss in Pediatric Patients

SYSTEM	MILD BLOOD LOSS (<30%)	MODERATE BLOOD LOSS (30–45%)	SEVERE BLOOD LOSS (>45%)
Cardiovascular	Increased heart rate; weak, thready	Markedly increased heart rate; weak, thready central pulses;	Tachycardia followed by bradycardia; central pulses very weak or absent;

	peripheral pulses; normal systolic blood pressure; normal pulse pressure	peripheral pulses absent; low normal systolic blood pressure; narrowed pulse pressure	peripheral pulses absent; hypotension; narrowed pulse pressure (or undetectable diastolic blood pressure).
Central nervous	Anxiety; irritability; confusion	Lethargy; dulled response to pain	Coma
Skin	Cool, mottled; capillary refill prolonged	Cyanotic; capillary refill markedly prolonged	Pale and cold
Urine output	Low to very low	Minimal	None

Adapted from American College of Surgeons Committee on Trauma: *Advanced trauma life support for doctors: student course manual,* ed 9, Chicago, 2012, American College of Surgeons.

Cannulating a larger vein, such as an antecubital vein, is usually the quickest way to achieve intravenous (IV) access. A short, large-bore catheter offers less resistance to flow, allowing for more rapid fluid administration. Ideally, a 2nd catheter should be placed within the first few minutes of resuscitation in a severely injured child. If IV access is not rapidly obtainable, an intraosseous (IO) needle should be inserted; all medications and fluids can be administered intraosseously. Other alternatives are central venous access using the Seldinger technique (e.g., in the femoral vein) and, rarely, surgical cutdown (e.g., in saphenous vein). Ultrasonography should be used to facilitate central venous catheter placement, if possible.

Traditionally, fluids are administered aggressively early in hemorrhagic shock to reverse and prevent further clinical deterioration. Isotonic crystalloid solution, such as lactated Ringer injection or normal saline (20 mL/kg), should be infused rapidly. When necessary, repeated crystalloid boluses may be given. Most children are stabilized with administration of crystalloid solution alone. However, if the patient remains in shock after boluses totaling 40-60 mL/kg of crystalloid, packed red blood cells should be transfused. Massive transfusion protocols (including fresh-frozen plasma) should be initiated early to prevent coagulopathy. When shock persists despite these measures, surgery to stop internal hemorrhage is usually indicated. Although literature is emerging regarding the benefits of permissive hypotension, hemostatic resuscitation, and damage control surgery for adult trauma patients, currently there are no pediatric data.

Neurologic Deficit

Neurologic status is briefly assessed by determining the level of consciousness and evaluating pupil size and reactivity. The level of consciousness can be classified using the mnemonic **AVPU** : Alert, responsive to Verbal commands, responsive to Painful stimuli, or Unresponsive.

At least 75% of pediatric blunt trauma deaths are accounted for by head injuries. Primary direct cerebral injury occurs within seconds of the event and is irreversible. Secondary injury is caused by subsequent anoxia or ischemia. *The goal is to minimize secondary injury by ensuring adequate oxygenation, ventilation, and perfusion, and maintaining normal cerebral perfusion pressure.* A child with severe neurologic impairment—i.e., with a Glasgow Coma Scale (GCS; see Chapter 85) score of ≤8—should undergo endotracheal intubation and supportive mechanical ventilation.

Signs of **increased intracranial pressure** (ICP), including progressive neurologic deterioration and evidence of transtentorial herniation, must be treated immediately (see Chapter 85). Hyperventilation lowers the arterial partial pressure of carbon dioxide (Pa_{CO_2}), resulting in cerebral vasoconstriction, reduced cerebral blood flow, and decreased ICP. Brief hyperventilation remains an immediate option for patients with acute increases in ICP. Prophylactic hyperventilation, or vigorous or prolonged hyperventilation, is not recommended, because the consequent vasoconstriction may excessively decrease cerebral perfusion and oxygenation. Mannitol lowers ICP and may improve survival. Because mannitol induces an osmotic diuresis, it can exacerbate hypovolemia and must be used cautiously. Hypertonic saline may be a more useful agent for control of increased ICP in patients with severe head injury. Neurosurgical consultation is mandatory. If signs of increased ICP persist, the neurosurgeon must decide whether to operate emergently.

Exposure and Environmental Control

All clothing should be cut away to reveal any injuries. Cutting is quickest and minimizes unnecessary patient movement. Children often arrive in the ED mildly hypothermic because of their higher body surface area-to-mass ratios. They can be warmed with use of radiant heat as well as heated blankets and IV fluids.

Secondary Survey

During the secondary survey, the physician completes a detailed, head-to-toe physical examination.

Head Trauma

A GCS or Pediatric GCS score (see Chapter 85) should be assigned to every child with significant head trauma. This scale assesses eye opening and motor and verbal responses. In the Pediatric GCS, the verbal score is modified for age. The GCS helps categorize neurologic disability, and serial measurements identify improvement or deterioration over time. Patients with low scores 6-24 hr after injuries have poorer prognosis.

In the ED, cranial CT scanning of the head without a contrast agent has become standard to determine the type of injury in patients with concerning findings. Diffuse cerebral injury with edema is a common and serious finding on CT scan in severely brain-injured children. Focal hemorrhagic lesions (e.g., epidural hematoma) that can be evacuated occur less often but may require immediate neurosurgical intervention (Fig. 82.3).

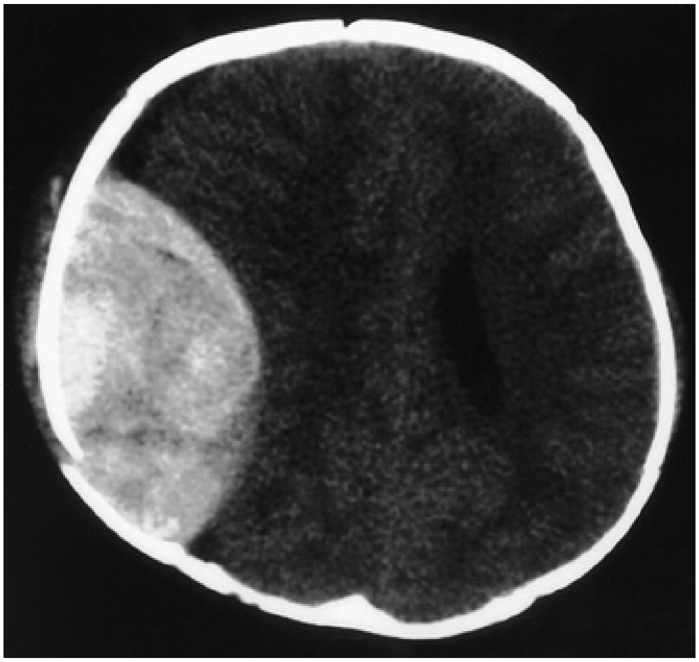

FIG. 82.3 **Epidural hematoma. CT head scan from 7 mo old girl who, according to the history provided, did not wake up for her nightly feeding and began vomiting in the morning. The mother's boyfriend reported that the infant had fallen from a chair the previous day. The CT scan shows a large epidural hematoma on the right and marked shift of the midline from right to left. The right lateral ventricle is compressed as a result of the mass effect, and the left lateral ventricle is slightly prominent. The infant underwent emergency surgical evacuation of the epidural hematoma and recovered uneventfully. (From O'Neill JA Jr: *Principles of pediatric surgery,* ed 2, St Louis, 2003, Mosby, p 191.)**

Monitoring of ICP should be strongly considered for children with severe brain injury, particularly for those with a GCS score of ≤8 and abnormal head CT findings (see Chapter 85). One advantage of an intraventricular catheter over an intraparenchymal device is that cerebrospinal fluid can be drained to treat acute increases in ICP. Hypoxia, hypercarbia, hypotension, and hyperthermia must be aggressively managed to prevent secondary brain injury. Cerebral perfusion pressure (i.e., the difference between mean arterial blood pressure and mean ICP) should be maintained >40 mm Hg, at least (and an even higher minimum, >50 mm Hg, especially for older children).

A child with a severe brain injury must be treated aggressively in the ED because it is difficult to predict the long-term neurologic outcome.

Cervical Spine Trauma

Cervical spine injuries occur in <3% of children with blunt trauma—with the risk being substantially higher in those with GCS scores ≤8—but they are associated with significant mortality and morbidity. Bony injuries occur mainly from C1 to C4 in children younger than 8 yr. In older children, they occur equally in the upper and lower cervical spine. The mortality rate is significantly higher in patients with upper C-spine injuries. **Spinal cord injury without radiographic abnormalities (SCIWORA***)* on plain films or CT may be present. Patients with SCIWORA have neurologic symptoms, and spinal cord abnormalities are nearly always noted on MRI. Approximately 30% of all patients with C-spine injuries have permanent neurologic deficits.

Evaluation begins with a detailed history and neurologic examination. Identifying the mechanism of injury helps in estimating the likelihood of a C-spine injury. Both the patient and the paramedic should be asked whether any neurologic symptoms or signs, such as weakness or abnormal sensation, were present before arrival in the ED. In a child with neurologic symptoms and normal findings on C-spine plain radiographs and CT scan, SCIWORA must be considered.

Whenever the history, physical examination, or mechanism of injury suggests a C-spine injury, radiographs should be obtained after initial resuscitation. The **National Emergency X-Radiography Utilization Study (NEXUS)** cervical spine rule helps identify low-risk patients who may not require radiographs (Table 82.5). The standard series of plain radiographs includes lateral, anteroposterior (AP), and odontoid views. Some centers use cervical spine CT as the primary diagnostic tool, particularly in patients with abnormal GCS scores and/or significant injury mechanisms, recognizing that CT is more sensitive in detecting bony injury than plain radiographs. CT is also helpful if an odontoid fracture is suspected, because young children typically do not cooperate enough to obtain an open-mouth (odontoid) radiographic view. Use of cervical spine CT scan must be balanced with the knowledge that CT exposes thyroid tissue to 90-200 times the amount of radiation from plain films. MRI is indicated in a child with suspected SCIWORA and in the evaluation of children who remain obtunded.

Table 82.5

National Emergency X-Radiography Utilization Study (NEXUS) to Rule Out Cervical Spine Injury Following Blunt Trauma

If ***none*** *of the following is present, the patient is at very low risk for clinically significant cervical spine injury:*

Midline cervical tenderness
Evidence of intoxication
Altered level of alertness
Focal neurologic deficit
Distracting painful injury

Data from Hoffman JR, Mower WR, Wolfson AB, et al: Validity of a set of clinical criteria to rule out injury to the cervical spine in patients with blunt trauma, *N Engl J Med* 343:94–99, 2000; and Viccellio P, Simon H, Pressman BD, et al: A prospective multicenter study of cervical spine injury in children, *Pediatrics* 108:e20, 2001.

Rapid diagnosis of spinal cord injury is essential. Initiating high-dose IV methylprednisolone within 8 hr of spinal cord injury has been reported to improve motor outcome, but this treatment has become controversial.

Thoracic Trauma

Pulmonary contusions occur frequently in young children with blunt chest trauma. A child's chest wall is relatively pliable; therefore, less force is absorbed by the rib cage, and more is transmitted to the lungs. Respiratory distress may be noted initially or may develop during the 1st 24 hr after injury.

Rib fractures result from significant external force. They are noted in patients with more severe injuries and are associated with a higher mortality rate. Flail chest, which is caused by multiple rib fractures, is rare in children. Table 82.6 lists indications for operative management in thoracic trauma. (See Table 82.2 for the differential diagnosis of immediately life-threatening cardiopulmonary injuries.)

Table 82.6

Indications for Operation in Thoracic Trauma

Thoracotomy Immediately or Shortly After Injury

- Massive continuing pneumothorax or large air leak from tracheobronchial injury (cannot expand lung and ventilate)
- Cardiac tamponade
- Open pneumothorax
- Esophageal injury
- Aortic or other vascular injury
- Acute rupture of the diaphragm

Delayed Thoracotomy

- Chronic rupture of the diaphragm
- Clotted hemothorax
- Persistent chylothorax
- Traumatic intracardiac defects
- Evacuation of large foreign bodies
- Chronic atelectasis from traumatic bronchial stenosis

Modified from O'Neill JA Jr: *Principles of pediatric surgery*, ed 2, St Louis, 2003, Mosby, p 157.

Abdominal Trauma

Liver and spleen contusions, hematomas, and lacerations account for the majority of intraabdominal injuries from blunt trauma. The kidneys, pancreas, and duodenum are relatively spared because of their retroperitoneal location. Pancreatic and duodenal injuries are more common after a bicycle handlebar impact or a direct blow to the abdomen.

Although a thorough examination for intraabdominal injuries is essential, achieving it often proves difficult. Misleading findings can result from gastric distention after crying or in an uncooperative toddler. Calm reassurance, distraction, and gentle, persistent palpation help with the examination. Important findings include distention, bruises, and tenderness. Specific symptoms and signs give insight into the mechanism of injury and the potential for particular injuries. Pain in the left shoulder may signify splenic trauma. A lap belt mark across the abdomen raises concern for bowel or mesentery injury. The presence of certain other injuries, such as lumbar spinal fractures and femur fractures, increases the likelihood of intraabdominal injury.

An abdominal (and pelvic) CT scan with IV contrast medium enhancement rapidly identifies structural abnormalities and is the preferred study in a stable child. Negative abdominal CT scan has been shown to have a negative predictive value (NPV) of 99.6%. It has excellent sensitivity and specificity for splenic (Fig. 82.4), hepatic (Fig. 82.5), and renal injuries, but is less sensitive for diaphragmatic, pancreatic, or intestinal injuries. Small amounts of free fluid or air or a mesenteric hematoma may be the only sign of an intestinal injury. Administration of an oral contrast agent is not routinely recommended for all abdominal CT scans, but it sometimes aids in identifying an intestinal, especially a duodenal, injury.

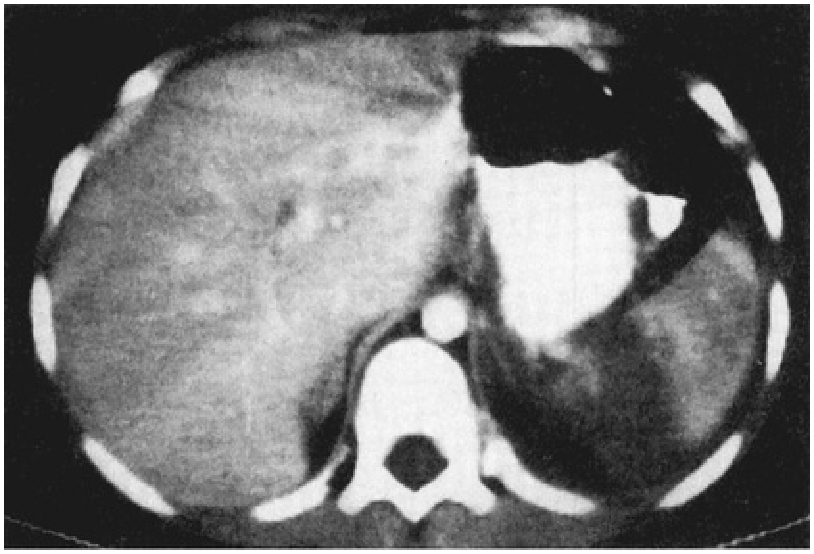

FIG. 82.4 Splenic rupture. CT scan with intravenous and gastrointestinal contrast enhancement shows an isolated splenic rupture that resulted from blunt trauma. This injury responded to nonoperative management, as do most splenic injuries. (From O'Neill JA Jr: *Principles of pediatric surgery,* ed 2, St Louis, 2003, Mosby, p 166.)

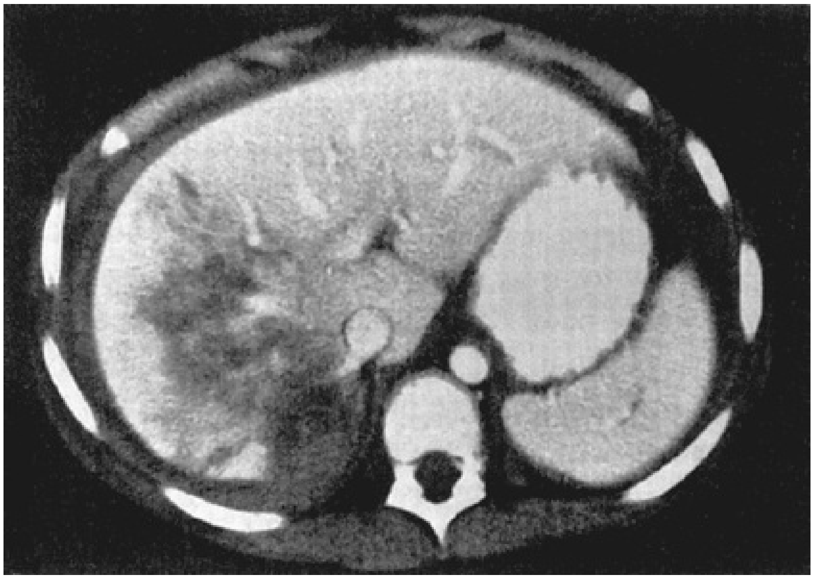

FIG. 82.5 Liver injury. CT scan performed after severe blunt injury of the abdomen shows a bursting injury of the liver. The patient was stable, and no operative intervention was required. The decision to perform surgery should be based on the patient's physiologic stability. (From O'Neill JA Jr: *Principles of pediatric surgery,* ed 2, St Louis, 2003, Mosby, p 168.)

Although the **FAST** examination helps detect hemoperitoneum, the variably low sensitivity of this test in children suggests that it should not be used alone to exclude intraabdominal injury in patients with a moderate to high pretest probability for injury. A positive FAST exam for hemoperitoneum requires further investigation. Serial FAST exams over time (by a skilled ultrasonographer) may be used to rule out injury in need of intervention. The FAST exam is most clinically useful in patients who have blunt trauma and are hemodynamically unstable or in patients who require operative intervention for nonabdominal injuries, because in these cases the performance of a CT scan may not be feasible.

Nonoperative treatment has become standard for hemodynamically stable children with splenic, hepatic, and renal injuries from blunt trauma. The majority of such children can be treated nonsurgically. In addition to avoiding perioperative complications, nonoperative treatment decreases the need for blood transfusions and shortens hospital stay. When laparotomy is indicated, splenic repair is preferable to splenectomy.

Pelvic Trauma

Pelvic fractures in children are much less common than in adults, occurring in approximately 4% of children with more severe blunt trauma. Pelvic fractures are typically caused by high forces (e.g., high-speed motor vehicle crashes or pedestrian impacts) and are often associated with intraabdominal and/or vascular injuries. The pelvis itself forms a ring, and high-force impacts can lead to disruption of this ring. When the ring is disrupted in >1 location, such as the symphysis pubis and the sacroiliac joint, the ring can become unstable and displaced, potentially injuring large pelvic vessels and leading to massive blood loss. Catheter-directed embolization to control bleeding, performed by an interventional radiologist, may be required.

The pelvis should be assessed for stability by means of compression-distraction maneuvers. If instability is noted, immediate external fixation with a pelvis-stabilizing device or a sheet should be applied and orthopedic consultation sought. A trauma patient with a potential pelvic fracture should receive an AP pelvic radiograph in the trauma bay, or a CT scan, if there is high suspicion of injury. Children *without* a high-risk clinical finding (i.e., GCS <14; abdominal pain or tenderness; pelvic tenderness, laceration, ecchymosis, or abrasion; gross hematuria or >20 red blood cells/high-power field on urinalysis; or femur fracture) or a high-risk mechanism of injury (i.e., unrestrained motor vehicle collision, motor vehicle collision with ejection, motor vehicle collision rollover, auto vs pedestrian, or auto vs bicycle), however, are unlikely to have pelvic fractures.

Lower Genitourinary Trauma

The perineum should be inspected and the stability of the bones of the pelvis assessed. Urethral injuries are more common in males. Findings suggestive of urethral injury include scrotal or labial ecchymosis, blood at the urethral meatus, gross hematuria, and a superiorly positioned prostate on rectal examination (in an adolescent male). Certain pelvic fractures also increase the risk for potential genitourinary injury. Any of these findings is a contraindication to urethral catheter insertion and warrants consultation with a urologist. Retrograde urethrocystogram and CT scan of the pelvis and abdomen are used to determine the extent of injury.

Extremity Trauma

Thorough examination of the extremities is essential because extremity fractures are among the most frequently overlooked injuries in children with multiple trauma. All limbs should be inspected for deformity, swelling, and bruises; palpated for tenderness; and assessed for active and passive range of motion, sensory function, and perfusion.

Before radiographs are obtained, suspected fractures and dislocations should be immobilized and an analgesic administered. Splinting a femur fracture helps alleviate pain and may decrease blood loss. An orthopedic surgeon should be consulted immediately to evaluate children with compartment syndrome, neurovascular compromise, open fracture, or most traumatic amputations.

Radiologic and Laboratory Evaluation

Most authorities recommend ordering multiple laboratory tests (e.g., complete blood cell count, electrolytes, glucose, blood urea nitrogen, creatinine, liver function tests, amylase, lipase, lactate, blood gas, prothrombin and partial thromboplastin times, type and cross-match, urinalysis) and x-ray films (e.g., lateral C-spine, AP chest, AP pelvis) in the ED. One benefit of standardizing the evaluation of patients with major trauma is that fewer decisions need to be made on an individual basis, possibly expediting ED management. Some of these studies have prognostic importance. A large base deficit is associated with a higher mortality rate, and elevated lactate values correlate with poor prognosis.

There are some limitations in standard tests. The lateral cervical spine radiograph can miss clinically significant injuries. Hemoglobin and hematocrit values provide baseline values in the ED, but they may not have yet equilibrated after a hemorrhage. Abnormal liver function test results or elevated serum amylase and lipase values may be noted in patients with significant abdominal trauma, but most patients with significant trauma to the abdomen already have clinical indications for CT scanning or surgery. The majority of previously healthy children have normal coagulation profiles; these may become abnormal after major head trauma. Although routine urinalysis or dipstick urine testing for blood has been recommended for children, other data suggest that this evaluation may be unnecessary in patients without gross hematuria, hypotension, or other associated abdominal injuries.

Clinical prediction rules that combine patient history with physical examination findings have been developed to identify those at low risk of injury for whom specific radiographic and laboratory studies may not be necessary. The NEXUS C-spine rule is a sensitive, easily applicable rule that was validated for adults and children, although there were fewer young patients studied (see Table 82.5). Several clinical prediction rules have been developed to identify children at low risk of traumatic brain injury (Table 82.7). Another clinical prediction rule has been developed to identify children at very low risk of clinically important intraabdominal injuries following blunt trauma (Table 82.8). Although this rule has an NPV of 99.9%, it needs to be externally validated before widespread implementation.

Table 82.7

Prediction Rule for Identification of Children at Very Low Risk of Clinically Important Brain Injuries After Head Trauma

*Children <2 yr old are at very low risk of clinically important traumatic brain injury if they have **none** of the following:*

Severe mechanism of injury
History of LOC >5 sec
GCS ≤14 or other signs of altered mental status

Not acting normally per parent
Palpable skull fracture
Occipital/parietal/temporal scalp hematoma

Children 2-18 yr old are at very low risk of clinically important traumatic brain injury if they have ***none*** *of the following:*

Severe mechanism of injury
History of LOC
History of vomiting
GCS ≤14 or other signs of altered mental status
Severe headache in the ED
Signs of basilar skull fracture

ED, Emergency department; GCS, Glasgow Coma Scale score; LOC, loss of consciousness.

Modified from Kuppermann N, Holmes JF, Dayan PS, et al: Identification of children at very low risk of clinically-important brain injuries after head trauma: a prospective cohort study, *Lancet* 374:1160–1170, 2009.

Table 82.8

Prediction Rule for Identification of Children at Very Low Risk of Clinically Important Intraabdominal Injuries After Blunt Trauma

If ***none*** *of the following is present, the patient is at very low risk for clinically significant intraabdominal injury:*

Glasgow Coma Scale score <14
Vomiting
Evidence of thoracic wall trauma
Decreased breath sounds
Evidence of abdominal wall trauma or seatbelt sign
Abdominal pain
Abdominal tenderness

Modified from Holmes JF, Lillis K, Monroe D, et al: Identifying children at very low risk of clinically important blunt abdominal injuries, *Ann Emerg Med*

62:107–116, e2, 2013.

Psychological and Social Support

Serious multisystem trauma may result in significant long-term psychological and social difficulties for the child and family, particularly when there is a major head injury. Like adults, children are at risk for depressive symptoms and posttraumatic stress disorder. Caregivers face persistent stress and have been noted to have more psychological symptoms. Psychological and social support, during the resuscitation period and afterward, is extremely important. Parents often prefer to be offered the choice to be present during resuscitations. A member of the resuscitation team should be made responsible for answering the family's questions and supporting them in the trauma room.

CHAPTER 83

Spinal Cord Injuries in Children

Mark R. Proctor

See also Chapter 729 .

Compared with adults, spine and spinal cord injuries are rare in children, particularly young children, because of both anatomic differences and etiologies of injury. The main mechanisms of injury to the spine are motor vehicle crashes, falls, sports, and violence, which affect young children less often (see Chapter 82).

Several anatomic differences affect the pediatric spine. The head of a young child is larger relative to body mass than in adults, and the neck muscles are still underdeveloped, which places the fulcrum of movement higher in the spine. Therefore, children <9 yr old have a higher percentage of injuries in the upper cervical spine than older children and adults. The spine of a small child also is very mobile, with pliable bones and ligaments, so fractures of the spine are exceedingly rare. However, this increased mobility is not always a positive feature. Transfer of energy leading to spinal distortion may not affect the structural integrity of the bones and ligaments of the spine but can still lead to significant injuries of the spinal cord. This phenomenon of **spinal cord injury without radiographic abnormalities (SCIWORA)** is more common in children than adults. The term is relatively outdated, since almost all injuries are detectable by MRI, but is still clinically useful when referring to spinal cord injuries evaluated by plain radiographs or CT. There seem to be 2 distinct forms of SCIWORA. The **infantile** form involves severe injury of the cervical or thoracic spinal cord; these patients have a poor chance of complete recovery. In older children and adolescents, SCIWORA is more likely to be a less severe injury, with a high likelihood of complete recovery over time. The **adolescent** form, also called *transient neurapraxia* , is assumed to be a spinal cord concussion or mild contusion, as opposed to the severe spinal cord injury related to the mobility of the spine in small children.

Although the mechanisms of spinal cord injury in children include birth trauma, falls, and child abuse, the major cause of morbidity and mortality across all ages remains **motor vehicle injuries** . Adolescents incur spinal cord injuries with epidemiology similar to that of adults, including significant male predominance and a high likelihood of fracture dislocations of the lower cervical spine or thoracolumbar region. In infants and children <5 yr old, fractures and mechanical disruption of spinal elements are more likely to occur in the upper cervical spine between the occiput and C3, for the reasons previously discussed.

Clinical Manifestations

One in 3 patients with significant trauma to the spine and spinal cord will have a concomitant severe head injury, which makes early diagnosis challenging. For these patients, clinical evaluation may be difficult. Patients with a potential spine injury need to be maintained in a protective environment, such as a collar, until the spine can be cleared by clinical and/or radiographic means. A careful neurologic examination is necessary for infants with suspected spinal cord injuries. Complete spinal cord injury will lead to **spinal shock** with early areflexia (see Chapter 729). Severe cervical spinal cord (C-spine) injuries will usually lead to paradoxical respiration in patients who are breathing spontaneously. **Paradoxical respiration** occurs when the diaphragm, which is innervated by the phrenic nerves with contributions from C3, C4, and C5, is functioning normally, but the intercostal musculature innervated by the thoracic spinal cord is paralyzed. In this situation, inspiration fails to expand of the chest wall but distends the abdomen. Other complications during the acute (2-48 hr) phase include autonomic dysfunction (brady- and tachyarrhythmias, orthostatic hypotension, hypertension), temperature instability, thromboembolism, dysphagia, and bowel/bladder dysfunction.

The *mildest* injury to the spinal cord is **transient quadriparesis** evident for seconds or minutes with complete recovery in 24 hr. This injury follows a concussion of the cord and is most frequently seen in adolescent athletes. If their imaging is normal, these children can generally return to normal activities after a period of rest from days to weeks, depending on the initial severity, similar to cerebral concussion management.

Significant spinal cord injury in the cervical region is characterized by: flaccid quadriparesis, loss of sphincter function, and a sensory level corresponding to the level of injury. An injury at the high cervical level (C1-C2) can cause respiratory arrest and death in the absence of ventilatory support. Injuries in the *thoracic* region are generally the result of fracture dislocations. They may produce paraplegia when at T10 or above, or the **conus medullaris syndrome** if at the T12-L1 level. This includes a loss of urinary and rectal sphincter control, flaccid weakness, and sensory disturbances of the legs. A **central cord lesion** may result from contusion and hemorrhage in the center of the spinal cord. It typically involves the upper extremities to a greater degree than the legs, because the motor fibers to the cervical and thoracic region are more centrally located in the spinal cord. There are lower motor neuron signs in the upper extremities and upper motor neuron signs in the legs, bladder dysfunction, and loss of sensation caudal to the lesion. There may be considerable recovery, particularly in the lower extremities, although sequelae are common (see Chapter 729).

Clearing the Cervical Spine in Children

The management of children following major trauma is challenging. For older children, the clearance is similar to a lucid adult, and the NEXUS (National Emergency X-Radiography Utilization Study) criteria are appropriate (see Chapter 82 , Table 82.5). Clearing the cervical spine in younger and uncooperative children involves similar issues as in adults with an altered level of consciousness. Small children generally have a difficult-to-assess physical examination, and it is difficult to determine if they have cervical pain. Plain radiography remains a mainstay for assessing the spine because it is easy to obtain. There has been increasing emphasis on MRI for evaluation of potential C-spine instability, but in small children MRI requires sedation and in most centers the presence of an anesthesiologist (Fig. 83.1). CT scan is another important study with high sensitivity and specificity, but the risk of radiation exposure must be considered.

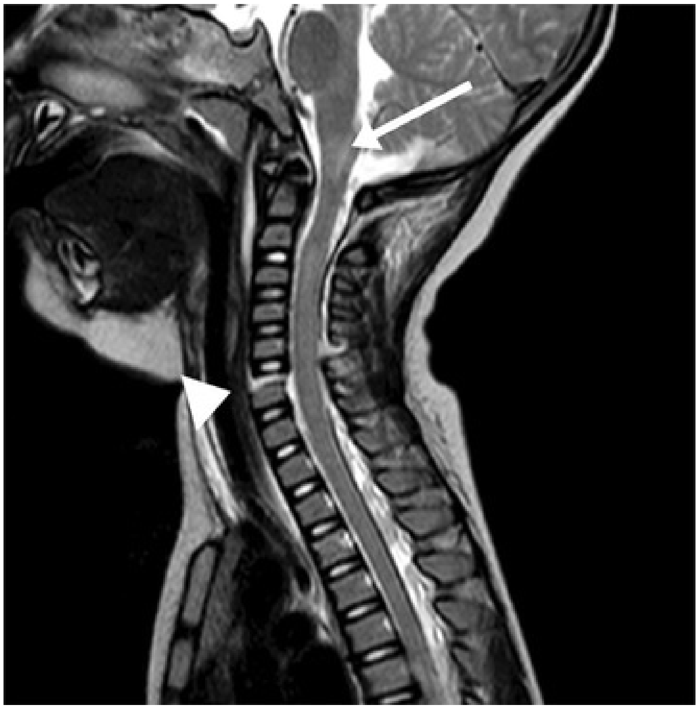

FIG. 83.1 T2-weighted MRI performed the day after the accident showed cervical spinal cord swelling combined with high signal intensity (C1-C3) (*arrow*) and dislocation of C5-C6 (*arrowhead*). (From Inoue K, Kumada T, Fujii T, Kimura N: Progressive cervical spinal cord atrophy after a traffic accident, *J Pediatr* 180:287, 2017, Fig 1, p 287.)

Treatment

The cervical spine should be immobilized in the field by the emergency medical technicians. In cases of acute spinal cord injury, weak data suggest the acute infusion of a bolus of high-dose (30 mg/kg) methylprednisolone, followed by a 23 hr infusion (5.4 mg/kg/hr). The data for this treatment are controversial and have not been tested specifically in children; *many centers no longer use it routinely* . Maintenance of euvolemia and normotension are very important, and vasopressors might be needed if the sympathetic nervous system has been compromised.

Surgical management of spinal injuries must be tailored to the patient's age but can be a crucial step in management. Any compression of the spinal cord must be surgically relieved to afford the best chance of a favorable outcome. In addition, spinal cord injury can be worsened by instability, so surgical stabilization can prevent further injury (Fig. 83.2). In general, younger children have a higher healing capacity for bones and ligaments, and external immobilization might be considered for injuries that require surgery in older children and adults. However, some injuries are highly unstable and always require surgery. **Occipitocervical dislocation** is one such highly unstable injury, and early surgery with fusion from the occiput to C2 or C3 should be performed, even in very young children. Fixation of the subaxial spine must be tailored to the size of the pedicles and other osseous structures of the developing axial skeleton.

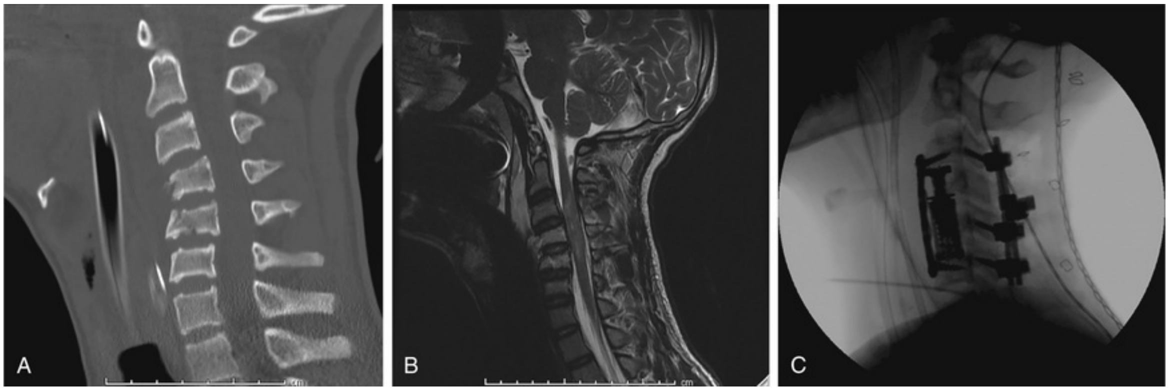

FIG. 83.2 A 15 yr old hockey player suffered acute paraplegia after his head struck the boards during a hockey game. **A,** CT scan shows compression fractures of C4 and C5. **B,** MRI shows severe spinal cord contusion. **C,** Because of the need to decompress the spinal cord and stabilize the spine, anterior and posterior surgery was performed. No meaningful recovery was obtained.

Prevention

The most important aspect of the care of spinal cord injuries in children is injury prevention. Use of appropriate child restraints in automobiles is the most important precaution. In older children and adolescents, rules against “spear tackling” in American football and the *Feet First, First Time* aimed at adolescents diving into swimming pools and natural water areas are important ways to help prevent severe cervical spinal cord injuries. Safe driving practices, such as using safety belts, avoiding distracted driving, and following the speed limit, can have substantial beneficial effects on injury rates.

CHAPTER 84

Care of Abrasions and Minor Lacerations

Joanna S. Cohen, Bruce L. Klein

Lacerations and Cuts

Lacerations are tears of the skin caused by blunt or shearing forces. A **cut** (or a *stab*), in contrast, is an injury inflicted by a sharp object. Although distinguishing between the two can be important for forensic purposes, their evaluation and management are similar. In this chapter, lacerations include cuts and stabs.

Epidemiology

More than half of the 12 million wounds treated annually in U.S. emergency departments (EDs) are lacerations. Approximately 30% occur in children younger than 18 yr. Approximately 2% of pediatric office visits are related to wound management.

Evaluation

The history should include the mechanism of injury, the amount of force, and the time the injury occurred. The mechanism helps determine whether there may be foreign material in the wound, which would increase the risk for infection. Particularly in children, it is essential to determine whether the injury was inflicted intentionally. *If nonaccidental trauma is suspected, child protective services should be notified.* The type of force causing the laceration also influences the risk of infection, because a significant crush injury is more likely to become infected than a shearing one. **Blunt injury** , such as bumping the head, is a common cause of lacerations in children and is less likely to become infected. Theoretically, the amount of bacteria in the wound should increase exponentially with the time from injury to repair; however, the length of time that results in a clinically significant increase in wound infection is unclear. Older wounds may require delayed primary closure or healing by secondary intention. The patient or parent should be asked about any special host factors that may predispose to infection or impede healing, such as diabetes, malnutrition, obesity, and corticosteroid therapy, as well as immunization status, with particular attention to tetanus administration.

On examination, the clinician should note the size and depth of the wound, as well as any associated vascular, neurologic, tendon, or other tissue injury. The laceration's location also is important with regard to both the risk for infection and the cosmetic outcome. Compared with lacerations in adults, those in children occur more often on the face and scalp and less often on the upper extremities. Because the face and scalp are more vascular, wounds located there are less likely to become infected. Lacerations overlying joints are more likely to develop wider scars as a result of tension during healing.

Treatment

The goals of treatment are to establish hemostasis, minimize the risk of infection, restore skin and underlying tissue integrity, and produce the most functionally and cosmetically acceptable result possible. Complications of wounds, including infection, hypertrophic scar formation, and functional limitation occur in approximately 8% of children.

Any significant bleeding must be controlled, usually with external pressure, before a thorough evaluation of the wound can occur. If there is a skin flap, it should be returned to its original position before application of pressure. Infrequently, a tourniquet may need to be applied if bleeding cannot be controlled with direct pressure. Clothing over the injury should be removed to minimize wound contamination. Jewelry encircling an injured extremity should be removed to prevent the jewelry from forming a constricting band when the extremity swells.

It is best to administer a **local anesthetic** early, before exploration and more meticulous cleansing of the wound. This anesthetic can be applied topically (e.g., lidocaine, epinephrine, and tetracaine gel) or infiltrated locally or as a regional nerve block (e.g., lidocaine or bupivacaine), depending on the location of the laceration and the complexity of the repair. Buffering the acidic lidocaine with sodium bicarbonate can reduce pain during injection. Sometimes, nonpharmacologic or additional pharmacologic methods of analgesia and anxiolysis are required for a young, frightened, or uncooperative child. The wound should be examined under proper light to enable identification of foreign bodies or damage to vessels, nerves, or tendons.

Many lacerations, especially heavily contaminated ones, benefit from **irrigation** , with either water or sterile saline, to reduce the risk of infection. It is important to recognize that many traumatic lacerations treated in the ED, or office, are only minimally contaminated, containing $<10^2$ bacterial colonies. In fact, in one of the few human studies on irrigation, irrigation did not decrease the infection rate of *minimally* contaminated scalp or facial lacerations in patients who presented to an ED within 6 hr of injury. Higher-pressure irrigation may actually increase tissue damage, making the wound and adjacent tissue more susceptible to infection and delaying healing. These caveats notwithstanding, irrigation has benefits, although which technique to use—that is, which device, what size syringe, what size needle, which solution, how much volume, how much pressure—remains to be determined. These features may vary for different types of lacerations. In heavily contaminated wounds, the benefit of higher-pressure irrigation likely outweighs the harm of tissue damage. For heavily contaminated lacerations, a typical recommendation is to use a 35-65 mL syringe attached to a plastic splatter shield, or a 19-gauge needle if a splatter shield is unavailable, and to irrigate with approximately 100 mL of solution per centimeter of wound. Conversely, for relatively clean wounds, lower-pressure irrigation minimizes tissue damage, which may be more important for outcome than any decrease in bacterial clearance that may ensue. Debridement of devitalized tissue with higher-pressure irrigation, scrubbing, or surgical excision can also be necessary in certain cases, such as crush injuries.

Most lacerations seen in the pediatric ED or office should be closed primarily. Contraindications exist to **primary closure** (e.g., certain bite wounds; see Chapter 743). Although it is accepted that the time from injury to repair should be as brief as possible to minimize the risk of infection, there is no universally accepted guideline as to what length of time is too long for primary wound closure. Also, this length of time varies for different types of lacerations. A prudent recommendation is that higher-risk wounds should be closed within 6 hr at most after the injury but that some low-risk wounds (e.g., clean facial lacerations) may be closed as late as 12-24 hr.

Many lacerations can be closed with simple, interrupted, 4-0, 5-0, or 6-0, **nonabsorbable sutures** . For certain lacerations, absorbable sutures for external skin closure are not necessarily inferior to nonabsorbable sutures, and may provide cost and time savings, as well as avoiding having to remove them, an unpleasant procedure in a young child. For lacerations under tension, horizontal or vertical mattress sutures, which provide added strength and may evert the wound edges better, can be used instead. For lacerations in cosmetically significant areas, a **running intradermal stitch** may produce a less conspicuous, more aesthetic scar than simple or mattress skin sutures, which can leave unattractive track marks. Deeper lacerations may need repair with an absorbable dermal and/or fascial layer. Other complex lacerations, such as those involving the ear, eyelid, nose, lip, tongue, genitalia, or fingertip, sometimes require more advanced techniques as well as subspecialty consultation.

Staples, topical skin adhesives, and surgical tape are acceptable alternatives to sutures, depending on the laceration's location and the healthcare provider's preference. **Staples** are particularly useful for scalp lacerations, where the scar's appearance tends to be less important. Topical **skin adhesives** (octyl cyanoacrylates or butyl cyanoacrylates) are ideal for linear, relatively superficial lacerations with easily approximated edges that are not under tension. Adhesives are particularly useful for lacerations located in areas where suture track marks are especially undesirable, or in situations where resources are constrained.

Maintaining a warm, moist, wound environment following repair accelerates wound healing without increasing the risk of infection. A topical antimicrobial ointment (e.g., bacitracin or bacitracin, neomycin, and polymyxin B combination) and conventional gauze dressing provide such an environment and reduce the infection rate. Compared with conventional dressings, **occlusive dressings** (hydrocolloids, hydrogels, polyurethane films) may be better at accelerating healing, reducing infection, and decreasing pain but are more expensive. Occlusive dressings that adhere (hydrocolloids or polyurethane films) are impractical for lacerations with protruding sutures. If the laceration overlies or is near a joint, **splinting** helps limit mobility and can speed healing and minimize dehiscence.

For most routine lacerations that are repaired early and meticulously, prophylactic systemic antibiotics are unnecessary because they do not decrease the rate of infection. **Antibiotic prophylaxis** is or may be indicated for human and many animal bites, for open fractures and joints, and for grossly contaminated wounds, as well as for wounds in patients who are immunosuppressed or have prosthetic devices. *Tetanus prophylaxis should be administered, if indicated,* according to U.S. Centers for Disease Control and Prevention guidelines (see Chapter 238).

Abrasions

An **abrasion** is a scrape to the epidermis, and sometimes the dermis, that is usually caused by friction of the skin against a rough surface. *Road rash* is a colloquial term for abrasions that result from friction of the skin against pavement. Motor vehicle collisions with pedestrians and cycling accidents are common causes of road rash in children. Road rash can be extensive, involving multiple areas on the body. These abrasions also can be deep, and they often contain embedded debris. A *rug burn* is an abrasion sustained by sliding across a carpet. Some abrasions display specific patterns and are called **imprint abrasions** . *Ligature marks* are a type of imprint abrasion caused by a rope or cord that has been tied around a part of the body and has rubbed against the skin. These injuries should alert the clinician to the likelihood of nonaccidental (including self-inflicted) trauma.

Treatment

All abrasions should be cleansed thoroughly and any debris or foreign material removed. If debris is not removed, abnormal skin pigmentation, known as **posttraumatic tattooing** , can occur and can be difficult to treat. A nonadherent occlusive dressing or a topical antibiotic and conventional dressing should be applied. *Tetanus prophylaxis should be administered, if indicated* (see Chapter 238). Large and/or deep abrasions that have not healed in a few weeks require consultation with a plastic surgeon for more advanced care.

CHAPTER 85

Neurologic Emergencies and Stabilization

Patrick M. Kochanek, Michael J. Bell

Neurocritical Care Principles

The brain has high metabolic demands, which are further increased during growth and development. Preservation of nutrient supply to the brain is the mainstay of care for children with evolving brain injuries. *Intracranial dynamics* describes the physics of the interactions of the contents—brain parenchyma, blood (arterial, venous, capillary), and cerebrospinal fluid (CSF)—within the cranium. Normally, brain parenchyma accounts for up to 85% of the contents of the cranial vault, and the remaining portion is divided between CSF and blood. The brain resides in a relatively rigid cranial vault, and cranial compliance decreases with age as the skull ossification centers gradually replace cartilage with bone. The **intracranial pressure (ICP)** is derived from the volume of its components and the bony compliance. The **perfusion pressure** of the brain (cerebral perfusion pressure, CPP) is equal to the pressure of blood entering the cranium (mean arterial pressure, MAP) minus the ICP, in most cases.

Increases in intracranial volume can result from swelling, masses, or increases in blood and CSF volumes. As these volumes increase, compensatory mechanisms decrease ICP by (1) decreasing CSF volume (CSF is displaced into the spinal canal or absorbed by arachnoid villi), (2) decreasing cerebral blood volume (venous blood return to the thorax is augmented), and/or (3) increasing cranial volume (sutures pathologically expand or bone is remodeled). Once compensatory mechanisms are exhausted (the increase in cranial volume is too large), small increases in volume lead to large increases in ICP, or intracranial hypertension (Fig. 85.1). As ICP continues to increase, brain ischemia can occur as CPP falls. Further increases in ICP can ultimately displace the brain downward into the foramen magnum—a process called **cerebral herniation,** which can become irreversible in minutes and may lead to severe disability or death; Fig. 85.2 notes other sites of brain herniation.

FIG. 85.1 The Munro-Kellie doctrine describes intracranial dynamics in the setting of an expanding mass lesion (i.e., hemorrhage, tumor) or brain edema. In the normal state, the brain parenchyma, arterial blood, cerebrospinal fluid (CSF), and venous blood occupy the cranial vault at a low pressure, generally <10 mm Hg. With an expanding mass lesion or brain edema, initially there is a compensated state as a result of reduced CSF and venous blood volumes, and intracranial pressure (ICP) remains low. Further expansion of the lesion, however, leads to an uncompensated state when compensatory mechanisms are exhausted, and intracranial hypertension results.

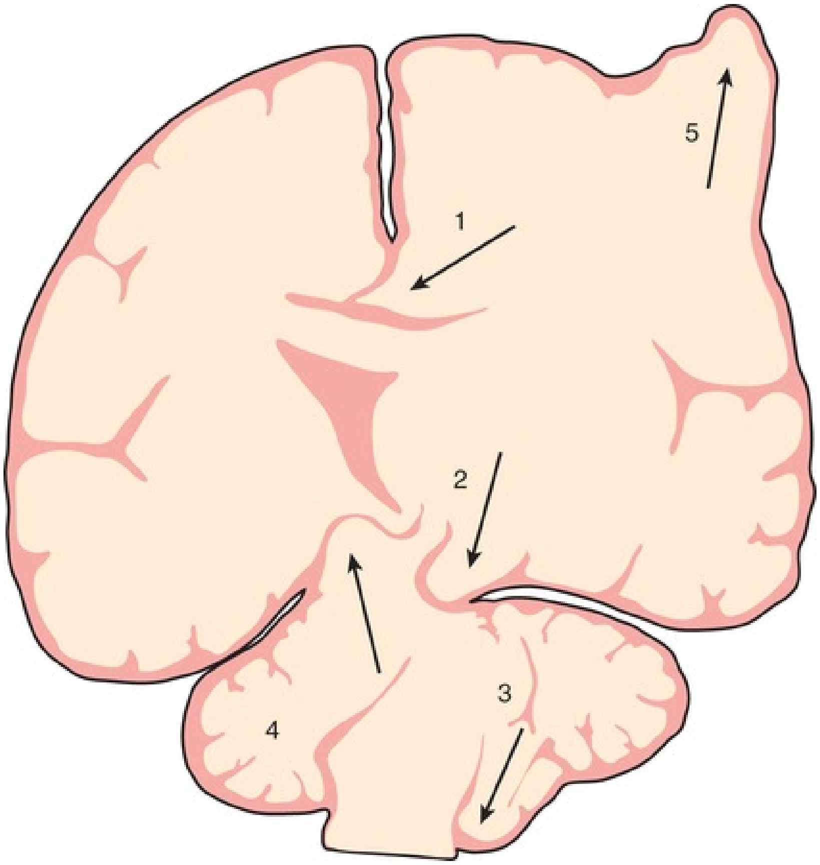

FIG. 85.2 Different forms of brain herniation. *1,* Cingulate. *2,* Uncal. *3,* Cerebellar tonsillar. *4,* Upward cerebellar. *5,* Transcalvarial. (From Fishman RA: *Cerebrospinal fluid in diseases of the nervous system,* Philadelphia, 1980, Saunders.)

Oxygen and glucose are required by brain cells for normal functioning, and these nutrients must be constantly supplied by cerebral blood flow (CBF). Normally, CBF is constant over a wide range of blood pressures (i.e., blood pressure autoregulation of CBF) via actions mainly within the cerebral arterioles. Cerebral arterioles are maximally dilated at lower blood pressures and maximally constricted at higher pressures so that CBF does not vary during normal fluctuations (Fig. 85.3). Above the upper limit of autoregulation, breakthrough dilation occurs, which if severe can produce hypertensive encephalopathy. Acid-base balance of the CSF, often reflected by acute changes in arterial partial pressure of carbon dioxide (Pa_{CO_2}), body/brain temperature, glucose utilization, blood viscosity, and other vasoactive mediators (i.e., adenosine, nitric oxide), can also affect the cerebral vasculature.

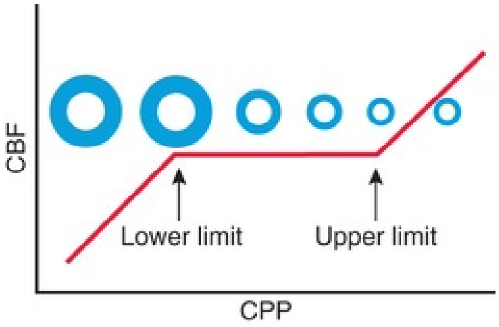

FIG. 85.3 **Schematic of the relationship between cerebral blood flow (CBF) and cerebral perfusion pressure (CPP). The diameter of a representative cerebral arteriole is also shown across the center of the *y* axis to facilitate understanding of the vascular response across CPP that underlies blood pressure autoregulation of CBF. CPP is generally defined as the mean arterial pressure (MAP) minus the intracranial pressure (ICP). At normal values for ICP, this generally represents MAP. Thus, normally, CBF is kept constant between the lower limit and upper limit of autoregulation; in normal adults, these values are approximately 50 mm Hg and 150 mm Hg, respectively. In children, the upper limit of autoregulation is likely proportionally lower than the adult value relative to normal MAP for age. However, according to the work of Vavilala et al. (2003) , lower-limit values are surprisingly similar in infants and older children. Thus, infants and young children may have less reserve for adequate CPP.**

Knowledge of these concepts is instrumental to preventing secondary brain injury. Increases in CSF pH that occur because of inadvertent hyperventilation (which decreases $\mathrm{Pa{CO}}_2$) can produce cerebral ischemia. Hyperthermia-mediated increases in cerebral metabolic demands may damage vulnerable brain regions after injury. Hypoglycemia can produce neuronal death when CBF fails to compensate. Prolonged seizures can lead to permanent injuries if hypoxemia occurs from loss of airway control.

Attention to detail and constant reassessment are paramount in managing children with critical neurologic insults. Among the most valuable tools for serial, objective assessment of neurologic condition is the **Glasgow Coma Scale (GCS)** (see Chapter 81 , Table 81.3). Originally developed for use in comatose adults, the GCS is also valuable in pediatrics. Modifications to the GCS have been made for nonverbal children and are available for infants and toddlers. Serial assessments of the GCS score along with a focused neurologic examination are invaluable to detection of injuries before permanent damage occurs in the vulnerable brain. The **full outline of unresponsiveness (FOUR)** score is a modification of the GCS, with eye and motor response, but eliminates the verbal response and adds 2 functional assessments of the brainstem (pupil, corneal, and cough reflexes) and respiratory patterns (Table 85.1).

Table 85.1

Commonly Used Coma Scores

POINTS	**DESCRIPTION**
GLASGOW COMA SCALE (GCS) SCORE	
Eye Opening	
1	Does not open eyes
2	Opens eyes in response to noxious stimuli
3	Opens eyes in response to voice
4	Opens eyes spontaneously
Verbal Output	
1	Makes no sounds
2	Makes incomprehensible sounds
3	Utters inappropriate words
4	Confused and disoriented
5	Speaks normally and oriented
Motor Response (Best)	
1	Makes no movements
2	Extension to painful stimuli
3	Abnormal flexion to painful stimuli
4	Flexion/withdrawal to painful stimuli
5	Localized to painful stimuli
6	Obeys commands
FULL OUTLINE OF UNRESPONSIVENESS (FOUR) SCORE	
Eye Response	
4	Eyelids open or opened, tracking, or blinking to command
3	Eyelids open but not tracking
2	Eyelids closed but open to loud voice
1	Eyelids closed but open to pain
0	Eyelids remain closed with pain
Motor Response	
4	Thumbs-up, fist, or “peace” sign
3	Localizing to pain
2	Flexion response to pain
1	Extension response to pain
0	No response to pain or generalized myoclonus status
Brainstem Reflexes	
4	Pupil and corneal reflexes present
3	One pupil wide and fixed
2	Pupil or corneal reflexes absent
1	Pupil and corneal reflexes absent
0	Absent pupil, corneal, and cough reflex
Respiration	
4	Not intubated, regular breathing pattern
3	Not intubated, Cheyne-Stokes breathing pattern
2	Not intubated, irregular breathing
1	Breathes above ventilatory rate
0	Breathes at ventilator rate or apnea

Adapted from Edlow JA, Rabinstein A, Traub SJ, Wijdicks EFM: Diagnosis of reversible causes of coma, *Lancet* 384:2064-2076, 2014.

The most studied monitoring device in clinical practice is the **ICP monitor** .

Monitoring is accomplished by inserting a catheter-transducer either into the cerebral ventricle or into brain parenchyma (i.e., externalized ventricular drain and parenchymal transducer, respectively). ICP-directed therapies are standard of care in traumatic brain injury (TBI) and are used in other conditions, such as intracranial hemorrhage, some cases of encephalopathy, meningitis, and encephalitis. Other devices being used include catheters that measure brain tissue oxygen concentration, external probes that noninvasively assess brain oxygenation by absorbance of near-infrared light (i.e., near-infrared spectroscopy), monitors of brain electrical activity (continuous electroencephalography [EEG] or somatosensory, visual, or auditory evoked potentials), and CBF monitors (transcranial Doppler, xenon CT, perfusion MRI, or tissue probes). In the severe TBI guidelines, brain tissue oxygen concentration monitoring received level III support and thus may be considered.

Traumatic Brain Injury

Etiology and Epidemiology

Mechanisms of TBI include motor vehicle crashes, falls, assaults, and abusive head trauma. Most TBIs in children are from closed-head injuries (Fig. 85.4). TBI is an important pediatric public health problem, with approximately 37,000 cases resulting in the death of >7,000 children annually in the United States.

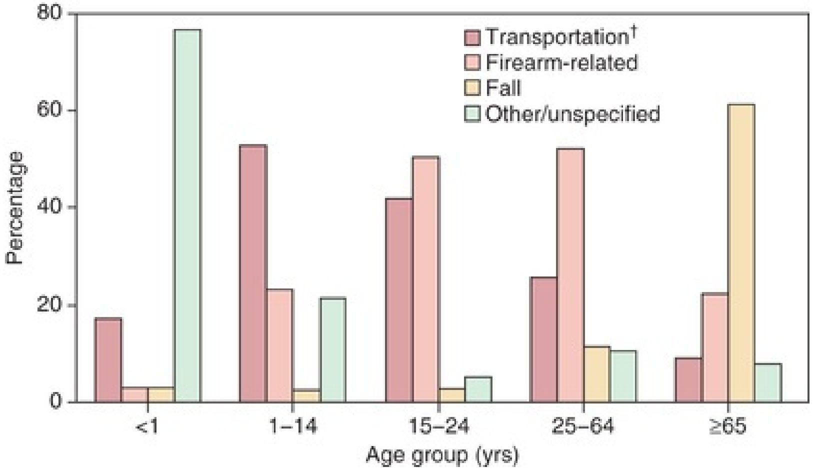

FIG. 85.4 Percentage of traumatic brain injury (TBI)–related deaths* by underlying cause and age group—United States, 2013. *TBI-related deaths were identified using the *International Classification of Diseases, Tenth Revision,* underlying cause of death codes of *U01–*U03, V01–Y36, Y85–Y87, or Y89 with a multiple cause of death code of

S01.0–S01.9, S02.0, S02.1, S02.3, S02.7–S02.9, S04.0, S06.0–S06.9, S07.0, S07.1, S07.8, S07.9, S09.7–S09.9, T01.0, T02.0, T04.0, T06.0, T90.1, T90.2, T90.4, T90.5, T90.8, or T90.9, for a total of 54,185 deaths in 2013 for all ages. † Transportation includes all modes, such as motor vehicle, motorcycle, pedal cycle, pedestrian, other land transport, railway, watercraft, and aircraft. The causes of injury that result in TBI-related deaths vary by age-group. In 2013, 77% of the TBI-related deaths among infants <1 yr old were from causes other than transportation, firearms, or falls and primarily resulted from assault and maltreatment. Transportation accounted for 53% of the TBI-related deaths among children 1-14 yr. Firearm-related injuries accounted for 50% and 52% of the TBI-related deaths for persons 15-24 and 25-64 yr, respectively. Most of the firearm-related TBI deaths in these 2 age-groups were suicides (62% and 83%, respectively). The majority (61%) of TBI-related deaths for those aged ≥65 yr resulted from falls. (From National Vital Statistics System mortality data. http://www.cdc.gov/nchs/deaths.htm . Additional information on TBI available at http://www.cdc.gov/traumaticbraininjury/ . The Lancet: The burden of traumatic brain injury in children, *Lancet* 391:813, 2018.)

Pathology

Epidural, subdural, and parenchymal intracranial hemorrhages can result. Injury to gray or white matter is also commonly seen and includes focal cerebral contusions, diffuse cerebral swelling, axonal injury, and injury to the cerebellum or brainstem. Patients with severe TBI often have multiple findings; diffuse and potentially delayed cerebral swelling is common.

Pathogenesis

TBI results in primary and secondary injury. Primary injury from the impact produces irreversible tissue disruption. In contrast, 2 types of secondary injury are targets of neurointensive care. First, some of the ultimate damage seen in the injured brain evolves over hours or days, and the underlying mechanisms involved (e.g., edema, apoptosis, secondary axotomy) are therapeutic targets. Second, the injured brain is vulnerable to additional insults because injury disrupts normal autoregulatory defense mechanisms; disruption of autoregulation of CBF can lead to ischemia from hypotension that would otherwise be tolerated by the uninjured brain.

Clinical Manifestations

The hallmark of **severe TBI** is coma (**GCS score 3-8**). Often, coma is seen immediately after the injury and is sustained. In some cases, such as with an epidural hematoma, a child may be alert on presentation but may deteriorate after a period of hours. A similar picture can be seen in children with diffuse swelling, in whom a “talk-and-die” scenario has been described. Clinicians should also not be lulled into underappreciating the potential for deterioration of a child with **moderate TBI** (**GCS score 9-12**) with a significant contusion, because progressive swelling can potentially lead to devastating complications. In the comatose child with severe TBI, the second key clinical manifestation is the development of *intracranial hypertension* . The development of increased ICP with impending herniation may be heralded by new-onset or worsening headache, depressed level of consciousness, vital sign changes (hypertension, bradycardia, irregular respirations), and signs of 6th (lateral rectus palsy) or 3rd (anisocoria [dilated pupil], ptosis, down-and-out position of globe as a result of rectus muscle palsies) cranial nerve compression. Increased ICP is managed with continuous ICP monitoring, as well as monitoring for clinical signs of increased ICP or impending herniation. The development of brain swelling is progressive. Significantly raised ICP (>20 mm Hg) can occur early after severe TBI, but peak ICP generally is seen at 48-72 hr. Need for ICP-directed therapy may persist for longer than a week. A few children have coma without increased ICP, resulting from axonal injury or brainstem injury. *In addition to head trauma, it is critical to identify potential cervical spine injury* (see Chapter 83).

Laboratory Findings

Cranial CT should be obtained immediately after resuscitation and cardiopulmonary stabilization (Figs. 85.5 to 85.11). In some cases, MRI can be diagnostic (Fig. 85.12). Generally, other laboratory findings are normal in isolated TBI, although occasionally coagulopathy or the development of the syndrome of inappropriate antidiuretic hormone (SIADH) secretion or, rarely, cerebral salt wasting (CSW) is seen. In the setting of TBI with polytrauma, other injuries can result in laboratory and radiographic abnormalities, and a **full trauma survey** is important in all patients with severe TBI (see Chapter 82).

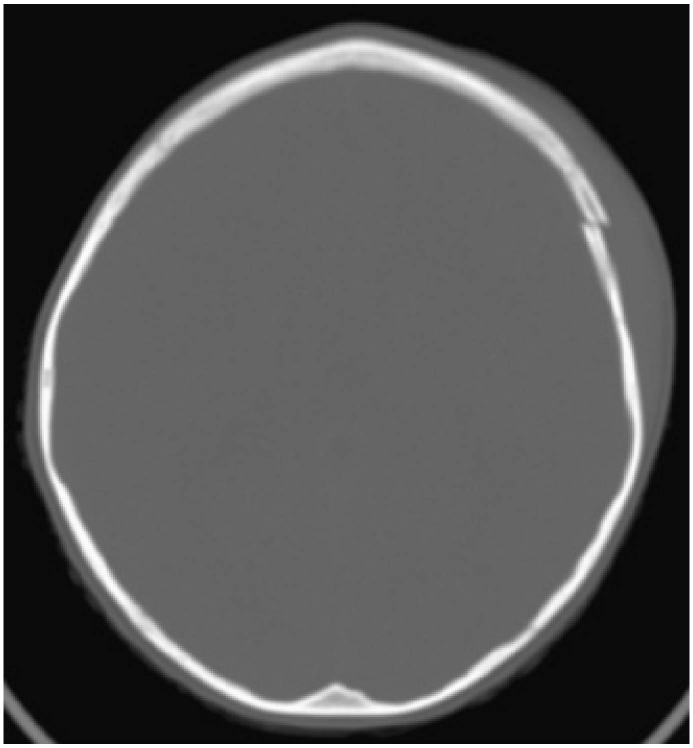

FIG. 85.5 Skull fracture. Mildly displaced skull fracture seen on CT imaging (bone window view) in a 4 yr old child who fell and hit her head on a curb.

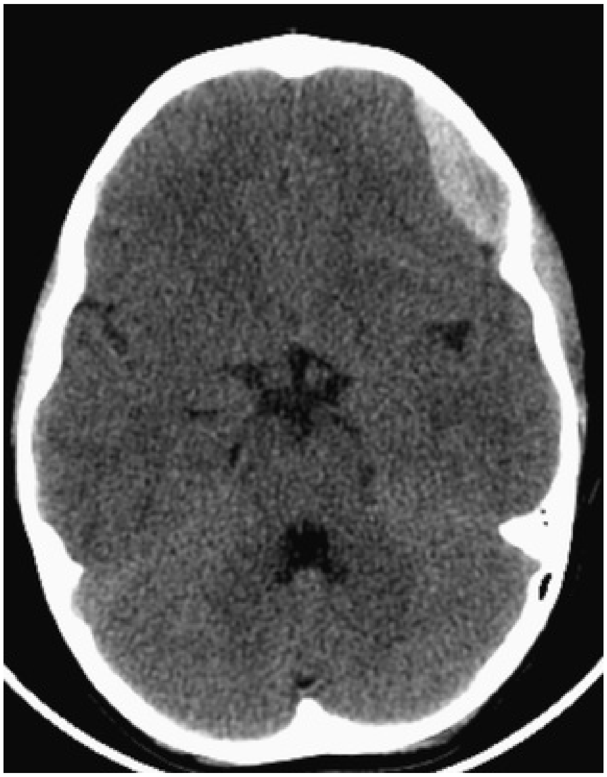

FIG. 85.6 Epidural hematoma. Left frontal epidural hematoma observed on CT imaging in a 12 yr old child who fell off his bike onto concrete surface.

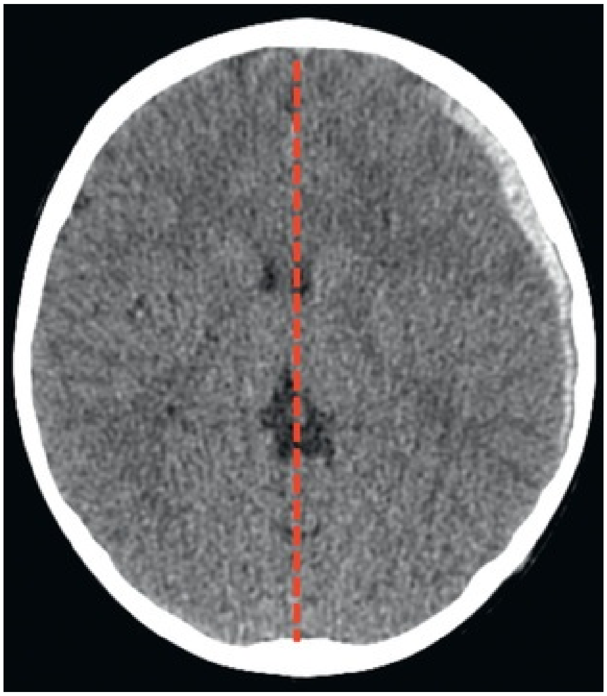

FIG. 85.7 Subdural hematoma. Left subdural hematoma observed on CT imaging in a 10 yr old child after motor vehicle crash. Note effacement of the left lateral ventricle and midline shift (see *dotted line* for midline reference).

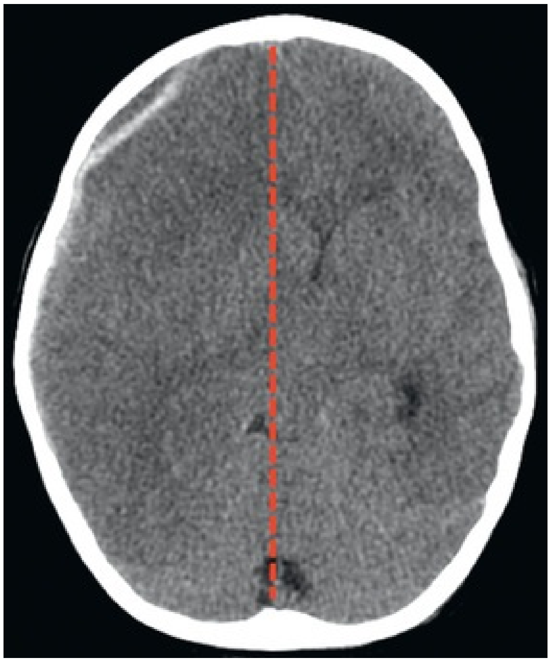

FIG. 85.8 Subdural hematoma. Hyperacute right frontal subdural hematoma observed on CT imaging in a 5 yr old child after motor vehicle crash. Note that the hyperacute aspect of the subdural hematoma is dark on CT imaging in the early stage after injury. Also, there is marked midline shift of intracranial contents, with both lateral ventricles displaced into the left side of the skull (*dotted line* for midline reference).

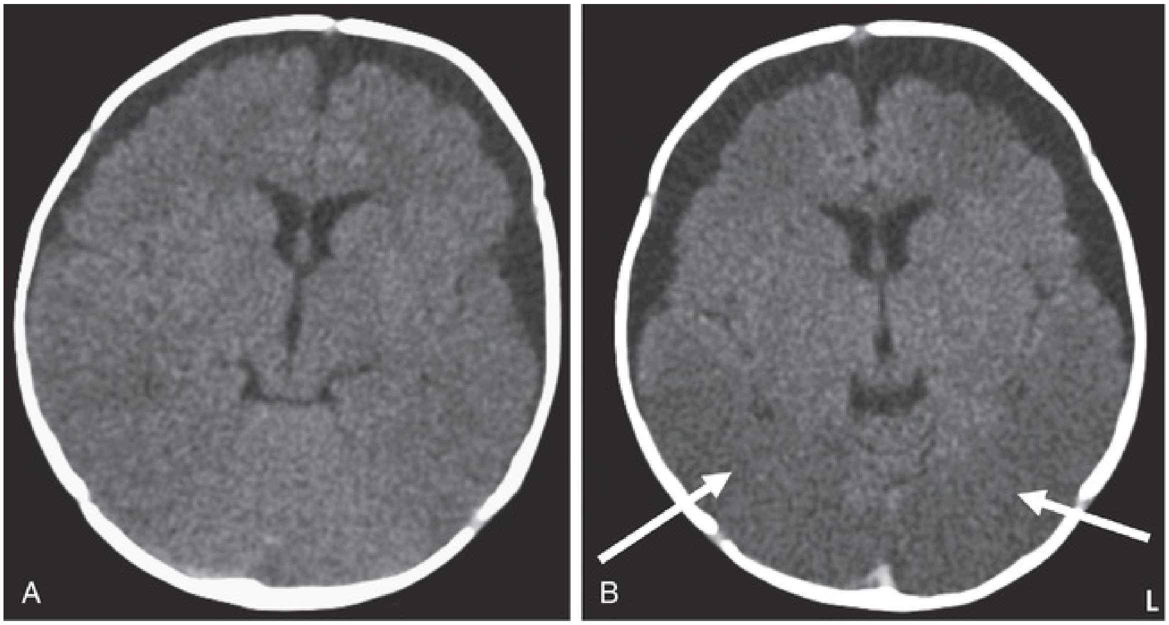

FIG. 85.9 Subdural hematoma. A, In a 3 mo old child who suffered from abusive head trauma, initial CT imaging demonstrates chronic subdural hematoma bilaterally. B, Three days after hospitalization, the subdural hematomas are slightly larger, but infarctions are noted in the posterior areas of brain parenchyma (*arrows*).

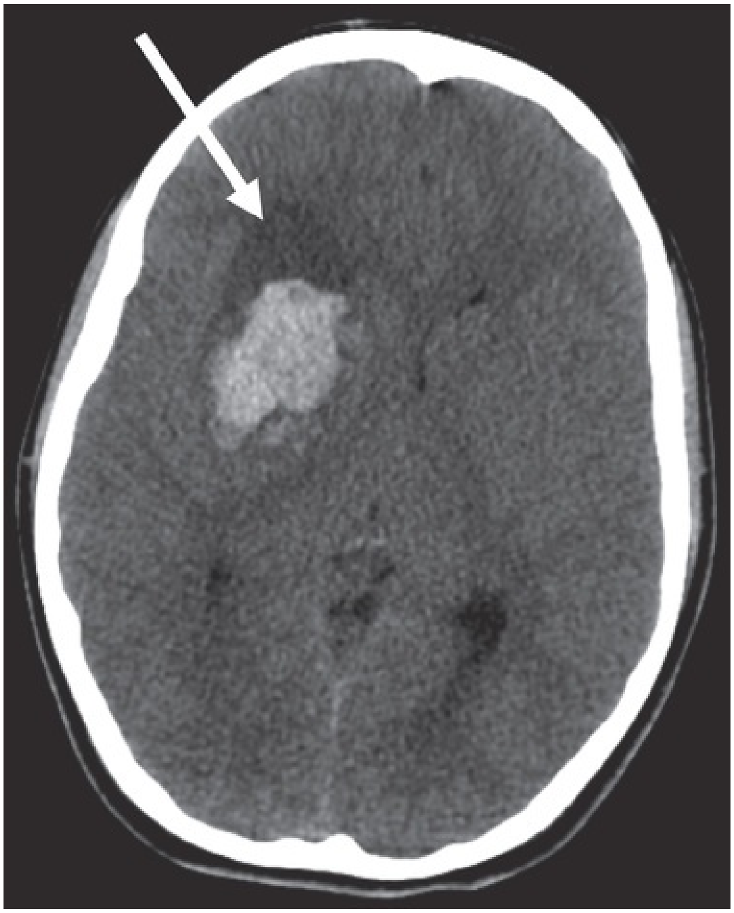

FIG. 85.10 Hemorrhage and edema. In a 16 yr old child who fell from his dirt bike, CT imaging demonstrates intraparenchymal hemorrhage and significant surrounding edema (*arrow*).

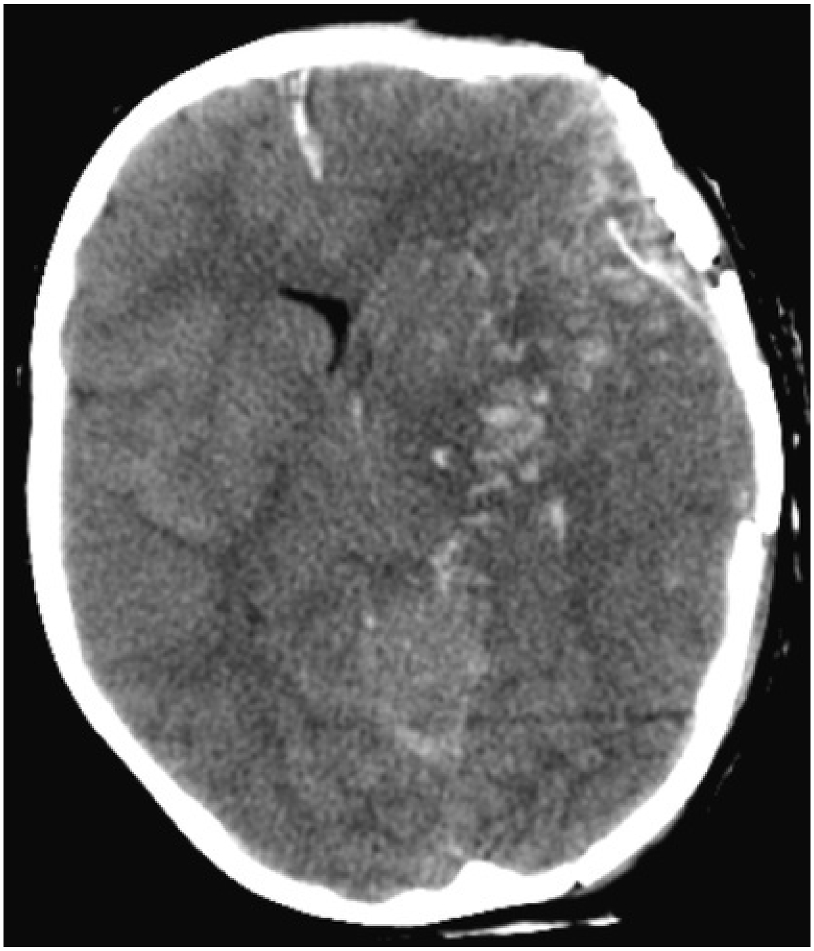

FIG. 85.11 Skull fractures and hemorrhage. An 11 yr old child was hit in the head by a horse, and CT imaging demonstrates multiple, comminuted skull fractures with fragments of bone within the brain parenchyma, multifocal areas of intraparenchymal hemorrhage, and obliteration of the left lateral ventricle.

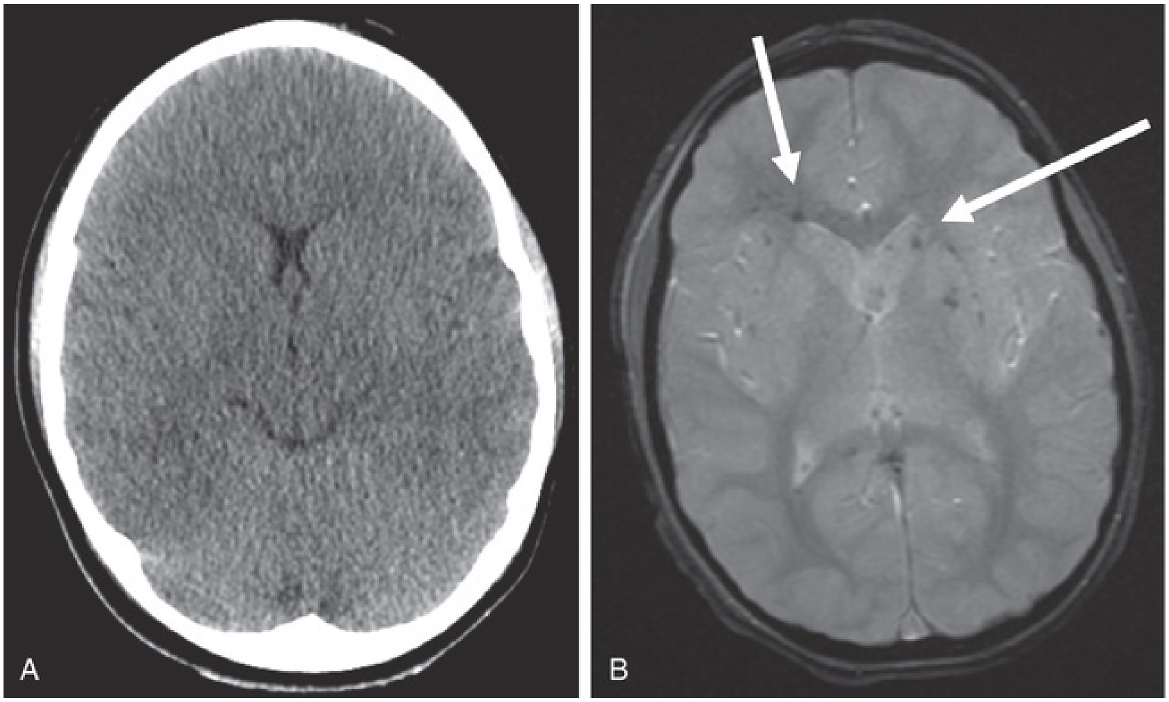

FIG. 85.12 Hemorrhages and axonal injury. A, In a 6 yr old child who was hit by a car while riding his bike, initial CT imaging demonstrated no obvious abnormality. B, However, immediate MRI demonstrates multiple areas of punctate hemorrhages (lucencies) consistent with diffuse axonal injury (*arrows*).

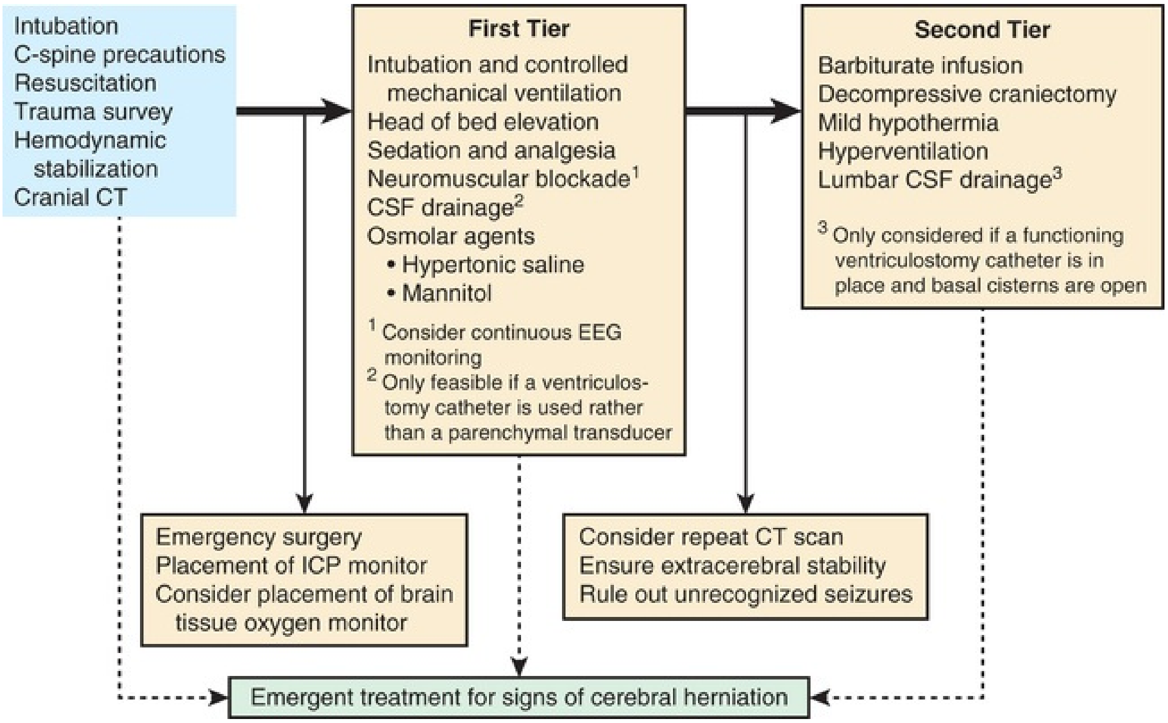
Diagnosis and Differential Diagnosis

In severe TBI the diagnosis is generally obvious from the history and clinical presentation. Occasionally, TBI severity can be overestimated because of concurrent alcohol or drug intoxication. The diagnosis of TBI can be problematic in cases of **abusive head trauma** or following an anoxic event such as drowning or smoke inhalation.

Treatment

Infants and children with severe or moderate TBI (GCS score 3-8 or 9-12, respectively) receive intensive care unit (ICU) monitoring. Evidence-based guidelines for management of severe TBI have been published (Fig. 85.13). This approach to ICP-directed therapy is also reasonable for other conditions in which ICP is monitored. Care involves a multidisciplinary team comprising pediatric caregivers from neurologic surgery, critical care medicine, surgery, and rehabilitation and is directed at preventing secondary insults and managing increased ICP. Initial stabilization of infants and children with severe TBI includes rapid sequence tracheal intubation with spine precautions along with maintenance of normal extracerebral hemodynamics, including blood gas values (PaO_2, $PaCO_2$), MAP, and temperature. Intravenous (IV) fluid boluses may be required to treat hypotension. Euvolemia is the target, and hypotonic fluids must be rigorously avoided; *normal saline is the fluid of choice* . Vasopressors may be needed as guided by monitoring of central venous pressure, with avoidance of both fluid overload and exacerbation of brain edema. A trauma survey should be performed. Once stabilized, the patient should be taken for CT scanning to rule out the need for emergency neurosurgical intervention. If surgery is not required, an ICP monitor should be inserted to guide the treatment of intracranial hypertension.



Intubation
C-spine precautions
Resuscitation
Trauma survey
Hemodynamic stabilization
Cranial CT
First Tier
Intubation and controlled mechanical ventilation
Head of bed elevation
Sedation and analgesia
Neuromuscular blockade[1]
CSF drainage[2]
Osmolar agents
• Hypertonic saline
• Mannitol
[1] Consider continuous EEG monitoring
[2] Only feasible if a ventriculostomy catheter is used rather than a parenchymal transducer
Second Tier
Barbiturate infusion
Decompressive craniectomy
Mild hypothermia
Hyperventilation
Lumbar CSF drainage[3]
[3] Only considered if a functioning ventriculostomy catheter is in place and basal cisterns are open
Emergency surgery
Placement of ICP monitor
Consider placement of brain tissue oxygen monitor
Consider repeat CT scan
Ensure extracerebral stability
Rule out unrecognized seizures
Emergent treatment for signs of cerebral herniation

FIG. 85.13 Schematic outlining the approach to management of a child with severe traumatic brain injury (TBI). This schematic is specifically presented for severe TBI, for which the experience with intracranial pressure (ICP)–directed therapy is greatest. Nevertheless, the general approach provided here is relevant to the management of intracranial hypertension in other conditions for which evidence-based data on ICP monitoring and ICP-directed therapy are lacking. The ICP and CPP targets are discussed in the text. (Based on 2012 guidelines for the management of severe TBI, along with minor modifications from later literature.)

During stabilization or at any time during the treatment course, patients can present with signs and symptoms of *cerebral herniation* (pupillary dilation, systemic hypertension, bradycardia, extensor posturing). Because herniation and its devastating consequences can sometimes be reversed if promptly addressed, it should be treated as a *medical emergency* , with use of hyperventilation, with a fraction of inspired oxygen of 1.0, and intubating doses of either thiopental or pentobarbital and either mannitol (0.25-1.0 g/kg IV) or hypertonic saline (3% solution, 5-10 mL/kg IV).

Intracranial pressure should be maintained at <20 mm Hg . Age-dependent cerebral perfusion pressure targets are approximately 50 mm Hg for children 2-6 yr old; 55 mm Hg for those 7-10 yr old; and 65 mm Hg for those 11-16 yr old. **First-tier** therapy includes elevation of the head of the bed, ensuring midline positioning of the head, controlled mechanical ventilation, and analgesia and sedation (i.e., narcotics and benzodiazepines). If neuromuscular blockade is needed, it may be desirable to monitor EEG continuously because status epilepticus can occur; this complication will not be recognized in a paralyzed patient and is associated with increased ICP and unfavorable outcome. If a ventricular rather than parenchymal catheter is used to monitor ICP, therapeutic CSF drainage is available and can be provided either continuously (often targeting an ICP >5 mm Hg) or intermittently in response to ICP spikes, generally >20 mm Hg. Other first-tier therapies include the osmolar agents **hypertonic saline** (often given as a continuous infusion of 3% saline at 0.1-1.0 mL/kg/hr) and **mannitol** (0.25-1.0 g/kg IV over 20 min), given in response to ICP spikes >20 mm Hg or with a fixed (every 4-6 hr) dosing interval. Use of hypertonic saline is more common and has stronger literature support than mannitol, although both are used; these 2 agents can be used concurrently. It is recommended to avoid serum osmolality >320 mOsm/L. A Foley urinary catheter should be placed to monitor urine output.

If increased ICP remains refractory to treatment, careful reassessment of the patient is needed to rule out unrecognized hypercarbia, hypoxemia, fever, hypotension, hypoglycemia, pain, and seizures. Repeat imaging should be considered to rule out a surgical lesion. Guidelines-based **second-tier** therapies for refractory raised ICP are available, but evidence favoring a given second-tier therapy is limited. In some centers, surgical decompressive **craniectomy** is used for refractory traumatic intracranial hypertension. Others use a **pentobarbital infusion** , with a loading dose of 5-10 mg/kg over 30 min followed by 5 mg/kg every hour for 3 doses and then maintenance with an infusion of 1 mg/kg/hr. Careful blood pressure monitoring is required because of the possibility of drug-induced hypotension and the frequent need for support with fluids and pressors.

Mild hypothermia (32-34°C [89.6-93.2°F]) in an attempt to control refractory ICP may be induced and maintained by means of surface cooling. Hypothermia for increased ICP after traumatic brain injury remains controversial for pediatric and adult patients. **Hyperthermia** *must* be avoided and if present should be treated aggressively. Sedation and neuromuscular blockade are used to prevent shivering, and rewarming should be slow, no faster than 1°C (1.8°F) every 4-6 hr. Hypotension should be prevented during rewarming. Refractory raised ICP can also be treated with hyperventilation ($\mathrm{Pa{\scriptstyle CO}}_2$ 25-30 mm Hg). Combinations of these second-tier therapies are often required.

Supportive Care

Euvolemia should be maintained, and isotonic fluids are recommended throughout the ICU stay. SIADH and CSW can develop and are important to differentiate, because management of SIADH is fluid restriction and that of CSW is sodium replacement. Severe hyperglycemia (blood glucose level >200 mg/dL) should be avoided and treated. The blood glucose level should be monitored frequently. Early nutrition with enteral feedings is advocated. Corticosteroids should generally not be used unless adrenal insufficiency is documented. Tracheal suctioning can exacerbate raised ICP. Timing of the use of analgesics or sedatives around suctioning events and use of tracheal or IV lidocaine can be helpful. Seizures are common after severe acute TBI. Early posttraumatic seizures (within 1 wk) will complicate management of TBI and are often difficult to treat. Anticonvulsant prophylaxis with fosphenytoin, carbamazepine, or levetiracetam is a common treatment option. Late posttraumatic seizures (≥7 days after TBI) and, if recurrent, late posttraumatic epilepsy are *not* prevented by prophylactic anticonvulsants, whereas early posttraumatic seizures are prevented by initiating anticonvulsants soon after TBI. Antifibrinolytic agents (tranexamic acid) reduce hemorrhage size, as well as the development of new focal ischemic cerebral lesions, and improve survival in adults with severe TBI.

Prognosis

Mortality rates for children with severe TBI who reach the pediatric ICU range between 10% and 30%. Ability to control ICP is related to patient survival, and the extent of cranial and systemic injuries correlates with quality of life. Motor and cognitive sequelae resulting from severe TBI generally benefit from rehabilitation to minimize long-term disabilities. Recovery from TBI may take months to achieve. Physical therapy, and in some centers methylphenidate or amantadine, helps with motor and behavioral recovery. Pituitary insufficiency may be an uncommon but significant complication of severe TBI.

CHAPTER 86

Brain Death

K. Jane Lee, Binod Balakrishnan

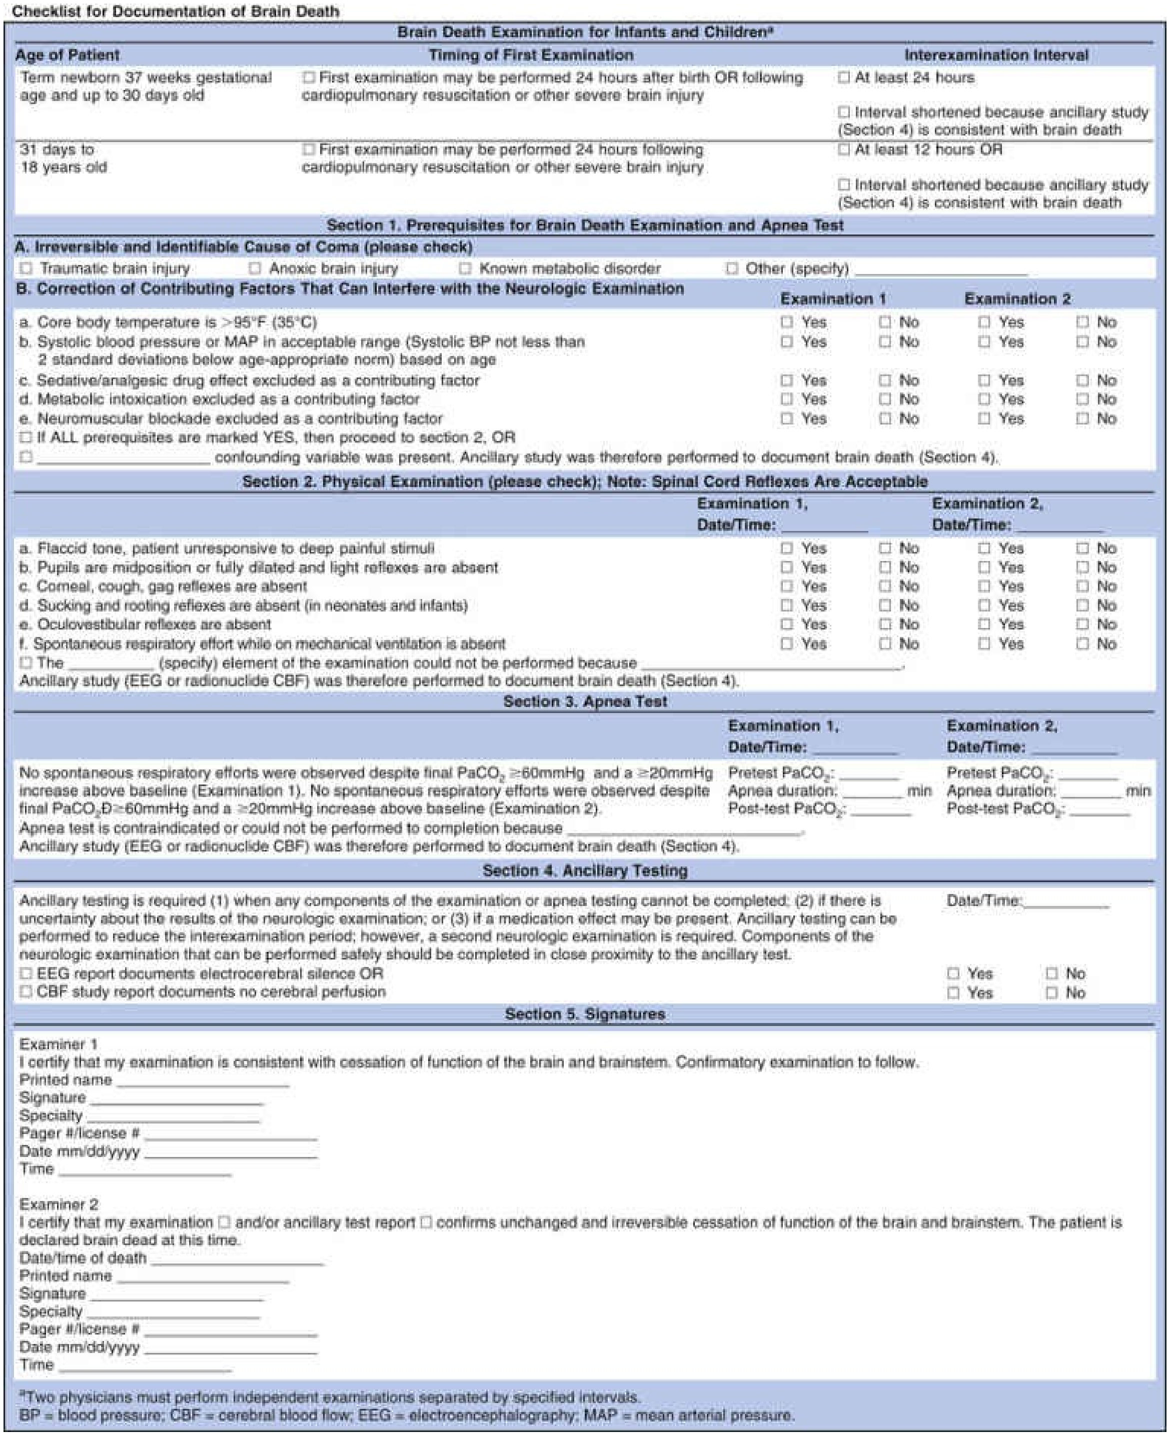
Brain death is the irreversible cessation of all functions of the entire brain, including the brainstem. It is also known as **death by neurologic criteria** and is legally accepted as death in the United States.

Epidemiology

In children, brain death usually develops after traumatic brain injury (TBI, including brain injury from nonaccidental trauma) or asphyxial injury. Pathogenesis is multifactorial, with the end result being irreversible loss of brain and brainstem function.

Clinical Manifestations and Diagnosis

Current guidelines do not apply to preterm infants <37 wk gestational age (Fig. 86.1).



Checklist for Documentation of Brain Death

Brain Death Examination for Infants and Children[a]

Age of Patient	Timing of First Examination	Interexamination Interval
Term newborn 37 weeks gestational age and up to 30 days old	☐ First examination may be performed 24 hours after birth OR following cardiopulmonary resuscitation or other severe brain injury	☐ At least 24 hours ☐ Interval shortened because ancillary study (Section 4) is consistent with brain death
31 days to 18 years old	☐ First examination may be performed 24 hours following cardiopulmonary resuscitation or other severe brain injury	☐ At least 12 hours OR ☐ Interval shortened because ancillary study (Section 4) is consistent with brain death

Section 1. Prerequisites for Brain Death Examination and Apnea Test

A. Irreversible and Identifiable Cause of Coma (please check)

☐ Traumatic brain injury ☐ Anoxic brain injury ☐ Known metabolic disorder ☐ Other (specify) ______________

B. Correction of Contributing Factors That Can Interfere with the Neurologic Examination	Examination 1		Examination 2	
a. Core body temperature is >95°F (35°C)	☐ Yes	☐ No	☐ Yes	☐ No
b. Systolic blood pressure or MAP in acceptable range (Systolic BP not less than 2 standard deviations below age-appropriate norm) based on age	☐ Yes	☐ No	☐ Yes	☐ No
c. Sedative/analgesic drug effect excluded as a contributing factor	☐ Yes	☐ No	☐ Yes	☐ No
d. Metabolic intoxication excluded as a contributing factor	☐ Yes	☐ No	☐ Yes	☐ No
e. Neuromuscular blockade excluded as a contributing factor	☐ Yes	☐ No	☐ Yes	☐ No

☐ If ALL prerequisites are marked YES, then proceed to section 2, OR

☐ ______________ confounding variable was present. Ancillary study was therefore performed to document brain death (Section 4).

Section 2. Physical Examination (please check); Note: Spinal Cord Reflexes Are Acceptable

	Examination 1, Date/Time: ________		Examination 2, Date/Time: ________	
a. Flaccid tone, patient unresponsive to deep painful stimuli	☐ Yes	☐ No	☐ Yes	☐ No
b. Pupils are midposition or fully dilated and light reflexes are absent	☐ Yes	☐ No	☐ Yes	☐ No
c. Corneal, cough, gag reflexes are absent	☐ Yes	☐ No	☐ Yes	☐ No
d. Sucking and rooting reflexes are absent (in neonates and infants)	☐ Yes	☐ No	☐ Yes	☐ No
e. Oculovestibular reflexes are absent	☐ Yes	☐ No	☐ Yes	☐ No
f. Spontaneous respiratory effort while on mechanical ventilation is absent	☐ Yes	☐ No	☐ Yes	☐ No

☐ The ________ (specify) element of the examination could not be performed because ____________________.
Ancillary study (EEG or radionuclide CBF) was therefore performed to document brain death (Section 4).

Section 3. Apnea Test

	Examination 1, Date/Time: ________	Examination 2, Date/Time: ________
No spontaneous respiratory efforts were observed despite final $PaCO_2 \geq 60$mmHg and a ≥20mmHg increase above baseline (Examination 1). No spontaneous respiratory efforts were observed despite final $PaCO_2$Đ≥60mmHg and a ≥20mmHg increase above baseline (Examination 2).	Pretest $PaCO_2$: ______ Apnea duration: ______ min Post-test $PaCO_2$: ______	Pretest $PaCO_2$: ______ Apnea duration: ______ min Post-test $PaCO_2$: ______

Apnea test is contraindicated or could not be performed to completion because ____________________.
Ancillary study (EEG or radionuclide CBF) was therefore performed to document brain death (Section 4).

Section 4. Ancillary Testing

Ancillary testing is required (1) when any components of the examination or apnea testing cannot be completed; (2) if there is uncertainty about the results of the neurologic examination; or (3) if a medication effect may be present. Ancillary testing can be performed to reduce the interexamination period; however, a second neurologic examination is required. Components of the neurologic examination that can be performed safely should be completed in close proximity to the ancillary test.

Date/Time:________

☐ EEG report documents electrocerebral silence OR	☐ Yes	☐ No
☐ CBF study report documents no cerebral perfusion	☐ Yes	☐ No

Section 5. Signatures

Examiner 1
I certify that my examination is consistent with cessation of function of the brain and brainstem. Confirmatory examination to follow.
Printed name ______________
Signature ______________
Specialty ______________
Pager #/license # ______________
Date mm/dd/yyyy ______________
Time ______________

Examiner 2
I certify that my examination ☐ and/or ancillary test report ☐ confirms unchanged and irreversible cessation of function of the brain and brainstem. The patient is declared brain dead at this time.
Date/time of death ______________
Printed name ______________
Signature ______________
Specialty ______________
Pager #/license # ______________
Date mm/dd/yyyy ______________
Time ______________

[a] Two physicians must perform independent examinations separated by specified intervals.
BP = blood pressure; CBF = cerebral blood flow; EEG = electroencephalography; MAP = mean arterial pressure.

FIG. 86.1 Checklist for documentation of brain death. (From Nakagawa TA, Ashwal S, Mathur M, et al. Guidelines for the determination of brain death in infants and children: an update of the 1987 Task Force recommendations—executive summary, Ann Neurol 71:573–585, 2012, Table 2.).

Brain death is determined by clinical assessment. Although ancillary tests such as electroencephalography (EEG) and cerebral blood flow (CBF) studies are sometimes used to assist in making the diagnosis, repeated clinical examination is the standard for diagnosis. The 3 components for determining brain death are demonstration of coexisting **irreversible coma with a known cause** , **absence of brainstem reflexes** , and **apnea** .

Before a determination of brain death may be made, it is of utmost importance that the cause of the coma be determined using the history, any radiology, and laboratory data, to rule out a reversible condition. *Potentially reversible causes of coma* include metabolic disorders, toxins, sedative drugs, paralytic agents, hypothermia, hypoxia, hypotension/shock, recent cardiopulmonary resuscitation (CPR), hypo-/hyperglycemia, hypo-/hypernatremia, hypercalcemia, hypermagnesemia, nonconvulsive status epilepticus, hypothyroidism, hypocortisolism, hypercarbia, liver or renal failure, sepsis, meningitis, encephalitis, subarachnoid hemorrhage, and surgically remediable brainstem lesions. Confounding factors must be corrected before initiation of brain death assessment.

Coma

The state of coma requires that the patient be unresponsive, even to noxious stimuli. Any purposeful motor response, such as localization, does not constitute coma. Likewise, any posturing (decerebrate or decorticate) is not consistent with coma, and therefore not consistent with brain death. The presence of spinal cord reflexes—even complex reflexes—does not preclude the diagnosis of brain death.

Brainstem Reflexes

Brainstem reflexes must be absent. Table 86.1 lists the brainstem reflexes to be tested, the brainstem location of each reflex, and the result of each test that is consistent with a diagnosis of brain death.

Table 86.1

Brainstem Reflex Testing to Determine Brain Death

BRAINSTEM REFLEX	AREA TESTED	HOW TO PERFORM EXAM	EXPLANATION OF RESULTS
Pupillary light	Cranial	Shine a light into the eyes	Midposition (4-6 mm) or fully dilated pupils

reflex	nerves (CNs) II and III, midbrain	while closely observing pupillary size.	that are not reactive to light are consistent with brain death. Pinpoint pupils, even if nonreactive, suggest intact function of the Edinger-Westphal nucleus in the midbrain and are therefore *not* consistent with brain death.
Oculocephalic reflex (doll's eyes reflex)	CNs III, VI, and VIII; midbrain; pons	Manually rotate the patient's head side to side and closely watch the position of the eyes. Should not be performed in a patient with a cervical spine injury.	In the intact patient, the eyes remain fixed on a distant spot, as if maintaining eye contact with that spot. In an exam consistent with brain death, the eyes move in concert with the patient's head movement.
Corneal reflex	CNs III, V, and VII; pons	Touch the patient's cornea with a cotton swab.	In the intact patient, the touch results in eyelid closure, and the eye may rotate upward. In an exam consistent with brain death, there is no response.
Oculovestibular reflex	CNs III, IV, VI, and VIII; pons; midbrain	Irrigate the tympanic membrane with iced water or saline and look for eye movement.	Absence of eye movement is consistent with brain death.
Gag and cough reflex	CNs IX and X, medulla	Touch the posterior pharynx with a tongue depressor or a cotton-tipped swab to stimulate a gag. Advance a suction catheter through the endotracheal tube to the carina to stimulate a cough.	Absence of both a cough and a gag is consistent with brain death.

Apnea

Apnea is the absence of respiratory effort in response to an adequate stimulus. An arterial partial pressure of carbon dioxide (Pa_{CO_2}) value ≥60 mm Hg *and* >20 mm Hg above baseline is a sufficient stimulus. Apnea is clinically confirmed through the apnea test. Because the apnea test has the potential to destabilize the patient, it is performed only if the 1st 2 criteria for brain death (irreversible coma and absence of brainstem reflexes) are already confirmed.

The **apnea test** assesses the function of the medulla in driving ventilation. It is performed by first ensuring appropriate hemodynamics and temperature (>35°C) and the absence of apnea-producing drug effects or significant metabolic derangements. The patient is then preoxygenated with 100% oxygen for approximately 10 min, and ventilation is adjusted to achieve a Pa_{CO_2} of approximately 40 mm Hg. A baseline arterial blood gas (ABG) result documents the starting values. During the test, oxygenation can be maintained with 100% oxygen via a T -piece attached to the endotracheal tube or via a resuscitation bag such as a Mapleson device. Throughout the test, the child's hemodynamics and pulse oximetry oxygen-hemoglobin saturation (Spo_2) are monitored while the physician observes for respiratory efforts. An ABG sample is obtained approximately 10 min into the test and every 5 min thereafter until the target $Paco_2$ is surpassed; ventilatory support is resumed at that time. If at any point during the test the patient becomes hypoxic (Spo_2 <85%) or hypotensive, the tes is aborted and ventilatory support resumed. Absence of respiratory efforts with a $Paco_2$ ≥60 mm Hg and >20 mm Hg above baseline is consistent with brain death.

Observation Periods

To determine brain death in the United States, the findings must remain consistent for 2 examinations performed by different attending physicians (apnea testing may be performed by the same physician) separated by an observation period. The 1st exam determines that the child has met the criteria for brain death, whereas the 2nd exam confirms brain death based on an unchanged and irreversible condition. Recommended observation periods are 24 hr for neonates from 37 wk gestation to term infants 30 days old, and 12 hr for infants and children >30 days old. An observation period of 24-48 hr before initiation of brain death assessment is recommended after CPR or severe acute brain injury.

Ancillary Studies

Ancillary studies are not required for the diagnosis of brain death unless the clinical examination including the apnea test cannot be safely or reliably completed. Examples include cervical spinal cord injury, presence of high therapeutic or supratherapeutic levels of sedative medications, or hemodynamic instability or Spo_2 desaturation during an apnea test. Ancillary studies may also be used to shorten the recommended observation period. In this case, 2 complete clinical examinations, including apnea test, should be carried out and documented along with the ancillary study. Ancillary studies are no substitute for the neurologic examination.

The 2 most widely used ancillary tests are EEG and radionuclide CBF studies. A valid **electroencephalogram** to support suspected brain death must be performed according to the American EEG Society standards and technical requirements, under conditions of normothermia and appropriate hemodynamics, and in the absence of drug levels sufficient to suppress the EEG response. An EEG that demonstrates **electrocerebral silence** over a 30 min recording time under these conditions supports the diagnosis of brain death. Advantages of this study are its wide availability and low risk. Disadvantages include potential confounders, such as artifact in the tracing and the presence of suppressing levels of drugs such as barbiturates.

A **radionuclide cerebral blood flow study** consists of intravenous (IV) injection of a radiopharmaceutical agent followed by imaging of the brain to look for cerebral uptake. As with EEG, nuclear medicine scans are widely available and low risk. Unlike EEG, radionuclide CBF studies are not affected by drug levels. A study that shows absence of uptake in the brain demonstrates absence of CBF and is supportive of brain death. Four-vessel intracranial contrast angiography was previously used as the definitive ancillary test, but practical technical difficulties and risks have led to the use of nuclear medicine scans instead.

Interpretation of both EEG and radionuclide CBF studies should be done by appropriately trained and qualified individuals. If the studies show electrical activity or presence of CBF, brain death cannot be declared. A 24 hr waiting period is recommended before repeating the clinical examination or ancillary study.

Documentation

Documentation is an important aspect of diagnosing brain death. Complete documentation should include statements of the following:

1. Etiology and irreversibility of the coma.
2. Absence of confounding factors: hypothermia, hypotension, hypoxia, significant metabolic derangement, and significant drug levels.
3. Absence of motor response to noxious stimulation.
4. Absence of brainstem reflexes: pupillary light reflex, oculocephalic/oculovestibular reflex, corneal reflex, cough reflex, and

gag reflex.

5. Absence of respiratory effort in response to an adequate stimulus; ABG values should be documented at the start and end of the apnea test.

Supportive Care

Following a diagnosis of brain death, supportive care may continue for hours to days as the family makes decisions about potential organ donation and comes to terms with the diagnosis. A diagnosis of brain death may not be accepted by the family for personal, religious, or cultural reasons. It is important for care providers to be patient and supportive of the family dealing with this difficult situation.

Objections to the Idea of Brain Death

Although the concept of brain death is widely accepted and very useful in facilitating organ transplantation, it is not accepted by all. Several countries do not recognize brain death, and some individuals, both medical personnel and laypeople, object to the idea of brain death.

It has been pointed out that some patients who meet brain death criteria continue to show evidence of *integrative functioning,* such as control over free-water homeostasis (absence of diabetes insipidus), control of temperature regulation, capacity for growth and wound healing, and variability of heart rate and blood pressure in response to stimulus. Along with scientific arguments, there are also philosophical arguments about what constitutes death and whether a person who lacks function of the brain, but not of the body, is truly dead.

CHAPTER 87

Syncope

Aarti S. Dalal, George F. Van Hare

Syncope is defined as a sudden transient loss of consciousness with inability to maintain postural tone. The most common cause of syncope in the normal pediatric population is **neurocardiogenic syncope** (vasovagal syncope, fainting). **Vasovagal syncope** is classically associated with a prodrome that includes diaphoresis, warmth, pallor, or feeling lightheaded and is often triggered by a specific event or situation such as pain, medical procedures, or emotional distress (Table 87.1). This type of syncope is characterized by hypotension and bradycardia. Approximately 30–50% of children will have had a **fainting** episode before 18 yr of age.

Table 87.1

Noncardiac Causes of Syncope

- Reflex vasodepressor syncope
    - Neurocardiogenic (vasovagal)
    - Emotion (seeing blood)
    - Pain (needle phobia)
- Miscellaneous situational reflex
    - Tussive
    - Sneeze
    - Exercise, after exercise
    - Swallowing
    - Stretching
    - Defecation
    - Micturition
    - Hair grooming

  - Valsalva (increased intrathoracic pressure)
  - Trumpet playing
  - Weightlifting
  - Breath-holding spells
- Systemic illness
  - Hypoglycemia
  - Anemia
  - Infection
  - Hypovolemia, dehydration
  - Adrenal insufficiency
  - Narcolepsy, cataplexy
  - Pulmonary embolism
  - Pheochromocytoma
  - Mastocytosis
  - Ruptured ectopic pregnancy
- Central nervous system
  - Seizure (atonic, absence, myoclonic-astatic)
  - Stroke, transient ischemic attack
  - Subarachnoid hemorrhage
- Dysautonomia
- Myotonic dystrophy
- Kearns-Sayre syndrome
- Friedreich ataxia
- Basilar artery migraine
- Drug effects
  - β-Blocking agents
  - Vasodilating agents
  - Opiates
  - Sedatives
  - Drugs prolonging QT interval
  - Diuretics
  - Anticonvulsant agents
  - Antihistamines
  - Antidepressant agents
  - Anxiolytic agents
  - Drugs of abuse
  - Insulin, oral hypoglycemic agents

    - Carbon monoxide
- Other etiologies
    - Carotid sinus sensitivity
    - Subclavian steal
    - Panic attack, anxiety
    - Conversion disorder

Most patients with a vasovagal syncope episode will have prodromal features followed by loss of motor tone. Once in a horizontal position, consciousness returns rapidly, in 1-2 min; some patients may have 30 sec of tonic-clonic motor activities, which should not be confused with a **seizure** (Table 87.2). Syncope must also be distinguished from **vertigo** and **ataxia** (Table 87.3).

Table 87.2

Comparison of Clinical Features of Syncope and Seizures

FEATURES	SYNCOPE	SEIZURES
Relation to posture	Common	No
Time of day	Diurnal	Diurnal or nocturnal
Precipitating factors	Emotion, injury, pain, crowds, heat, exercise, fear, dehydration, coughing, micturition	Sleep loss, drug/alcohol withdrawal
Skin color	Pallor	Cyanosis or normal
Diaphoresis	Common	Rare
Aura or premonitory symptoms	Long	Brief
Convulsion	Rare, brief	Common
Other abnormal movements	Minor twitching	Rhythmic jerks
Injury	Rare	Common (with convulsive seizures)
Urinary incontinence	Rare	Common
Tongue biting	No	Can occur with convulsive seizures
Postictal confusion	Rare	Common
Postictal headache	No	Common
Focal neurologic signs	No	Occasional
Cardiovascular signs	Common (cardiac syncope)	No
Abnormal findings on EEG	Rare (generalized slowing may occur during the event)	Common

From Bruni J: Episodic impairment of consciousness. In Daroff RB, Jankovic JM, Mazziotta JC, Pomeroy SL, editors: *Bradley's neurology in clinical practice,* ed 7, Philadelphia, 2016, Elsevier.

Table 87.3

Syncope and Dizziness

	VERTIGO	PRESYNCOPE	DISEQUILIBRIUM	LIGHTHEADEDNESS
Patient complaint	"My head is spinning." "The room is whirling."	"I feel I might pass out." "I feel faint." "I feel like blacking out."	"I feel unsteady." "My balance is off."	"I feel dizzy." "I feel disconnected, drugged."
Associated features	Motion, swaying, spinning, nystagmus	Syncope: loss of postural tone, brief loss of consciousness Situational	Poor balance No vertigo or ataxia	Anxiety, hyperventilation, paresthesias, respiratory alkalosis, panic attacks
Usual cause	Vestibular disorders	Impaired cerebral perfusion	Sensory and/or central neurologic dysfunction	Anxiety and/or depressive disorders
Key differential diagnoses	Peripheral (labyrinthine-cochlear) vs central neurologic disorder	Neurocardiogenic (vagal) vs cardiac syncope vs neuropsychiatric syncope	Sensory deficit vs central neurologic disease	Anxiety/depression vs hyperventilation vs medication effects

From Cohen G: Syncope and dizziness. In *Nelson pediatric symptom-based diagnosis,* Philadelphia, 2018, Elsevier (Table 6.1, p 84).

Although this type of syncope is very common in adolescence and has an excellent prognosis, other causes for loss of consciousness are more dangerous; thus syncope may be the first sign of more serious conditions (Table 87.4). Indeed, the occurrence of syncope may well be the pediatrician's best opportunity to diagnose a life-threatening condition before the patient subsequently succumbs. The task of the clinician, therefore, is not only to counsel the family and the patient concerning the common form, but also to rule out a number of important life-threatening cardiac problems.

Table 87.4

Life-Threatening Cardiac Causes as Risk With Syncope

- Long QT syndromes (congenital and drug induced)
- Short QT syndromes
- Cardiomyopathies
    - Hypertrophic cardiomyopathy
    - Dilated cardiomyopathy
    - Arrhythmogenic right ventricular dysplasia
- Brugada syndrome

Catecholaminergic polymorphic ventricular tachycardia
Myocarditis
Lyme myocarditis
Chagas disease
Wolff-Parkinson-White syndrome
Coronary artery anomalies
Late postoperative arrhythmias
Adult congenital heart patients
Congenital or acquired complete atrioventricular block
Aortic, mitral, or pulmonic valve stenosis
Primary pulmonary hypertension
Eisenmenger syndrome
Dissecting aortic aneurysm (Marfan syndrome)
Cardiac tumor
Pacemaker malfunction
Takotsubo cardiomyopathy

Mechanisms

Syncope by whatever mechanism is caused by a lack of adequate cerebral blood flow with loss of consciousness and inability to remain upright.

Primary **cardiac causes** of syncope (Table 87.4) include arrhythmias such as long QT syndrome (LQTS), Wolff-Parkinson-White syndrome (particularly with atrial fibrillation), ventricular tachycardia (VT), and occasionally supraventricular tachycardia (see Chapter 462). VT may be associated with hypertrophic cardiomyopathy (HCM), arrhythmogenic cardiomyopathy, repaired congenital heart disease, or a genetic cause such as catecholaminergic polymorphous ventricular tachycardia (CPVT). Other arrhythmias that may lead to syncope are bradyarrhythmias such as sinus node dysfunction and high-grade second- or third-degree atrioventricular (AV) block. Patients with congenital complete AV block may present with syncope. Syncope may also be caused by cardiac obstructive lesions, such as critical aortic stenosis, or coronary artery anomalies, such as an aberrant left coronary artery arising from the right sinus of Valsalva. Patients with primary pulmonary hypertension or Eisenmenger syndrome may experience syncope. In all the obstructive forms of syncope, exercise increases the likelihood of an episode because the obstruction interferes with the ability of the heart to increased cardiac output in response to exercise.

Noncardiac causes of loss of consciousness include epilepsy, as well as basilar artery migraine, hysterical syncope, and pseudoseizures (see Table 87.1). Occasionally, patients with narcolepsy may present with syncope. Hypoglycemia and hyperventilation may also present as syncope.

Evaluation

The most important goal in the evaluation of the new patient with syncope is to diagnose life-threatening causes of syncope so that these causes can be managed. Many patients presenting with sudden cardiac arrest caused by conditions such as LQTS will have previously experienced an episode of syncope, so the presentation with syncope is an opportunity to prevent sudden death.

The most important tool in evaluation is a careful **history** . The characteristics of cardiac syncope differ significantly from the prodrome seen in neurocardiogenic syncope (Table 87.5). Several red flags can be identified that should lead the clinician to suspect that the mechanism is a life-threatening cardiac cause rather than simple fainting (Table 87.6). The occurrence during exercise suggests an arrhythmia or coronary obstruction. Injury because of an episode of syncope indicates sudden occurrence with a lack of adequate prodromal symptoms and suggests an arrhythmia. The occurrence of syncope while recumbent would be quite unusual in a patient with neurocardiogenic syncope and therefore suggests a cardiac or neurologic cause. Occasionally, a patient with syncope caused by a tachyarrhythmia will report the sensation of a racing heart before the event, but this is unusual.

Table 87.5

Differentiating Features for Causes of Syncope

NEUROCARDIOGENIC
Symptoms after prolonged motionless standing, sudden unexpected pain, fear, or unpleasant sight, sound, or smell; pallor Syncope in a well-trained athlete *after* exertion (without heart disease) Situational syncope during or immediately after micturition, cough, swallowing, or defecation Syncope with throat or facial pain (glossopharyngeal or trigeminal neuralgia)
ORGANIC HEART DISEASE (PRIMARY ARRHYTHMIA, OBSTRUCTIVE HYPERTROPHIC CARDIOMYOPATHY, PULMONARY HYPERTENSION)
Brief sudden loss of consciousness, no prodrome, history of heart disease Syncope while sitting or supine Syncope with exertion History of palpitations

Family history of sudden death
NEUROLOGIC
Seizures: preceding aura, post event symptoms lasting > 5 min (includes postictal state of decreased level of consciousness, confusion, headache or paralysis) Migraine: syncope associated with antecedent headaches with or without aura
OTHER VASCULAR
Carotid sinus: syncope with head rotation or pressure on the carotid sinus (as in tumors, shaving, tight collars) Orthostatic hypotension: syncope immediately on standing especially after prolonged bed rest
DRUG INDUCED
Patient is taking a medication that may lead to long QT syndrome, orthostasis, or bradycardia
PSYCHIATRIC ILLNESS
Frequent syncope, somatic complaints, no heart disease

From Cohen G: Syncope and dizziness. In Kliegman RM, Lye PS, Bordini BJ, et al, editors: Nelson pediatric symptom-based diagnosis. Philadelphia, 2018, Elsevier, Table 6.4.

Table 87.6

Red Flags in Evaluation of Patients With Syncope

- Syncope with activity or exercise or supine
- Syncope not associated with prolonged standing
- Syncope precipitated by loud noise or extreme emotion
- Absence of presyncope or lightheadedness
- Family history of syncope, drowning, sudden death, familial ventricular arrhythmia syndromes,* cardiomyopathy
- Syncope requiring CPR
- Injury with syncope
- Anemia
- Other cardiac symptoms
- Chest pain
- Dyspnea
- Palpitations
- History of cardiac surgery
- History of Kawasaki disease
- Implanted pacemaker
- Abnormal physical examination
    - Murmur
    - Gallop rhythm
    - Loud and single second heart sound
    - Systolic click

Increased apical impulse (tachycardia)
Irregular rhythm
Hypo- or hypertension
Clubbing
Cyanosis

---

[*] Long QT syndrome, Brugada syndrome, catecholamine polymorphic ventricular tachycardia, arrhythmogenic right ventricular dysplasia.

A careful family history is essential in evaluation of syncope. Specifically, if there are first-degree relatives with inherited syndromes, such as a LQTS or HCM, this should lead to more specific evaluation of the patient. Also, if relatives died suddenly at a young age without a clear and convincing cause, inherited cardiac arrhythmias or cardiomyopathies should also be suspected.

Patients with a history of heart disease, especially cardiac repair, may have causes that are specific to their repair. Sinus node dysfunction is common after the Senning or Mustard procedure for transposition of the great vessels. VT may be seen after repair of tetralogy of Fallot. A patient with a history of septal defect repair should be evaluated for the late occurrence of AV block, and patients with an implanted pacemaker should be evaluated for pacemaker lead failure.

The physical examination may also offer clues (Table 87.6). Patients with HCM may have a prominent cardiac impulse and/or an ejection murmur, as will patients with aortic stenosis. The patient with primary pulmonary hypertension will have a loud and single second heart sound and may also have an ejection click and the murmur of pulmonary insufficiency. Scars from prior cardiac surgery and pacemaker implantation would be evident.

All patients presenting with a first episode of syncope *must* have an electrocardiogram obtained, looking primarily for QT interval prolongation, preexcitation, ventricular hypertrophy, T-wave abnormalities, and conduction abnormalities. Other tests that may be needed depending on the results of the initial evaluation may include echocardiography, exercise testing, cardiac MRI, or 24 hr Holter monitoring. In patients for whom there is a strong suspicion of a paroxysmal arrhythmia, an implantable loop recorder may be the most effective means of diagnosis. Additional tests to look for anemia, hypoglycemia, drugs of abuse, and other etiologies noted in Table 87.1 will be determined by the history and physical examination.

Treatment

Therapy for vasovagal syncope includes avoiding triggering events (if possible), fluid and salt supplementation, and if needed, midodrine (see Chapter 87.1 , Table 87.7). Immediately after the event, the patient should remain supine until symptoms abate to avoid recurrence.

Table 87.7

First-Line Medications in Treatment of Postural Tachycardia Syndrome (POTS)

DRUG	MECHANISM OF ACTION	SIDE EFFECTS	TREATMENT GUIDELINES
Fludrocortisone	Low dose: sensitizes α receptors Higher doses: mineralocorticoid effect	Peripheral edema, headache, irritability, hypokalemia, hypomagnesemia, acne	Monitor basic metabolic panel and magnesium.
Midodrine	α_1 -Agonist; produces vasoconstriction	Scalp tingling, urinary retention, goose bumps, headache, supine hypertension	Monitor supine blood pressure 30-60 min after dose.
Metoprolol succinate/tartrate	β-Blocker	Worsening of asthma, dizziness, fatigue	Use with caution in asthma. If fatigue is severe, use at bedtime.
Propranolol	Nonselective β-blocker	Bradycardia, gastrointestinal symptoms, lightheadedness, sleepiness, hypotension, syncope	Use with caution in diabetes and asthma.
Pyridostigmine	Peripheral acetylcholinesterase inhibitor that increases synaptic acetylcholine in autonomic ganglia and at peripheral muscarinic receptors	Symptoms of excessive cholinergic activity (diarrhea, urinary incontinence, salivation)	Very useful if patient has POTS and constipation. Use with caution in asthma. Contraindicated in urinary or bowel obstruction.

Treatment for cardiac causes of syncope will be determined by the diagnosis. If a reentrant tachycardia (AVNRT, AVRT) is found, then a catheter ablation is indicated. If bradycardia from AV block was the cause of the syncope, a pacemaker may be warranted. Patients with syncope from medically refractory malignant arrhythmias, as may be seen in HCM, LQTS, arrhythmogenic cardiomyopathy, or CPVT, require an implantable cardioverter-defibrillator. Patients with structural heart disease (valvular disease or coronary artery anomalies) should be referred for surgery.

87.1

Postural Tachycardia Syndrome

Gisela G. Chelimsky, Thomas C. Chelimsky

Keywords

orthostatic hypotension
POTS
reflex syncope

Several complex and interrelated mechanisms allow humans to stand despite the pull of gravity on the cerebral circulation. In the supine posture, most blood sits in the thoracic cavity, with 25–30% of total volume in the splanchnic vasculature. When an adult stands up, about 500 mL of blood shifts to the lower extremities and to the splanchnic vasculature. The decrease in hydrostatic pressure in the carotid sinuses produces vasoconstriction in the peripheral vessels mediated by sympathetic outflow, as well as in the splanchnic vasculature. This action is mediated by norepinephrine, adenosine triphosphate (ATP), and neuropeptide Y. The muscles in the legs and gluteal area work as a pump when the individual is upright and during exercise, to help return the blood to the heart.

Understanding postural tachycardia syndrome (**POTS**), or postural orthostatic tachycardia syndrome, requires an understanding of other orthostatic conditions.

Many adolescents have lightheadedness or tunnel vision in the first few seconds of assuming the upright posture. This phenomenon, termed **initial orthostatic hypotension (IOH)** , can lead to *syncope* , but usually is very short, perhaps 30-60 sec, and occurs primarily with active standing, not passive upright tilt. Blood pressure (BP) may drop 30% of baseline at 10-20 sec of standing and may be associated with tachycardia. BP returns to baseline in 30-60 sec, whereas heart rate (HR) typically returns to a new, higher value above the baseline when supine. Because of its transient rapidity, IOH escapes detection with standard BP machines and requires beat-to-beat monitoring of BP and HR. The clinical diagnosis requires a careful history. The symptoms usually happen after prolonged recumbence and when the individual stands. The person complains of lightheadedness and “blacking out” or tunnel vision 5-10 sec after standing.

In contrast to IOH, **orthostatic hypotension (OH)** is defined as a *sustained* decrease in the systolic BP of >20 mm Hg or diastolic BP >10 mm Hg in the 1st 3 min of upright tilt. This 2nd type of orthostatic disorder rarely occurs in children. The patient frequently has no orthostatic symptoms while upright despite very low pressures (Fig. 87.1). This distinguishes OH from POTS, which *requires* symptoms while upright. A 3rd orthostatic disorder, **reflex syncope** (i.e., vasovagal or neurally mediated), is defined as relatively sudden change in autonomic nervous system activity that leads to a sudden decrease in BP, HR, and cerebral perfusion (Fig. 87.2).

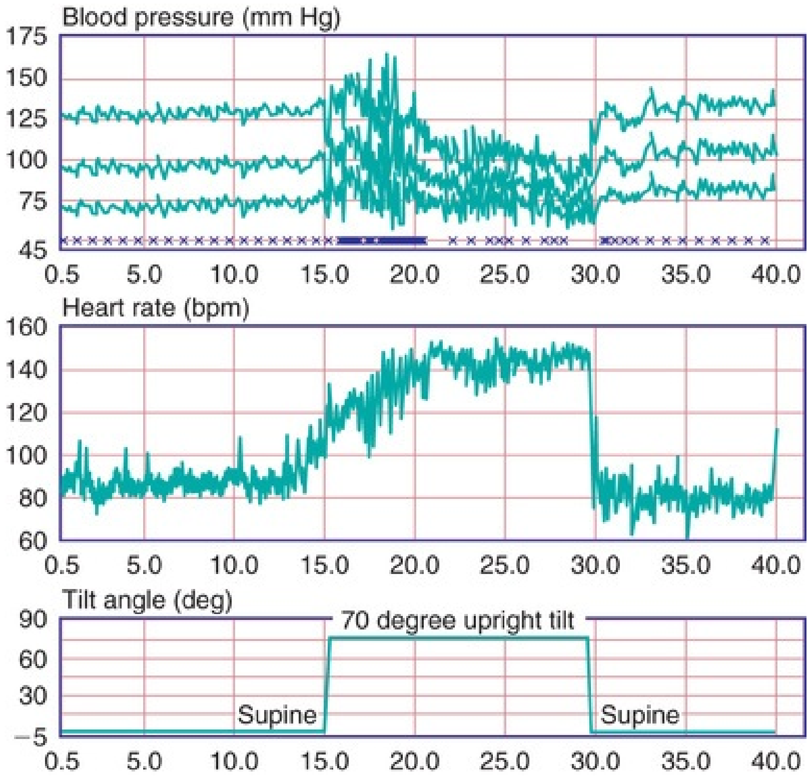

FIG. 87.1 **Example of orthostatic hypotension.**

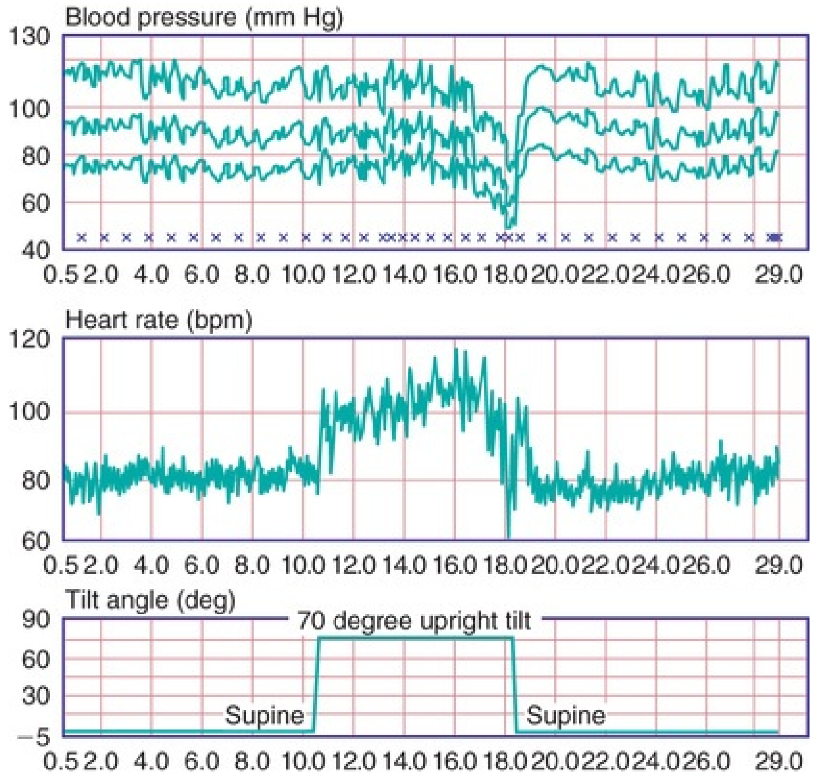

FIG. 87.2 **Example of neurally mediated syncope.**

In children, POTS is defined as a syndrome characterized by HR increase of >40 beats/min during the 1st 10 min of upright tilt test without associated hypotension, (>30 beats/min if >19 yr old) while replicating orthostatic symptoms that occur when upright (Fig. 87.3). Improvement of symptoms in the supine position is expected. The diagnosis of POTS also requires *daily* orthostatic symptoms. In patients with POTS, the larger decline in cardiac stroke volume appears to be the primary trigger for the tachycardia, which may result from various pathophysiologic mechanisms, such as the following:

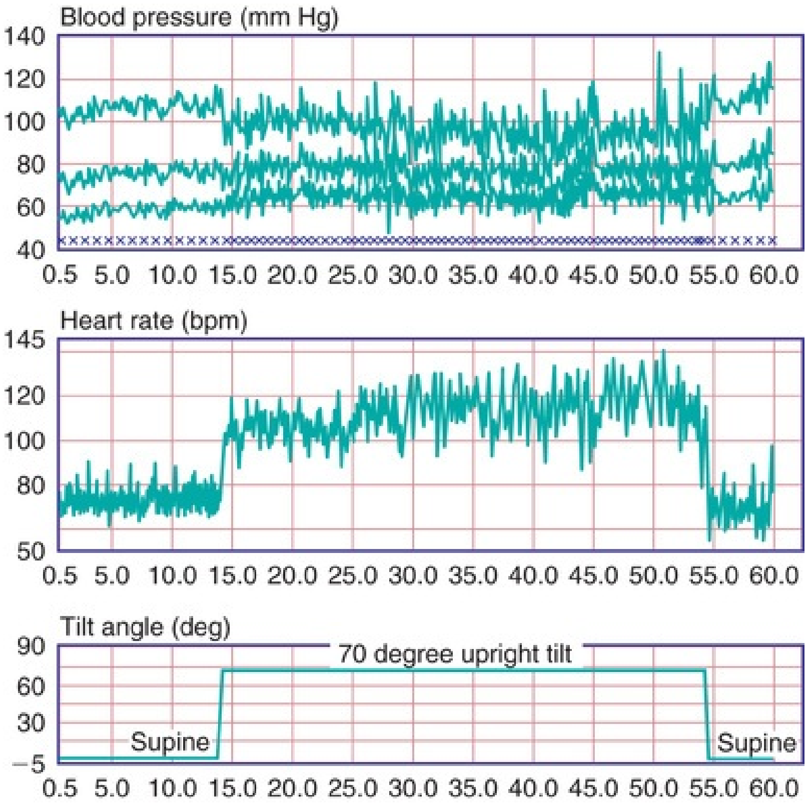

FIG. 87.3 **Example of postural tachycardia syndrome.**

◆ **Neuropathic** POTS, an autonomic neuropathy impairing sympathetic venoconstriction in the lower extremities or splanchnic circulation, decreasing stroke volume, and consequently resulting in a tachycardia

◆ **Hypovolemic** POTS, a common contributor, often related to decreased aldosterone with reduced renin activity, resulting in a tachycardia caused by decrease blood volume

◆ **Hyperadrenergic** POTS, with norepinephrine levels rising 3-4–fold in the standing position (norepinephrine normally doubles on standing), which may occur in norepinephrine transporter deficiency or strong stimulation of central baroreflex responses

◆ **Autoimmune** POTS, typically assumed based on a postviral chronology, but seldom proven; such a form may or may not exist. The antiganglionic antibody is almost never elevated in these patients. Nonetheless, a group of patients report that intravenous immune globulin (IVIG) is helpful to them. Whether they benefit from the increase in intravascular volume or an actual immune effect is unknown.

Some patients have orthostatic symptoms while upright but do not meet criteria for syncope, OH, or POTS. This group has **orthostatic intolerance otherwise not specified (OI-NOS)** .

Clinical Presentation

The symptoms that intrinsically relate to POTS are those that are replicated during upright tilt testing or standing. Many other symptoms also occur in patients with POTS, fitting the description of comorbid conditions, but not reproduced while upright. A patient may have nausea while upright associated with lightheadedness and has a diagnosis of POTS. Another patient may complain of nausea on awakening and have POTS, but has no nausea while upright. In the former patient the nausea is a symptom of POTS itself, whereas in the latter nausea is an associated condition. The symptoms that often directly relate to POTS include lightheadedness, orthostatic nausea, sometimes orthostatic headaches, fatigue, tunnel vision, and brain fog. About 20–30% of pediatric patients with POTS will also have syncope (Fig. 87.4). Other comorbid conditions frequently occur in these patients but are not caused by POTS (i.e., not an orthostatic phenomenon). These comorbidities include (1) sleep issues, usually delayed onset of sleep, frequent awakening, and not feeling refreshed in the morning; (2) aches in different parts of the body; (3) abdominal pain; (4) headaches and migraines; (5) nausea and vomiting; and (6) Raynaud like symptoms and other, less frequent problems (e.g., urinary symptoms).

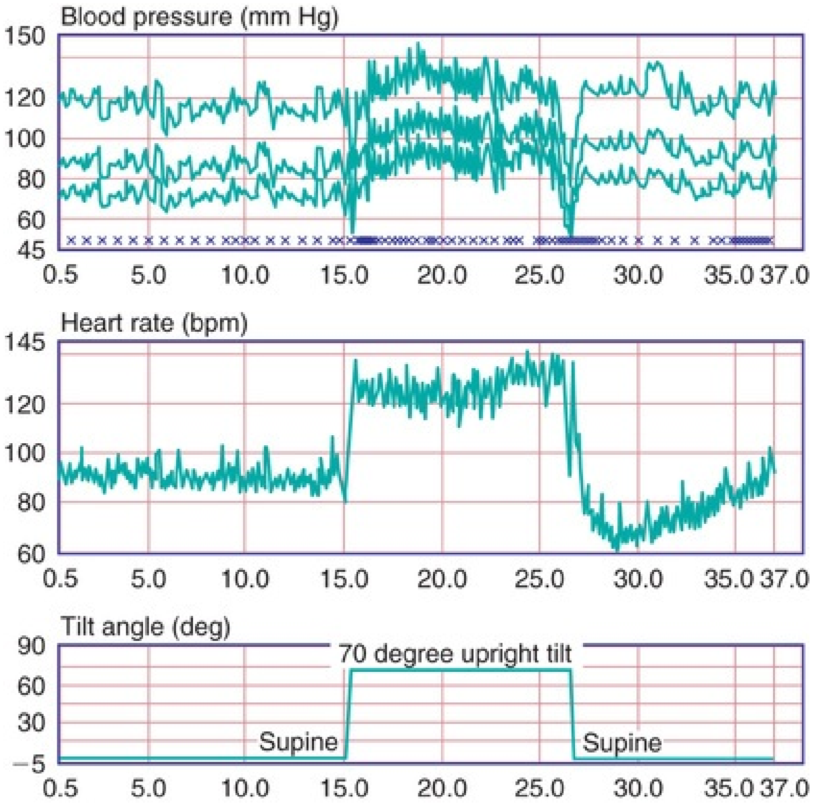

FIG. 87.4 **Example of postural tachycardia syndrome (POTS) followed by a neurally mediated syncope.**

The association of upper gastrointestinal (GI) symptoms and POTS are well described. Nausea, early satiety, and bloating are described in association with POTS. Such GI symptoms relate mechanistically to POTS only when they occur in the upright position. Many patients with POTS have comorbid GI symptom that are not a consequence of the orthostatic challenge. Therefore, only the GI symptoms replicated during tilt testing will improve with treatment aimed at orthostasis. Patients with POTS have changes in the electrical activity of the stomach while upright, which may explain the upright GI symptoms; they usually do not have delayed gastric emptying. The emptying is either normal or accelerated, implying that the cause of nausea is not gastroparesis.

Patients with **hypermobility Ehlers-Danlos syndrome** (h-EDS) may have POTS. Typically, such individuals have more migraine and syncope. Joint hypermobility itself in *adults* is associated with more autonomic complaints such as syncope, presyncope, palpitations, chest discomfort, fatigue, and heat intolerance. Those with hypermobility have more frequent positive tilt tests than healthy controls. Interestingly, in children, joint hypermobility does not influence the number of comorbidities or autonomic disorders. Similarly, those with pediatric chronic overlapping pain conditions with or without POTS have the same comorbidities, suggesting that neither POTS nor hypermobility are drivers of the comorbidities or the chronic overlapping pain condition, but rather another associated disorder (Chapter 147).

Diagnosis

Orthostatic intolerance is clinically diagnosed by detailed history attending specifically to symptoms as they relate to body position. Dizziness that begins in the supine position cannot be a manifestation of orthostatic intolerance. Furthermore, those symptoms that do develop while upright should improve or resolve when supine. Importantly, the history should include a detailed description of current physical exercise habits, with frequency, type, and endurance. One should also assess sleep, diet (mainly evaluating intake of salt), fluid intake, and other comorbidities. The physical examination is also important and should include a cardiac and neurologic evaluation with supine and standing BP and HR. Examination of the extremities may provide information about venous pooling, such as mild edema or reddish purple discoloration when sitting or standing. Cold, clammy hands can signify excess sympathetic activity.

To diagnose POTS the patient needs to undergo a *head-up tilt test for at least 10 min* . It is important to have the patient supine for at least 20 min before the tilt test. POTS can also be assessed by a standing test, measuring BP and HR at 1, 3, 5, and 10 min standing, but to have a reliable test similar to the tilt test, the patient needs to be supine for 1 hr before standing. The HR increase with active standing is typically less than with tilt, because the lower-extremity muscle pump is less active in tilt. The diagnosis of POTS requires replication of the day-to-day symptoms while upright, not just the increased HR while upright. A small but significant proportion of healthy teenagers in school will have an increased HR that may be diagnosed as POTS but will not have associated symptoms.

Other tests may include electrocardiogram, echocardiogram, and Holter monitor when there is concern of a primary cardiac cause of tachycardia, or if there is a need to determine if symptoms correlate with tachycardia (see Chapter 87). Supine and standing plasma catecholamines help confirm the diagnosis of POTS, as one expects to see either the normal doubling of norepinephrine levels from supine to standing, or a tripling with hyperadrenergic POTS. Beyond tilt table testing, autonomic testing will also include cardiac response to deep breathing (checking cardiac parasympathetic function), Valsalva maneuver (checking cardiac sympathetic and parasympathetic functions and vasomotor sympathetic function), and quantitative axon reflex sudomotor test (to assess for an autonomic neuropathy and vasomotor sympathetic dysfunction).

Additional studies depend on the clinical symptoms and include morning cortisol (to rule out Addison disease) and hypo- or hyperthyroid studies if the patient has unusually severe fatigue or is not responsive to usual treatment. Serum tryptase and urine methylhistamine are tested if mast cell activation disorder is suspected, based on a history of flushing during the spells. If an autoimmune cause for the POTS is a concern, antibodies such as voltage-gated potassium channel and acetylcholine receptor antibodies could be checked, but this etiology for POTS is being questioned. Patients rarely (<5 in 1000) benefit from IVIG; if this mechanism is really causing POTS, such patients will experience peak benefit at about 10 days after the infusion, rather than immediately, which may simply reflect increasing intravascular volume. If the patient has hypertension, plasma and urine metanephrines should be measured to test for a pheochromocytoma. In addition, if symptoms are associated with perimenstrual timing, an assessment of sex hormone axis is helpful, with occult polycystic ovarian syndrome or low testosterone levels sometimes present.

Management

The core of POTS management is **nonpharmacologic** . Medications will be of little benefit without these measures being undertaken first. The best measure for treating POTS is a regular **aerobic exercise** program. Given the combination of orthostatic symptoms and severe deconditioning found in most patients, the exercise program must be introduced in a slow, progressive manner. Patients with POTS typically have moderate to severe exercise intolerance, and compared with sedentary healthy controls, have decreased peak oxygen uptake. After 3 mo of exercise, POTS patients have an increase in cardiac mass and size, blood volume, and peak oxygen uptake, as reflected in a better exercise performance. The tachycardia in POTS is caused by a decrease in stroke volume and not an intrinsic circulatory problem. An exercise program should start with water exercises combined with recumbent aerobic activities (recumbent bike or rowing machine). Slowly increase the exercise time to 45 min at least 5 times per week. When tolerance increases, patients can advance to more upright aerobic activities. These aerobic activities need to be combined with light core- and limb-strengthening exercises.

Exercise usually cannot be performed without simultaneous expansion of the intravascular volume. To this end, encourage teenagers to drink >80 oz of fluids daily and to add 2 g of salt to usual diet in both the morning and the early afternoon. **Salt supplementation** increases plasma and blood volume, improves orthostatic tolerance, and decreases baroreflex sensitivity. Salt also reduces nitric oxide production, resulting in less vasodilation. Trial and error of different salt formulation can help to identify the best method for each individual patient. Salt tablets are simple and inexpensive but may make some people nauseous. An alternative is simply to obtain empty capsules on the internet and fill them with table salt. A “0” size capsule contains about 400 mg of salt.

The content of sodium in the body determines the extracellular fluid volume that in turn dictates orthostatic tolerance. Patients with POTS who have lower urinary sodium excretion have more symptoms than those with higher urinary sodium (> 123 mmol/24 hr), and they often respond less well to salt supplementation. Those with severe orthostatic symptoms either in the morning or before sports should drink 16 oz of plain water, which is known to increase sympathetic response mainly in individuals with baroreflex dysregulation. The effect starts soon after drinking the water and lasts for about 1 hr. Compression garments may also be useful. These can be thigh or waist high; the waist-high compression garments may not be tolerated.

Medications can be added when the nonpharmacologic interventions are not insufficient (). Different centers use different strategies, and there is no single correct evidence-based approach. Table 87.3 addresses first-line medications that primary care physicians could use; only the most common side effects are included.

CHAPTER 88

Shock

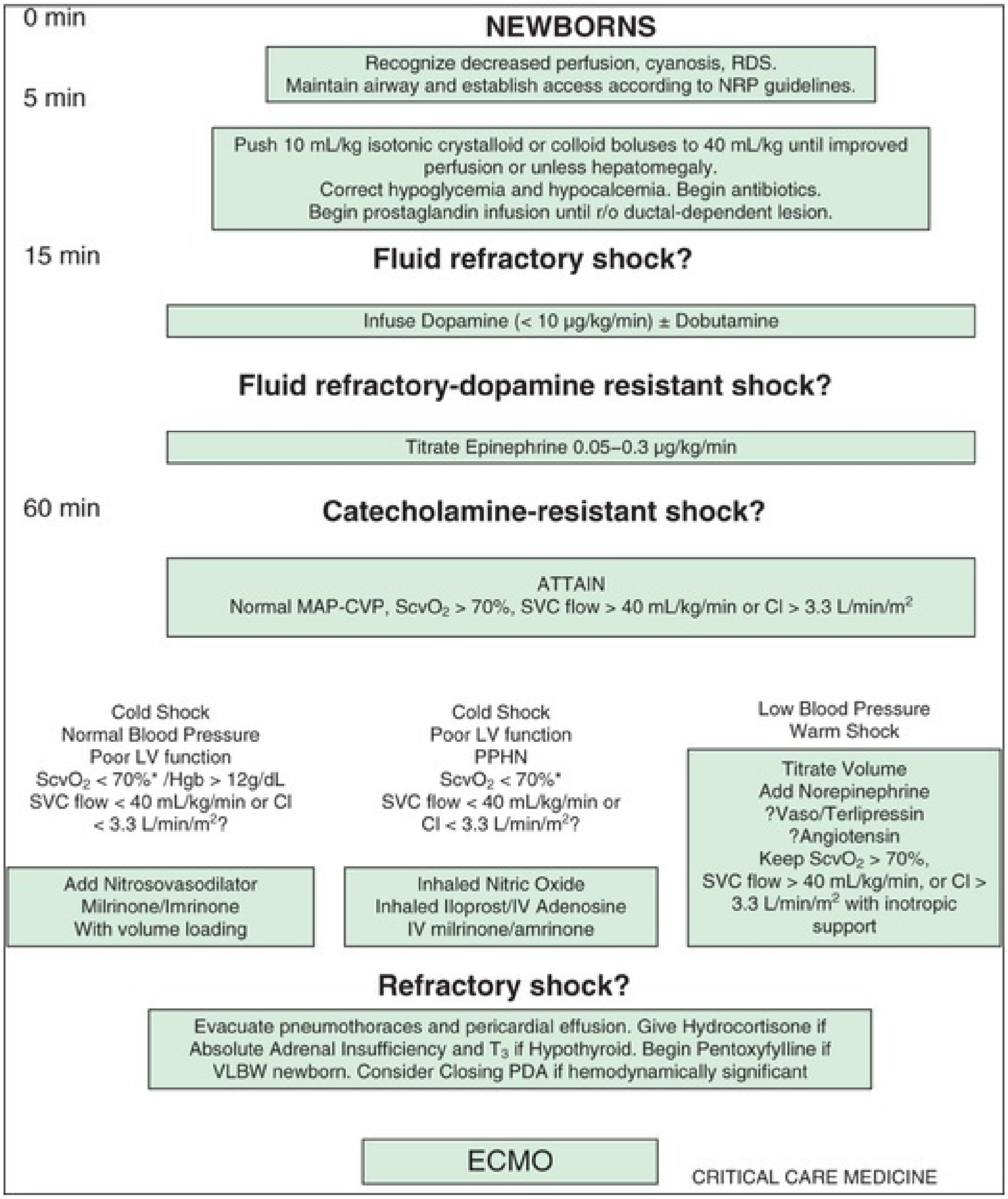
David A. Turner, Ira M. Cheifetz

Shock is an acute process characterized by the body's inability to deliver adequate oxygen to meet the metabolic demands of vital organs and tissues. Insufficient oxygen at the tissue level is unable to support normal aerobic cellular metabolism, resulting in a shift to less efficient anaerobic metabolism. As shock progresses, increases in tissue oxygen extraction are unable to compensate for this deficiency in oxygen delivery, leading to progressive clinical deterioration and lactic acidosis. If inadequate tissue perfusion persists, adverse vascular, inflammatory, metabolic, cellular, endocrine, and systemic responses worsen physiologic instability.

Compensation for inadequate oxygen delivery involves a complex set of responses that attempt to preserve oxygenation of the vital organs (i.e., brain, heart, kidneys, liver) at the expense of other organs (i.e., skin, gastrointestinal tract, muscles). Of importance, the brain is especially sensitive to periods of poor oxygen supply given its lack of capacity for anaerobic metabolism. Initially, shock is often well compensated, but it may rapidly progress to an *uncompensated* state requiring more aggressive therapies to achieve clinical recovery. The combination of a continued presence of an inciting trigger and the body's exaggerated and potentially harmful neurohumoral, inflammatory, and cellular responses lead to the progression of shock. Irrespective of the underlying cause of shock, the specific pattern of response, pathophysiology, clinical manifestations, and treatment may vary significantly depending on the specific etiology (which may be unknown), the clinical circumstances, and an individual patient's biologic response to the shock state. Untreated shock causes irreversible tissue and organ injury (i.e., *irreversible shock*) and, ultimately, death.

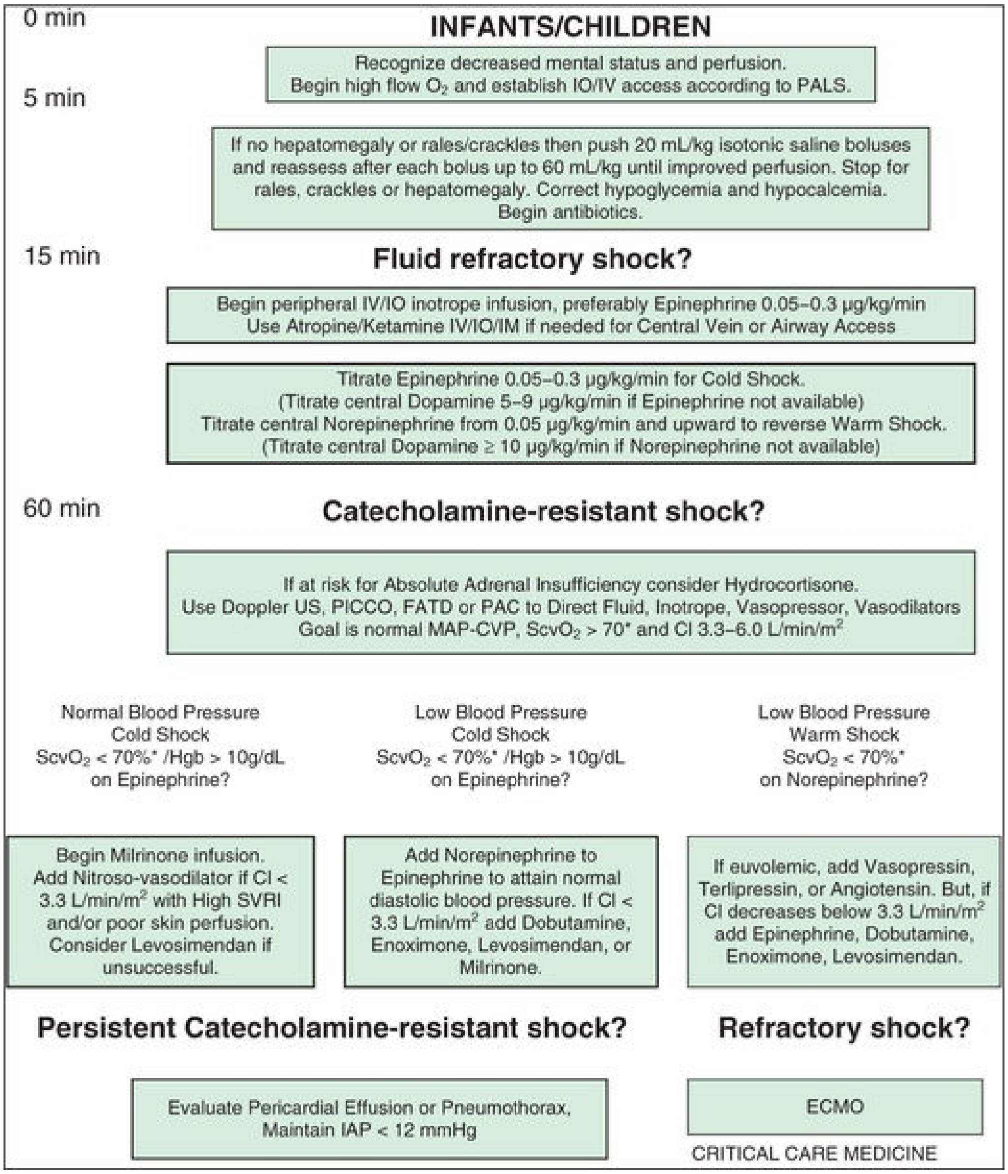
Epidemiology

Shock occurs in approximately 2% of all hospitalized infants, children, and adults in developed countries, and the mortality rate varies substantially depending on the etiology and clinical circumstances. Of patients who do not survive, most do not die in the acute hypotensive phase of shock, but rather as a result of associated complications and **multiple-organ dysfunction syndrome (MODS).** MODS is defined as any alteration of organ function that requires medical support for maintenance, and the presence of MODS in patients with shock substantially increases the probability of death. In pediatrics, educational efforts and the utilization of standardized management guidelines that emphasize early recognition and intervention along with the rapid transfer of critically ill patients to a pediatric intensive care unit (PICU) have led to decreases in the mortality rate for shock (Figs. 88.1 and 88.2).



0 min
NEWBORNS
Recognize decreased perfusion, cyanosis, RDS.
Maintain airway and establish access according to NRP guidelines.
5 min
Push 10 mL/kg isotonic crystalloid or colloid boluses to 40 mL/kg until improved perfusion or unless hepatomegaly.
Correct hypoglycemia and hypocalcemia. Begin antibiotics.
Begin prostaglandin infusion until r/o ductal-dependent lesion.
15 min
Fluid refractory shock?
Infuse Dopamine (< 10 μg/kg/min) ± Dobutamine
Fluid refractory-dopamine resistant shock?
Titrate Epinephrine 0.05–0.3 μg/kg/min
60 min
Catecholamine-resistant shock?
ATTAIN
Normal MAP-CVP, $ScvO_2$ > 70%, SVC flow > 40 mL/kg/min or CI > 3.3 L/min/m^2
Cold Shock
Normal Blood Pressure
Poor LV function
$ScvO_2$ < 70%* /Hgb > 12g/dL
SVC flow < 40 mL/kg/min or CI < 3.3 L/min/m^2?
Cold Shock
Poor LV function
PPHN
$ScvO_2$ < 70%*
SVC flow < 40 mL/kg/min or CI < 3.3 L/min/m^2?
Low Blood Pressure
Warm Shock
Titrate Volume
Add Norepinephrine
?Vaso/Terlipressin
?Angiotensin
Keep $ScvO_2$ > 70%,
SVC flow > 40 mL/kg/min, or CI > 3.3 L/min/m^2 with inotropic support
Add Nitrosovasodilator
Milrinone/Imrinone
With volume loading
Inhaled Nitric Oxide
Inhaled Iloprost/IV Adenosine
IV milrinone/amrinone
Refractory shock?
Evacuate pneumothoraces and pericardial effusion. Give Hydrocortisone if Absolute Adrenal Insufficiency and T_3 if Hypothyroid. Begin Pentoxyfylline if VLBW newborn. Consider Closing PDA if hemodynamically significant
ECMO
CRITICAL CARE MEDICINE

FIG. 88.1 **American College of Critical Care Medicine algorithm for time-sensitive, goal-directed stepwise management of hemodynamic support in *newborns* . Proceed to next step if shock persists. (1) First-hour goals—restore and maintain heart rate thresholds, capillary refill ≤ 2 sec, and normal blood pressure in the 1st hr. (2) Subsequent ICU goals—restore normal perfusion pressure (mean arterial pressure – central venous pressure), preductal and postductal oxygen saturation difference < 5%, and either $ScvO_2$ > 70% (*except congenital heart patients with mixing lesions), superior vena cava flow > 40 mL/kg/min, or cardiac index > 3.3 L/min/m^2 in NICU. (From Davis AL, Carcillo JA, Aneja RK, et al: American College of Critical Care Medicine clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock, *Crit Care Med* 45:1061–1093, 2017, Fig 4.)**



Recognize decreased mental status and perfusion. Begin high flow O_2 and establish IO/IV access according to PALS.

If no hepatomegaly or rales/crackles then push 20 mL/kg isotonic saline boluses and reassess after each bolus up to 60 mL/kg until improved perfusion. Stop for rales, crackles or hepatomegaly. Correct hypoglycemia and hypocalcemia. Begin antibiotics.

Fluid refractory shock?

Begin peripheral IV/IO inotrope infusion, preferably Epinephrine 0.05–0.3 μg/kg/min Use Atropine/Ketamine IV/IO/IM if needed for Central Vein or Airway Access

Titrate Epinephrine 0.05–0.3 μg/kg/min for Cold Shock. (Titrate central Dopamine 5–9 μg/kg/min if Epinephrine not available) Titrate central Norepinephrine from 0.05 μg/kg/min and upward to reverse Warm Shock. (Titrate central Dopamine ≥ 10 μg/kg/min if Norepinephrine not available)

Catecholamine-resistant shock?

If at risk for Absolute Adrenal Insufficiency consider Hydrocortisone. Use Doppler US, PICCO, FATD or PAC to Direct Fluid, Inotrope, Vasopressor, Vasodilators Goal is normal MAP-CVP, $ScvO_2 > 70^*$ and CI 3.3–6.0 L/min/m^2

Normal Blood Pressure Cold Shock $ScvO_2 < 70\%^*$ /Hgb > 10g/dL on Epinephrine?

Low Blood Pressure Cold Shock $ScvO_2 < 70\%^*$ /Hgb > 10g/dL on Epinephrine?

Low Blood Pressure Warm Shock $ScvO_2 < 70\%^*$ on Norepinephrine?

Begin Milrinone infusion. Add Nitroso-vasodilator if CI < 3.3 L/min/m^2 with High SVRI and/or poor skin perfusion. Consider Levosimendan if unsuccessful.

Add Norepinephrine to Epinephrine to attain normal diastolic blood pressure. If CI < 3.3 L/min/m^2 add Dobutamine, Enoximone, Levosimendan, or Milrinone.

If euvolemic, add Vasopressin, Terlipressin, or Angiotensin. But, if CI decreases below 3.3 L/min/m^2 add Epinephrine, Dobutamine, Enoximone, Levosimendan.

Persistent Catecholamine-resistant shock?

Refractory shock?

Evaluate Pericardial Effusion or Pneumothorax, Maintain IAP < 12 mmHg

ECMO

FIG. 88.2 **American College of Critical Care Medicine algorithm for time-sensitive, goal-directed stepwise management of hemodynamic support in *infants and children* . Proceed to next step if shock persists. (1) First-hour goals—restore and maintain heart rate thresholds, capillary refill ≤ 2 sec, and normal blood pressure in the 1st hr/emergency department. (2) Subsequent ICU goals—if shock not reversed, proceed to restore and maintain normal perfusion pressure (MAP – CVP) for age, $ScvO_2 > 70\%$ (*except congenital heart patients with mixing lesions), and cardiac index > 3.3 and < 6.0 L/min/m^2 in PICU. (From Davis AL, Carcillo JA, Aneja RK, et al: American College of Critical Care Medicine clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock, *Crit Care Med* 45:1061–1093, 2017, Fig 2.)**

Types of Shock

Shock classification systems generally define 5 major types of shock:

hypovolemic, cardiogenic, distributive, obstructive, and septic (Table 88.1). **Hypovolemic shock** , the most common cause of shock in children worldwide, is most frequently caused by diarrhea, vomiting, or hemorrhage. **Cardiogenic shock** is seen in patients with congenital heart disease (before or after surgery, including heart transplantation) or those with congenital or acquired cardiomyopathies, including acute myocarditis. **Obstructive shock** stems from any lesion that creates a mechanical barrier that impedes adequate cardiac output, which includes pericardial tamponade, tension pneumothorax, pulmonary embolism, and ductus-dependent congenital heart lesions. **Distributive shock** is caused by inadequate vasomotor tone, which leads to capillary leak and maldistribution of fluid into the interstitium. **Septic shock** is often discussed synonymously with distributive shock, but the septic process usually involves a more complex interaction of distributive, hypovolemic, and cardiogenic shock.

Table 88.1

Types of Shock

HYPOVOLEMIC	CARDIOGENIC	DISTRIBUTIVE	SEPTIC	OBSTRUCTIVE
Decreased preload secondary to internal or external losses	Cardiac pump failure secondary to poor myocardial function	Abnormalities of vasomotor tone from loss of venous and arterial capacitance	Encompasses multiple forms of shock Hypovolemic: third spacing of fluids into the extracellular, interstitial space Distributive: early shock with decreased afterload Cardiogenic: depression of myocardial function by endotoxins	Decreased cardiac output secondary to direct impediment to right- or left-sided heart outflow or restriction of all cardiac chambers
POTENTIAL ETIOLOGIES				
Blood loss: hemorrhage Plasma loss: burns, nephrotic syndrome Water/electrolyte loss: vomiting, diarrhea	Congenital heart disease Cardiomyopathies: infectious or acquired, dilated or restrictive Ischemia Arrhythmias	Anaphylaxis Neurologic: loss of sympathetic vascular tone secondary to spinal cord or brainstem injury Drugs	Bacterial Viral Fungal (immunocompromised patients are at increased risk)	Tension pneumothorax Pericardial tamponade Pulmonary embolism Anterior mediastinal masses Critical coarctation of aorta

Pathophysiology

An initial insult triggers shock, leading to inadequate oxygen delivery to organs and tissues. Compensatory mechanisms attempt to maintain blood pressure (BP) by increasing cardiac output and systemic vascular resistance (SVR). The body also attempts to optimize oxygen delivery to the tissues by increasing oxygen extraction and redistributing blood flow to the brain, heart, and kidneys at the expense of the skin and gastrointestinal (GI) tract. These responses lead to an initial state of **compensated shock** in which BP is maintained. If treatment is not initiated or is inadequate during this period, **decompensated shock** develops, with hypotension and tissue damage that may lead to **multisystem organ dysfunction** and, ultimately, death (Tables 88.2 and 88.3).

Table 88.2

Criteria for Organ Dysfunction

ORGAN SYSTEM	**CRITERIA FOR DYSFUNCTION**
Cardiovascular	Despite administration of isotonic intravenous fluid bolus ≥60 mL/kg in 1 hr: decrease in BP (hypotension) systolic BP <90 mm Hg, mean arterial pressure <70 mm Hg, <5th percentile for age, or systolic BP <2 SD below normal for age *or* Need for vasoactive drug to maintain BP in normal range (dopamine >5 μg/kg/min or dobutamine, epinephrine, or norepinephrine at any dose) *or* Two of the following: Unexplained metabolic acidosis: base deficit >5.0 mEq/L Increased arterial lactate: >1 mmol/L or >2× upper limit of normal Oliguria: urine output <0.5 mL/kg/hr Prolonged capillary refill: >5 sec Core-to-peripheral temperature gap: >3°C (5.4°F)
Respiratory	PaO_2 /FIO_2 ratio <300 in absence of cyanotic heart disease or preexisting lung disease *or* $PaCO_2$ >65 torr or 20 mm Hg over baseline $PaCO_2$ *or* Need for >50% FIO_2 to maintain saturation ≥92% *or* Need for nonelective invasive or noninvasive mechanical ventilation
Neurologic	GCS score ≤11 *or* Acute change in mental status with decrease in GCS score ≥3 points from abnormal baseline
Hematologic	Platelet count <100,000/mm^3 or decline of 50% in platelet count from highest value recorded over last 3 days (for patients with chronic hematologic or oncologic disorders) *or* INR >1.5 *or* Activated prothrombin time >60 sec
Renal	Serum creatinine >0.5 mg/dL, ≥2× upper limit of normal for age, or 2-fold increase in baseline creatinine value

Hepatic	Total bilirubin ≥4 mg/dL (not applicable for newborn) Alanine transaminase level 2× upper limit of normal for age

BP, Blood pressure; FIO_2, fraction of inspired oxygen; GCS, Glasgow Coma Scale; INR, international normalized ratio; $PaCO_2$, arterial partial pressure of carbon dioxide; PaO_2, partial pressure arterial oxygen; SD, standard deviations.

Table 88.3

Signs of Decreased Perfusion

ORGAN SYSTEM	↓ PERFUSION	↓↓ PERFUSION	↓↓↓ PERFUSION
Central nervous system	—	Restless, apathetic, anxious	Agitated/confused, stuporous, coma
Respiration	—	↑ Ventilation	↑↑ Ventilation
Metabolism	—	Compensated metabolic acidemia	Uncompensated metabolic acidemia
Gut	—	↓ Motility	Ileus
Kidney	↓ Urine volume	Oliguria (<0.5 mL/kg/hr)	Oliguria/anuria
	↑ Urinary specific gravity		
Skin	Delayed capillary refill	Cool extremities	Mottled, cyanotic, cold extremities
Cardiovascular system	↑ Heart rate	↑↑ Heart rate	↑↑ Heart rate
		↓ Peripheral pulses	↓ Blood pressure, central pulses only

In the early phases of shock, multiple compensatory physiologic mechanisms act to maintain BP and preserve tissue perfusion and oxygen delivery. Cardiovascular effects include increases in heart rate (HR), stroke volume, and vascular smooth muscle tone, which are regulated through sympathetic nervous system activation and neurohormonal responses. Respiratory compensation involves greater carbon dioxide (CO_2) elimination in response to the metabolic acidosis and increased CO_2 production from poor tissue perfusion. Renal excretion of hydrogen ions (H^+) and retention of bicarbonate (HCO_3^-) also increase in an effort to maintain normal body pH (see Chapter 68.7). Maintenance of intravascular volume is facilitated via sodium regulation through the renin-angiotensin-aldosterone and atrial natriuretic factor axes, cortisol and catecholamine synthesis and release, and antidiuretic hormone secretion. Despite these compensatory mechanisms, the underlying shock and host response lead to vascular endothelial cell injury and significant leakage of intravascular fluids into the interstitial extracellular space.

Another important aspect of the initial pathophysiology of shock is the impact on cardiac output. All forms of shock affect cardiac output through several mechanisms, with changes in HR, preload, afterload, and myocardial contractility occurring separately or in combination (Table 88.4). **Hypovolemic shock** is characterized primarily by fluid loss and decreased preload. Tachycardia and an increase in SVR are the initial compensatory responses to maintain cardiac output and systemic BP. Without adequate volume replacement, hypotension develops, followed by tissue ischemia and further clinical deterioration. When there is preexisting low plasma oncotic pressure (caused by nephrotic syndrome, malnutrition, hepatic dysfunction, acute severe burns, etc.), even further volume loss and exacerbation of shock may result from endothelial breakdown and worsening capillary leak.

Table 88.4

Pathophysiology of Shock

Extracorporeal Fluid Loss

Hypovolemic shock may be a result of direct blood loss through hemorrhage or abnormal loss of body fluids (diarrhea, vomiting, burns, diabetes mellitus or insipidus, nephrosis).

Lowering Plasma Oncotic Forces

Hypovolemic shock may also result from hypoproteinemia (liver injury, or as a progressive complication of increased capillary permeability).

Abnormal Vasodilation

Distributive shock (neurogenic, anaphylaxis, or septic shock) occurs when there is loss of vascular tone—venous, arterial, or both (sympathetic blockade, local substances affecting permeability, acidosis, drug effects, spinal cord transection).

Increased Vascular Permeability

Sepsis may change the capillary permeability in the absence of any change in capillary hydrostatic pressure (endotoxins from sepsis, excess histamine release in anaphylaxis).

Cardiac Dysfunction

Peripheral hypoperfusion may result from any condition that affects the heart's ability to pump blood efficiently (ischemia, acidosis, drugs, constrictive pericarditis, pancreatitis, sepsis).

In contrast, the underlying pathophysiologic mechanism leading to **distributive shock** is a state of abnormal vasodilation and decreased SVR. Sepsis, hypoxia, poisoning, anaphylaxis, spinal cord injury, or mitochondrial dysfunction can cause *vasodilatory shock* (Fig. 88.3). The lowering of SVR is accompanied initially by a maldistribution of blood flow away from vital organs and a compensatory increase in cardiac output. This process leads to significant decreases in both preload and afterload. Therapies for distributive shock must address both these problems simultaneously.

↓ Plasma vasopressin
Vasodilation

FIG. 88.3 **Mechanisms of vasodilatory shock. Septic shock and states of prolonged shock causing tissue hypoxia with lactic acidosis increase nitric oxide synthesis, activate the adenosine triphosphate (ATP)–sensitive and calcium-regulated potassium channels (K_{ATP} and K_{Ca} , respectively) in vascular smooth muscle, and lead to depletion of vasopressin. cGMP, Cyclic guanosine monophosphate. (From Landry DW, Oliver JA:**

The pathogenesis of vasodilatory shock, *N Engl J Med* 345:588.595, 2001.)

Cardiogenic shock may be seen in patients with myocarditis, cardiomyopathy, arrhythmias and congenital heart disease (generally following cardiac surgery) (see Chapter 461). In these patients, myocardial contractility is affected, leading to systolic and/or diastolic dysfunction. The later phases of all forms of shock frequently have a negative impact on the myocardium, leading to development of a cardiogenic component to the initial shock state.

Septic shock is generally a unique combination of distributive, hypovolemic, and cardiogenic shock. Hypovolemia from intravascular fluid losses occurs through capillary leak. Cardiogenic shock results from the myocardial-depressant effects of sepsis, and distributive shock is the result of decreased SVR. The degree to which a patient exhibits each of these responses varies, but there are frequently alterations in preload, afterload, and myocardial contractility.

In septic shock, it is important to distinguish between the inciting infection and the host inflammatory response. Normally, host immunity prevents the development of sepsis through activation of the reticular endothelial system along with the cellular and humoral immune systems. This host immune response produces an *inflammatory cascade* of toxic mediators, including hormones, cytokines, and enzymes. If this inflammatory cascade is uncontrolled, derangement of the microcirculatory system leads to subsequent organ and cellular dysfunction.

The **systemic inflammatory response syndrome** (**SIRS**) is an inflammatory cascade that is initiated by the host response to an infectious or noninfectious trigger (Table 88.5). This inflammatory cascade is triggered when the host defense system does not adequately recognize and/or eliminate the triggering event. The inflammatory cascade initiated by shock can lead to hypovolemia, cardiac and vascular failure, acute respiratory distress syndrome (ARDS), insulin resistance, decreased cytochrome P450 activity (decreased steroid synthesis), coagulopathy, and unresolved or secondary infection. Tumor necrosis factor (TNF) and other inflammatory mediators increase vascular permeability, causing diffuse capillary leak, decreased vascular tone, and an imbalance between perfusion and metabolic demands of the tissues. TNF and interleukin (IL)-1 stimulate the release of proinflammatory and antiinflammatory mediators, causing fever and vasodilation. Proinflammatory mediators include IL-6, IL-12, interferon-γ, and macrophage migration inhibitory factor; antiinflammatory cytokines include IL-10, transforming growth factor-β, and IL-4. Arachidonic acid metabolites lead to the development of fever, tachypnea, ventilation-perfusion abnormalities, and lactic acidosis. Nitric oxide (NO), released from the endothelium or inflammatory cells, is a major contributor to hypotension. Myocardial depression is caused directly by myocardial-depressant factors, TNF, and some interleukins and is further depressed by depleted catecholamines, increased β-endorphin, and production of myocardial NO.

Table 88.5

Differential Diagnosis of Systemic Inflammatory Response Syndrome (SIRS)

Infection

Bacteremia or meningitis (*Streptococcus pneumoniae, Haemophilus influenzae* type b, *Neisseria meningitidis*, group A streptococcus, *Staphylococcus aureus*)
Viral illness (influenza, enteroviruses, hemorrhagic fever group, herpes simplex virus, respiratory syncytial virus, cytomegalovirus, Epstein-Barr virus)
Encephalitis (arboviruses, enteroviruses, herpes simplex virus)
Rickettsiae (Rocky Mountain spotted fever, *Ehrlichia,* Q fever)
Syphilis
Vaccine reaction (pertussis, influenza, measles)
Toxin-mediated reaction (toxic shock, staphylococcal scalded skin syndrome)

Cardiopulmonary

Pneumonia (bacteria, virus, mycobacteria, fungi, allergic reaction)
Pulmonary emboli
Heart failure
Arrhythmia
Pericarditis
Myocarditis

Metabolic-Endocrine

Adrenal insufficiency (adrenogenital syndrome, Addison disease, corticosteroid withdrawal)
Electrolyte disturbances (hypo- or hypernatremia; hypo- or hypercalcemia)
Diabetes insipidus
Diabetes mellitus
Inborn errors of metabolism (organic acidosis, urea cycle, carnitine deficiency, mitochondrial disorders)
Hypoglycemia
Reye syndrome

Gastrointestinal

Gastroenteritis with dehydration
Volvulus
Intussusception
Appendicitis
Peritonitis (spontaneous, associated with perforation or peritoneal dialysis)
Necrotizing enterocolitis
Hepatitis
Hemorrhage
Pancreatitis

Hematologic

Anemia (sickle cell disease, blood loss, nutritional)
Methemoglobinemia
Splenic sequestration crisis
Leukemia or lymphoma
Hemophagocytic syndromes

Neurologic

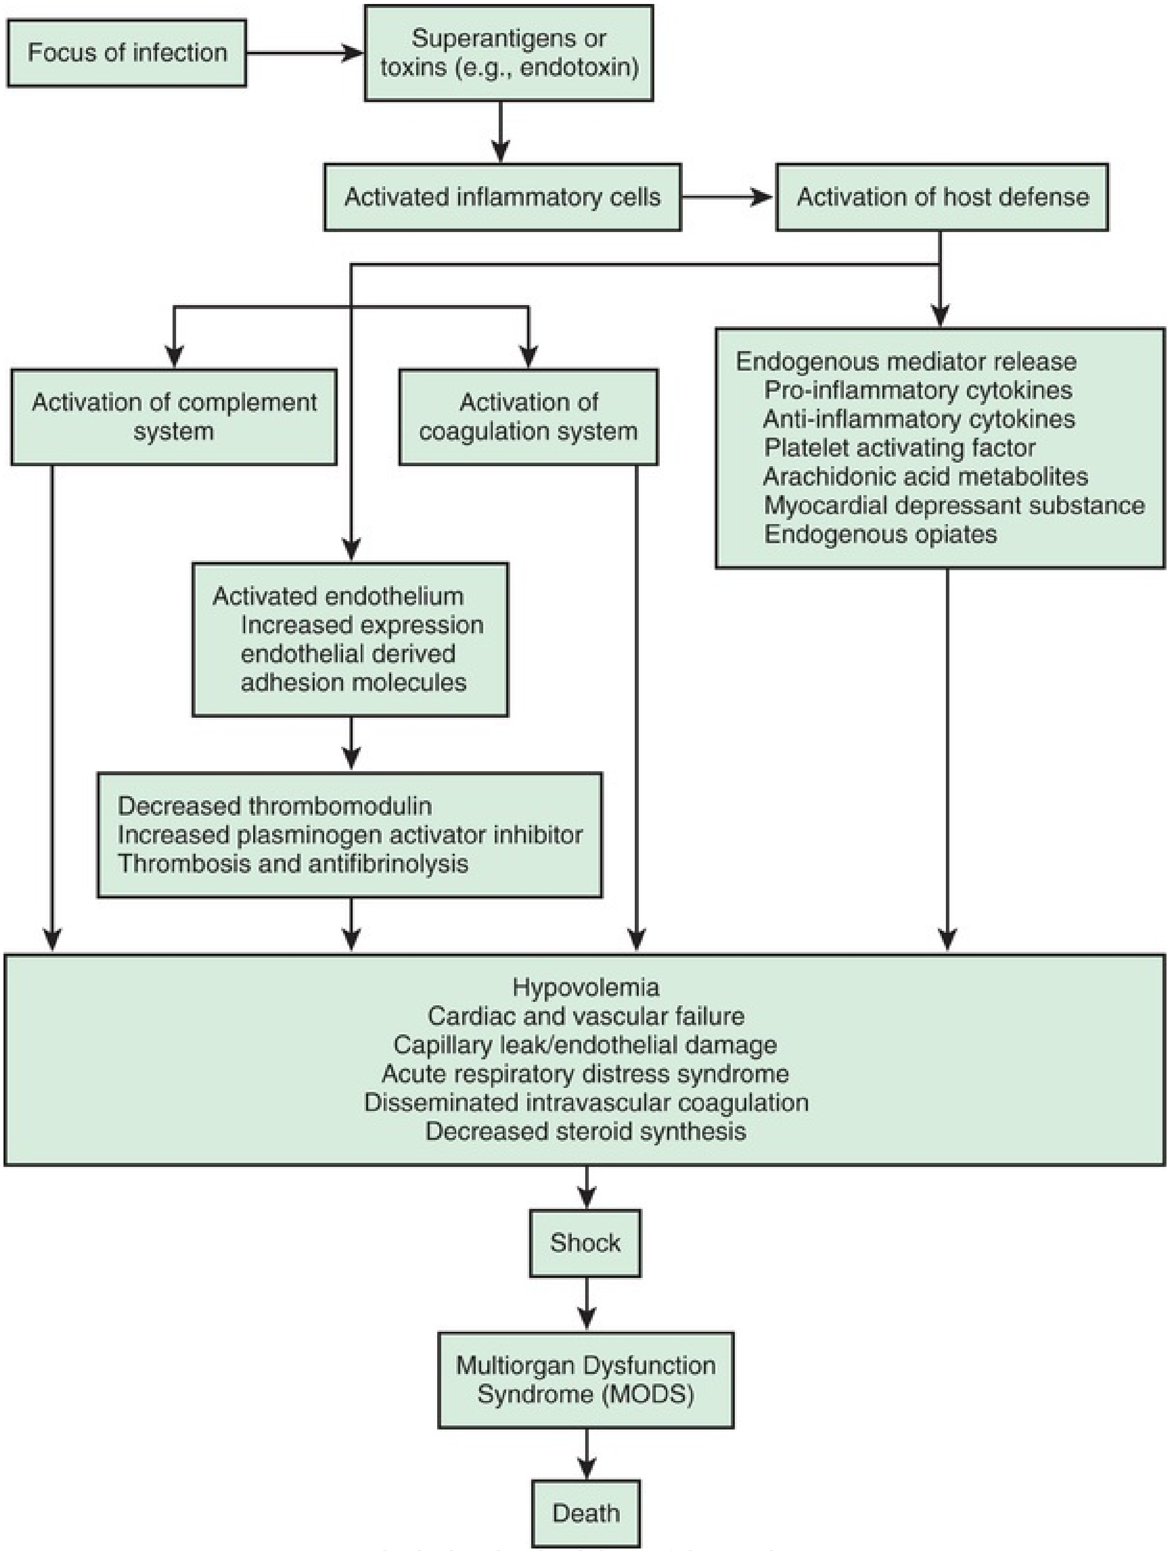
Intoxication (drugs, carbon monoxide, intentional or accidental overdose)

Intracranial hemorrhage
Infant botulism
Trauma (child abuse, accidental)
Guillain-Barré syndrome
Myasthenia gravis

Other

Anaphylaxis (food, drug, insect sting)
Hemolytic-uremic syndrome
Kawasaki disease
Erythema multiforme
Hemorrhagic shock–encephalopathy syndrome
Poisoning
Toxic envenomation
Macrophage activation syndrome
Idiopathic systemic capillary leak (Clarkson) syndrome

The inflammatory cascade is initiated by toxins or superantigens through macrophage binding or lymphocyte activation (Fig. 88.4). The vascular endothelium is both a target of tissue injury and a source of mediators that may cause further injury. Biochemical responses include the production of arachidonic acid metabolites, release of myocardial-depressant factors and endogenous opiates, activation of the complement system, and production and release of other mediators, which may be proinflammatory or antiinflammatory. The balance among these mediator groups for an individual patient contributes to the progression (and resolution) of disease and affects the prognosis.



Focus of infection
Superantigens or toxins (e.g., endotoxin)
Activated inflammatory cells
Activation of host defense
Activation of complement system
Activation of coagulation system
Endogenous mediator release
Pro-inflammatory cytokines
Anti-inflammatory cytokines
Platelet activating factor
Arachidonic acid metabolites
Myocardial depressant substance
Endogenous opiates
Activated endothelium
Increased expression endothelial derived adhesion molecules
Decreased thrombomodulin
Increased plasminogen activator inhibitor
Thrombosis and antifibrinolysis
Hypovolemia
Cardiac and vascular failure
Capillary leak/endothelial damage
Acute respiratory distress syndrome
Disseminated intravascular coagulation
Decreased steroid synthesis
Shock
Multiorgan Dysfunction Syndrome (MODS)
Death

FIG. 88.4 Hypothetical pathophysiology of the septic process.

Clinical Manifestations

Table 88.1 shows a classification system for shock. Categorization is important, but there may be significant overlap among these groups, especially in septic shock. The clinical presentation of shock depends in part on the underlying etiology, but if unrecognized and untreated, all forms of shock follow a common and untoward progression of clinical signs and pathophysiologic changes that may ultimately lead to irreversible organ injury and death.

Shock may initially manifest as only tachycardia, with or without tachypnea. Progression leads to decreased urine output, poor peripheral perfusion, respiratory distress or failure, alteration of mental status, and low BP (see Table 88.3). A significant misconception is that shock occurs only with low BP; hypotension is often a late finding and is not a criterion for the diagnosis of shock because of a complex set of compensatory mechanisms that attempt to preserve BP and peripheral perfusion. Hypotension reflects an advanced state of decompensated shock and is associated with increased morbidity and mortality.

Hypovolemic shock often manifests initially as orthostatic hypotension and is associated with dry mucous membranes, dry axillae, poor skin turgor, and decreased urine output. Depending on the degree of dehydration, the patient with hypovolemic shock may present with either normal or slightly cool distal extremities, and pulses may be normal, decreased, or absent depending on disease severity. The presenting signs of **cardiogenic shock** are tachypnea, cool extremities, delayed capillary filling time, poor peripheral and/or central pulses, declining mental status, and decreased urine output caused by the combination of decreased cardiac output and compensatory peripheral vasoconstriction (see Chapter 469.1). **Obstructive shock** often also manifests as inadequate cardiac output because of a physical restriction of forward blood flow, and the acute presentation may quickly progress to cardiac arrest. **Distributive shock** manifests initially as peripheral vasodilation and increased but inadequate cardiac output.

Regardless of etiology, uncompensated shock, with hypotension, high SVR, decreased cardiac output, respiratory failure, obtundation, and oliguria, occurs late in the progression of disease. Table 88.6 lists the hemodynamic findings in various shock states. Additional clinical findings in shock include cutaneous lesions such as petechiae, diffuse erythema, ecchymoses, ecthyma gangrenosum, and peripheral gangrene. Jaundice can be present either as a sign of infection or as a result of MODS.

Table 88.6

Hemodynamic Variables in Different Shock States

TYPE OF SHOCK	CARDIAC OUTPUT	SYSTEMIC VASCULAR RESISTANCE	MEAN ARTERIAL PRESSURE	CAPILLARY WEDGE PRESSURE	CENTRAL VENOUS PRESSURE
Hypovolemic	↓	↑	↔ or ↓	↓↓↓	↓↓↓
Cardiogenic[*]					
Systolic	↓↓	↑↑↑	↔ or ↓	↑↑	↑↑
Diastolic	↔	↑↑	↔	↑↑	↑
Obstructive	↓	↑	↔ or ↓	↑↑ [†]	↑↑ [†]
Distributive	↑↑	↓↓↓	↔ or ↓	↔ or ↓	↔ or ↓
Septic					
Early	↑↑↑	↓↓↓	↔ or ↓ [‡]	↓	↓
Late	↓↓	↓↓	↓↓	↑	↑ or ↔

[*] Systolic or diastolic dysfunction.

[†] Wedge pressure, central venous pressure, and pulmonary artery diastolic pressures are equal.

[‡] Wide pulse pressure.

Sepsis is defined as SIRS resulting from a suspected or proven infectious etiology. The clinical spectrum of sepsis begins when a *systemic* (e.g., bacteremia, rickettsial disease, fungemia, viremia) or *localized* (e.g., meningitis, pneumonia, pyelonephritis, peritonitis, necrotizing fasciitis) infection progresses from sepsis to **severe sepsis** (i.e., presence of sepsis combined with organ dysfunction). Further clinical deterioration leads to **septic shock** (severe sepsis plus the persistence of hypoperfusion or hypotension despite adequate fluid resuscitation or a requirement for vasoactive agents), MODS, and possibly death (Table 88.7). This is a complex spectrum of clinical problems that is a leading cause of mortality in children worldwide. Mortality can be mitigated and outcomes improved with early recognition and treatment.

Table 88.7

International Consensus Definitions for Pediatric Sepsis

Infection

Suspected or proven infection or a clinical syndrome associated with high probability of infection.

Systemic Inflammatory Response Syndrome (SIRS)

Two of 4 criteria, 1 of which must be abnormal temperature or abnormal leukocyte count:

1. Core temperature >38.5°C (101.3°F) or <36°C (96.8°F) (rectal, bladder, oral, or central catheter)
2. Tachycardia:

   Mean heart rate >2 SD above normal for age in absence of external stimuli, chronic drugs or painful stimuli

   or

   Unexplained persistent elevation over 0.5-4 hr

   or

   In children <1 yr old, persistent bradycardia over 0.5 hr (mean heart rate <10th percentile for age in absence of vagal stimuli, β-blocker drugs, or congenital heart disease)
3. Respiratory rate >2 SD above normal for age or acute need for mechanical ventilation not related to neuromuscular disease or general anesthesia
4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy) or >10% immature neutrophils

Sepsis

SIRS plus a suspected or proven infection

Severe Sepsis

Sepsis plus 1 of the following:

1. Cardiovascular organ dysfunction, defined as:

   Despite >40 mL/kg of isotonic intravenous fluid in 1 hr:

   - Hypotension <5th percentile for age or systolic blood pressure <2 SD below normal for age

   or

   - Need for vasoactive drug to maintain blood pressure

   or

   Two of the following:

   - Unexplained metabolic acidosis: base deficit >5 mEq/L

- Increased arterial lactate: >2 times upper limit of normal
- Oliguria: urine output <0.5 mL/kg/hr
- Prolonged capillary refill: >5 sec
- Core-to-peripheral temperature gap: >3°C (5.4°F)

2. Acute respiratory distress syndrome (ARDS), as defined by the presence of a PaO_2/FIO_2 ratio ≤300 mm Hg, bilateral infiltrates on chest radiograph, and no evidence of left-sided heart failure.

or

Sepsis plus ≥2 organ dysfunctions (respiratory, renal, neurologic, hematologic, or hepatic).

Septic Shock

Sepsis plus cardiovascular organ dysfunction as defined above.

Multiple-Organ Dysfunction Syndrome (MODS)

Presence of altered organ function such that homeostasis cannot be maintained without medical intervention.

FIO_2, Fraction of inspired oxygen; PaO_2, partial pressure of arterial oxygen; SD, standard deviations.

Although **septic shock** is primarily distributive in nature, multiple other elements of pathophysiology are represented in this disease process. The initial signs and symptoms of sepsis include alterations in temperature regulation (hyperthermia or hypothermia), tachycardia, and tachypnea. In the early stages (hyperdynamic phase, low SVR, or *warm* shock), cardiac output increases to maintain adequate oxygen delivery and meet the greater metabolic demands of the organs and tissues. As septic shock progresses, cardiac output falls in response to the effects of numerous inflammatory mediators, leading to a compensatory elevation in SVR and the development of *cold* shock.

Diagnosis

Shock is a clinical diagnosis based on a thorough history and physical examination (see Tables 88.2 and 88.3). Septic shock has a specific consensus conference definition (see Table 88.7). In cases of suspected septic shock, an infectious etiology should be sought through culture of clinically appropriate specimens and prompt initiation of empirical antimicrobial therapy based on patient age, underlying disease, and geographic location, recognizing that time is necessary for incubation of cultures, and results often are not positive. Additional evidence for identifying an infectious etiology as the cause of SIRS includes physical examination findings, imaging, presence of white blood cells in normally sterile body fluids, and suggestive rashes such as petechiae and purpura. Affected children should be admitted to a PICU or other highly monitored environment as indicated by clinical status and the resources of the medical facility. These patients necessitate continuous monitoring, with a combination of noninvasive (e.g., pulse oximetry, capnography, near-infrared spectroscopy) and invasive (e.g., central venous pressure, arterial BP) techniques as clinically indicated.

Laboratory Findings

Laboratory findings often include evidence of hematologic abnormalities and electrolyte disturbances. Hematologic abnormalities may include thrombocytopenia, prolonged prothrombin and partial thromboplastin times, reduced serum fibrinogen level, elevation of fibrin split products, and anemia. Elevated neutrophil counts and increased immature forms (i.e., bands, myelocytes, promyelocytes), vacuolation of neutrophils, toxic granulations, and Döhle bodies can be seen with infection. Neutropenia or leukopenia may be an ominous sign of overwhelming sepsis.

Glucose dysregulation, a common stress response, may manifest as hyperglycemia or hypoglycemia. Other electrolyte abnormalities are hypocalcemia, hypoalbuminemia, and metabolic acidosis. Renal and/or hepatic function may also be abnormal. Patients with ARDS or pneumonia have impairment of oxygenation (decreased partial pressure of arterial oxygen [$Pa{O_2}$]) as well as of ventilation (increased arterial partial pressure of carbon dioxide [$Pa{CO_2}$]) in the later stages of lung injury (see Chapter 89).

The hallmark of *uncompensated* shock is an imbalance between oxygen delivery ($D{O_2}$) and oxygen consumption ($V{O_2}$). Oxygen delivery normally exceeds oxygen consumption by threefold. The oxygen extraction ratio is approximately 25%, thus producing a normal mixed venous oxygen saturation (SvO_2) of approximately 75%. A falling SvO_2 value, as measured by cooximetry reflects an increasing oxygen extraction ratio and documents a decrease in oxygen delivery relative to consumption. This increase in oxygen extraction by the end organs is an attempt to maintain adequate oxygen delivery at the cellular level. This state is manifested clinically by increased lactic acid production (e.g., high anion gap, metabolic acidosis) caused by anaerobic metabolism and a compensatory increase in tissue oxygen extraction. The gold standard measurement of SvO_2 is from a pulmonary arterial catheter, but measurements from this location are often not clinically feasible. Sites such as the right ventricle, right atrium, superior vena cava ($SvCO_2$), or inferior vena cava can be as surrogate measures of mixed venous blood to follow the adequacy of oxygen delivery and effectiveness of therapeutic interventions. *Elevated blood lactate levels reflect poor tissue oxygen delivery noted in all forms of shock.*

Treatment

Initial Management

Early recognition and prompt intervention are extremely important in the management of all forms of shock (Tables 88.8 to 88.12 ; see Figs. 88.1 and 88.2). *The vital sign targets and dose recommendations in Tables 88.9 to 88.12 should be adjusted to pediatric-size patients.* Baseline mortality is much lower in pediatric shock than in adult shock, and further improvements in mortality are associated with early interventions (see Fig. 81.1). The initial assessment and treatment of the pediatric shock patient should include stabilization of airway, breathing, and circulation as established by the American Heart Association's pediatric advanced life support and neonatal advanced life support guidelines (see Chapter 81). Depending on the severity of shock, further airway intervention, including intubation and mechanical ventilation, may be necessary to lessen the work of breathing and decrease the body's overall metabolic demands.

Table 88.8

Goal-Directed Therapy of Organ System Dysfunction in

Shock

SYSTEM	DISORDERS	GOALS	THERAPIES
Respiratory	Acute respiratory distress syndrome	Prevent/treat: hypoxia and respiratory acidosis	Oxygen Noninvasive ventilation
	Respiratory muscle fatigue Central apnea	Prevent barotrauma Decrease work of breathing	Early endotracheal intubation and mechanical ventilation
			Positive end-expiratory pressure (PEEP) Permissive hypercapnia High-frequency ventilation Extracorporeal membrane oxygenation (ECMO)
Renal	Prerenal failure Renal failure	Prevent/treat: hypovolemia, hypervolemia, hyperkalemia, metabolic acidosis, hypernatremia/hyponatremia, and hypertension Monitor serum electrolytes	Judicious fluid resuscitation Establishment of normal urine output and blood pressure for age Furosemide (Lasix) Dialysis, ultrafiltration, hemofiltration
Hematologic	Coagulopathy (disseminated intravascular coagulation)	Prevent/treat: bleeding	Vitamin K Fresh-frozen plasma Platelets
	Thrombosis	Prevent/treat: abnormal clotting	Heparinization
Gastrointestinal	Stress ulcers Ileus	Prevent/treat: gastric bleeding Avoid aspiration, abdominal distention	Histamine H_2 -receptor–blocking agents or proton pump inhibitors Nasogastric tube
	Bacterial translocation	Avoid mucosal atrophy	Early enteral feedings
Endocrine	Adrenal insufficiency, primary or secondary to chronic steroid therapy	Prevent/treat: adrenal crisis	Stress-dose steroids in patients previously given steroids Physiologic dose for presumed primary insufficiency in sepsis
Metabolic	Metabolic acidosis	Correct etiology Normalize pH	Treatment of hypovolemia (fluids), poor cardiac function (fluids, inotropic agents) Improvement of renal acid excretion Low-dose (0.5-2.0 mEq/kg) sodium bicarbonate if patient is not showing response, pH <7.1, and ventilation (CO_2 elimination) is adequate

Table 88.9

Recommendations for Shock: Initial Resuscitation and Infection Issues—Adults

Initial Resuscitation

1. Protocolized, quantitative resuscitation of patients with sepsis-induced tissue hypoperfusion (defined as hypotension persisting after initial fluid challenge or blood lactate concentration ≥4 mmol/L). Goals during the 1st 6 hr of resuscitation:
    a. Central venous pressure 8-12 mm Hg
    b. Mean arterial pressure (MAP) ≥65 mm Hg
    c. Urine output ≥0.5 mL kg^{-1} hr
    d. Central venous (superior vena cava) or mixed venous oxygen saturation: 70% or 65%, respectively
2. In patients with elevated lactate levels, targeting resuscitation to normalize lactate as rapidly as possible.

Screening for Sepsis and Performance Improvement

1. Routine screening of potentially infected seriously ill patients for severe sepsis to allow earlier implementation of therapy.
2. Hospital-based performance improvement efforts in severe sepsis.

Diagnosis

1. Cultures as clinically appropriate before antimicrobial therapy if no significant delay (>45 min) in the start of antimicrobial(s). At least 2 sets of blood cultures (both aerobic and anaerobic bottles) should be obtained before antimicrobial therapy with at least 1 drawn percutaneously and 1 drawn through each vascular access device, unless the device was recently (<48 hr) inserted.
2. Use of the 1,3 β-D -glucan assay, mannan and antimannan antibody assays, if available, and invasive candidiasis is in differential diagnosis of cause of infection.
3. Imaging studies performed promptly to confirm a potential source of infection.

Antimicrobial Therapy

1. Administration of effective intravenous antimicrobials within the 1st hr of

recognition of septic shock and severe sepsis without septic shock as the goal of therapy.

2a. Initial empirical antiinfective therapy of 1 or more drugs that have activity against all likely pathogens (bacterial and/or fungal or viral) and that penetrate in adequate concentrations into tissues presumed to be the source of sepsis.

2b. Antimicrobial regimen should be reassessed daily for potential deescalation.

3. Use of low procalcitonin levels or similar biomarkers to assist the clinician in the discontinuation of empirical antibiotics in patients who initially appeared septic, but have no subsequent evidence of infection.

4a. Combination empirical therapy for neutropenic patients with severe sepsis and for patients with difficult-to-treat, multidrug-resistant bacterial pathogens such as *Acinetobacter* and *Pseudomonas* spp.

    For patients with severe infections associated with respiratory failure and septic shock, combination therapy with an extended-spectrum β-lactam and either an aminoglycoside or a fluoroquinolone is for *Pseudomonas aeruginosa* bacteremia. A combination of β-lactam and macrolide for patients with septic shock from bacteremic *Streptococcus pneumoniae* infections.

4b. Empirical combination therapy should not be administered for more than 3-5 days. Deescalation to the most appropriate single therapy should be performed as soon as the susceptibility profile is known.

5. Duration of therapy typically 7-10 days; longer courses may be appropriate in patients who have a slow clinical response, undrainable foci of infection, bacteremia with *Staphylococcus aureus* , some fungal and viral infections, or immunodeficiencies (e.g., neutropenia).

6. Antiviral therapy initiated as early as possible in patients with severe sepsis or septic shock of viral origin.

7. Antimicrobial agents should *not* be used in patients with severe inflammatory states determined to be of noninfectious cause.

Source Control

1. A specific anatomic diagnosis of infection requiring consideration for

emergent source control should be sought and diagnosed or excluded as rapidly as possible, and intervention undertaken for source control within the 1st 12 hr after the diagnosis is made, if feasible.
2. When infected peripancreatic necrosis is identified as a potential source of infection, definitive intervention is best delayed until adequate demarcation of viable and nonviable tissues has occurred.
3. When source control in a severely septic patient is required, the effective intervention associated with the least physiologic insult should be used (e.g., percutaneous rather than surgical drainage of an abscess).
4. If intravascular access devices are a possible source of severe sepsis or septic shock, these should be removed promptly after other vascular access has been established.

Infection Prevention

1a. Selective oral decontamination and selective digestive decontamination should be introduced and investigated as a method to reduce the incidence of ventilator-associated pneumonia; this infection control measure can then be instituted in healthcare settings and regions where this methodology is found to be effective.

1b. Oral chlorhexidine gluconate be used as a form of oropharyngeal decontamination to reduce the risk of ventilator-associated pneumonia in ICU patients with severe sepsis.

Adapted from Dellinger PR, Levy MM, Rhodes A, et al: Surviving sepsis campaign: International guidelines for management of severe sepsis and septic shock: 2012, *Crit Care Med* 41(2):580–637, 2013 (Table 5, p 589).

Table 88.10

Surviving Sepsis Campaign: Care Bundles

To be completed within 3 hr:

1. Measure lactate level.
2. Obtain blood cultures before administration of antibiotics.
3. Administer broad-spectrum antibiotics.
4. Administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L.

To completed within 6 hr:

5. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) ≥65 mm Hg.
6. In the event of persistent arterial hypotension despite volume resuscitation (septic shock) or initial lactate ≥4 mmol/L (36 mg/dL):
    Measure central venous pressure (CVP).*
    Measure central venous oxygen saturation ($ScvO_2$).*
7. Remeasure lactate if initial lactate was elevated.*

---

[*] Targets for quantitative resuscitation included in the guidelines are CVP of ≥8 mm Hg, $ScvO_2$ of ≥70%, and normalization of lactate.

Adapted from Dellinger PR, Levy MM, Rhodes A, et al: Surviving Sepsis campaign: international guidelines for management of severe sepsis and septic shock: 2012. *Crit Care Med* 41(2):580–637, 2013 (Fig 1, p 591).

Table 88.11

Recommendations for Shock: Hemodynamic Support and Adjunctive Therapy—Adults

Fluid Therapy of Severe Sepsis

1. Crystalloids as the initial fluid of choice in the resuscitation of severe sepsis and septic shock.
2. Against the use of hydroxyethyl starches for fluid resuscitation of severe sepsis and septic shock.
3. Albumin in the fluid resuscitation of severe sepsis and septic shock when patients require substantial amounts of crystalloids.
4. Initial fluid challenge in patients with sepsis-induced tissue hypoperfusion with suspicion of hypovolemia, to achieve a minimum of 30 mL/kg of crystalloids (a portion of this may be albumin equivalent). More rapid administration and greater amounts of fluid may be needed in some patients.
5. Fluid challenge technique be applied in which fluid administration is continued as long as there is hemodynamic improvement either based on

dynamic (e.g., change in pulse pressure, stroke volume variation) or static (e.g., arterial pressure, heart rate) variables.

Vasopressors

1. Vasopressor therapy initially to target a mean arterial pressure (MAP) of 65 mm Hg.
2. Norepinephrine as the first-choice vasopressor.
3. Epinephrine (added to and potentially substituted for norepinephrine) when an additional agent is needed to maintain adequate blood pressure.
4. Vasopressin 0.03 units/min can be added to norepinephrine (NE) with intent of either raising MAP or decreasing NE dosage.
5. Low-dose vasopressin is not recommended as the single initial vasopressor for treatment of sepsis-induced hypotension, and vasopressin doses >0.03-0.04 units/min should be reserved for salvage therapy (failure to achieve adequate MAP with other vasopressor agents).
6. Dopamine as an alternative vasopressor agent to NE only in highly selected patients (e.g., with low risk of tachyarrhythmias and absolute or relative bradycardia).
7. Phenylephrine is not recommended in the treatment of septic shock except in circumstances where (a) NE is associated with serious arrhythmias, (b) cardiac output is known to be high and blood pressure persistently low, or (c) as salvage therapy when combined inotrope/vasopressor drugs and low-dose vasopressin have failed to achieve MAP target.
8. Low-dose dopamine should not be used for renal protection.
9. All patients requiring vasopressors have an arterial catheter placed as soon as practical if resources are available.

Inotropic Therapy

1. A trial of dobutamine infusion up to 20 µg/kg/min be administered or added to vasopressor (if in use) in the presence of (a) myocardial dysfunction as suggested by elevated cardiac filling pressures and low cardiac output, or (b) ongoing signs of hypoperfusion, despite achieving adequate intravascular volume and adequate MAP.
2. Not using a strategy to increase cardiac index to predetermined

supranormal levels.

Corticosteroids

1. Not using intravenous hydrocortisone to treat adult septic shock patients, if adequate fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability (see goals for Initial Resuscitation). In the event this is not achievable, we suggest IV hydrocortisone alone at a dose of 200 mg/day.
2. Not using the ACTH stimulation test to identify adults with septic shock who should receive hydrocortisone.
3. In treated patients, hydrocortisone tapered when vasopressors are no longer required.
4. Corticosteroids should *not* be administered for the treatment of sepsis in the absence of shock.
5. When hydrocortisone is given, use continuous flow.

Adapted from Dellinger PR, Levy MM, Rhodes A, et al: Surviving Sepsis campaign: international guidelines for management of severe sepsis and septic shock: 2012, *Crit Care Med* 41(2):580–637, 2013 (Table 6, p 596).

Table 88.12

Recommendations for Shock: Special Considerations in Pediatric Patients

Initial Resuscitation

1. For respiratory distress and hypoxemia, start with face mask oxygen or, if needed and available, high-flow nasal cannula oxygen or nasopharyngeal CPAP (NP CPAP). For improved circulation, peripheral intravenous access or intraosseous access can be used for fluid resuscitation and inotrope infusion when a central line is not available. If mechanical ventilation is required, cardiovascular instability during intubation is less likely after appropriate cardiovascular resuscitation.
2. Initial therapeutic end-points of resuscitation of septic shock: capillary refill of ≤2 sec, normal blood pressure for age, normal pulses with no

differential between peripheral and central pulses, warm extremities, urine output >1 mL kg^{-1} hr^{-1} , and normal mental status. Scv_{O_2} saturation ≥70% and cardiac index between 3.3 and 6.0 L/min/m^2 should be targeted thereafter.
3. Follow American College of Critical Care Medicine–Pediatric Advanced Life Support (ACCM-PALS) guidelines for the management of septic shock.
4. Evaluate for and reverse pneumothorax, pericardial tamponade, or endocrine emergencies in patients with refractory shock.

Antibiotics and Source Control

1. Empirical antibiotics should be administered within 1 hr of the identification of severe sepsis. Blood cultures should be obtained before administering antibiotics when possible, but this should not delay administration of antibiotics. The empirical drug choice should be changed as epidemic and endemic ecologies dictate (e.g., H1N1, methicillin-resistant *Staphylococcus aureus* [MRSA], chloroquine-resistant malaria, penicillin-resistant pneumococci, recent ICU stay, neutropenia).
2. Clindamycin and antitoxin therapies for toxic shock syndromes with refractory hypotension.
3. Early and aggressive source control.
4. *Clostridium difficile* colitis should be treated with enteral antibiotics if tolerated. Oral vancomycin is preferred for severe disease.

Fluid Resuscitation

1. In the industrialized world with access to inotropes and mechanical ventilation, initial resuscitation of hypovolemic shock begins with infusion of isotonic crystalloids or albumin with boluses of up to 20 mL/kg crystalloids (or albumin equivalent) over 5-10 min, titrated to reversing hypotension, increasing urine output, and attaining normal capillary refill, peripheral pulses, and level of consciousness without inducing hepatomegaly or rales. If hepatomegaly or rales present, inotropic support should be implemented, not fluid resuscitation. In

nonhypotensive children with severe hemolytic anemia (severe malaria or sickle cell crises), blood transfusion is considered superior to crystalloid or albumin bolus.

Inotropes, Vasopressors, and Vasodilators

1. Begin peripheral inotropic support until central venous access can be attained in children who are not responsive to fluid resuscitation.
2. Patients with low cardiac output and elevated systemic vascular resistance states with normal blood pressure should be given vasodilator therapies in addition to inotropes.

Extracorporeal Membrane Oxygenation

1. Consider ECMO for refractory pediatric septic shock and respiratory failure.

Corticosteroids

1. Timely hydrocortisone therapy in children with fluid-refractory, catecholamine-resistant shock and suspected or proven absolute (classic) adrenal insufficiency.

Protein C and Activated Protein Concentrate

No recommendations (no longer available).

Blood Products and Plasma Therapies

1. Similar hemoglobin targets in children as in adults. During resuscitation of low superior vena cava oxygen saturation shock (<70%), hemoglobin levels of 10 g/dL are targeted. After stabilization and recovery from shock and hypoxemia, a lower target (>7.0 g/dL) can be considered reasonable.
2. Similar platelet transfusion targets in children as in adults.

3. Use plasma therapies in children to correct sepsis-induced thrombotic purpura disorders, including progressive disseminated intravascular coagulation, secondary thrombotic microangiopathy, and thrombotic thrombocytopenic purpura.

Mechanical Ventilation

1. Lung-protective strategies during mechanical ventilation.

Sedation, Analgesia, and Drug Toxicities

1. We recommend use of sedation with a sedation goal in critically ill, mechanically ventilated patients with sepsis.
2. Monitor drug toxicity lab results because drug metabolism is reduced during severe sepsis, putting children at greater risk of adverse drug-related events.

Glycemic Control

1. Control hyperglycemia using a similar target as in adults (≤180 mg/dL). Glucose infusion should accompany insulin therapy in newborns and children because some hyperglycemic children make no insulin whereas others are insulin resistant.

Diuretics and Renal Replacement Therapy

1. Use diuretics to reverse fluid overload when shock has resolved, and if unsuccessful, use continuous venovenous hemofiltration (CVVH) or intermittent dialysis to prevent >10% total body weight fluid overload.

Deep Vein Thrombosis (DVT) Prophylaxis

No recommendation on the use of DVT prophylaxis in prepubertal children with severe sepsis.

Stress Ulcer (SU) Prophylaxis

No recommendation on the use of SU prophylaxis in prepubertal children with severe sepsis.

Nutrition

1. Enteral nutrition given to children who can be fed enterally, and parenteral feeding in those who cannot (grade 2C).

CPAP, Continuous positive airway pressure.

Adapted from Dellinger PR, Levy MM, Rhodes A, et al: Surviving Sepsis campaign: *I* nternational guidelines for management of severe sepsis and septic shock: 2012, *Crit Care Med* 41(2):580–637, 2013 (Table 9, p 614).

Given the predominance of sepsis and hypovolemia as the most common causes of shock in the pediatric population, most therapeutic regimens are based on guidelines established in these settings. Immediately following establishment of intravenous (IV) or intraosseous (IO) access, aggressive, early goal-directed therapy should be initiated unless there are significant concerns for cardiogenic shock as an underlying pathophysiology. Rapid IV administration of 20 mL/kg isotonic fluid should be initiated to reverse the shock state. This bolus should be repeated quickly up to 60-80 mL/kg; it is not unusual for severely affected patients to require this volume within the 1st 3 hr of treatment.

Rapid fluid resuscitation totaling 60-80 mL/kg or more is associated with improved survival without an increased incidence of pulmonary edema. Fluid resuscitation in increments of 20 mL/kg should be titrated to normalize HR (according to age-based HRs), urine output (to 1 mL/kg/hr), capillary refill time (to <2 sec), and mental status. If shock remains refractory following 60-80 mL/kg of volume resuscitation, vasopressor therapy (e.g., norepinephrine, epinephrine) should be instituted while additional fluids are administered. Pediatric guidelines for septic shock unresponsive to fluid resuscitation suggest epinephrine (Fig. 88.2) or dopamine (Fig. 88.1), whereas adult guidelines recommend norepinephrine.

Fluid resuscitation may sometimes require as much as 200 mL/kg or greater. It must be stressed that hypotension is often a late and ominous finding, and BP normalization alone is not a reliable end-point for assessing the effectiveness of resuscitation. Although the type of fluid (crystalloid vs colloid) is an area of ongoing debate, fluid resuscitation (usually crystalloid) in the 1st hr is unquestionably essential to survival in septic shock, regardless of the fluid type administered.

Additional Early Considerations

In **septic shock** specifically, early (*within 1 hr*) administration of broad-spectrum antimicrobial agents is associated with a reduction in mortality. The choice of antimicrobial agents depends on the predisposing risk factors and the clinical situation. Bacterial resistance patterns in the community and/or hospital should be considered in the selection of optimal antimicrobial therapy. Neonates should be treated with ampicillin plus cefepime and/or gentamicin. Acyclovir should be added if herpes simplex virus is suspected clinically. In infants and children, community-acquired infections with *Neisseria meningitidis* can initially be treated empirically with a third-generation cephalosporin (e.g., ceftriaxone, cefepime), as can *Haemophilus influenzae* infections. The prevalence of resistant *Streptococcus pneumoniae* requires the addition of vancomycin. Suspicion of community- or hospital-acquired, methicillin-resistant *Staphylococcus aureus* (MRSA) infection warrants coverage with vancomycin, depending on local resistance patterns. If an intraabdominal process is suspected, anaerobic coverage should be included with an agent such as metronidazole, clindamycin, or piperacillin-tazobactam.

Nosocomial sepsis should generally be treated with at least a third- or fourth-generation cephalosporin or a penicillin with an extended gram-negative spectrum (e.g., piperacillin-tazobactam). An aminoglycoside should be added as the clinical situation warrants. Vancomycin should be added to the regimen if the patient has an indwelling medical device (see Chapter 206), if gram-positive cocci are isolated from the blood, if MRSA infection is suspected, or as empirical coverage for *S. pneumoniae* in a patient with meningitis. Empirical coverage for fungal infections should be considered for selected immunocompromised patients (see Chapter 205). It should be noted that these are broad, generalized recommendations that must be tailored to the individual clinical scenario and to the local resistance patterns of the community and hospital.

Distributive shock that is not secondary to sepsis is caused by a primary abnormality in vascular tone. Cardiac output in affected patients is usually maintained and may initially be supranormal. These patients may benefit temporarily from volume resuscitation, but the early initiation of a vasoconstrictive agent to increase SVR is an important element of clinical care. Patients with spinal cord injury and spinal shock may benefit from either phenylephrine or vasopressin to increase SVR; epinephrine is the treatment of choice for patients with anaphylaxis (Table 88.13). Epinephrine has peripheral α-adrenergic as well as inotropic effects that may improve the myocardial depression seen with anaphylaxis and its associated inflammatory response (see Chapter 174).

Table 88.13

Cardiovascular Drug Treatment of Shock

DRUG	EFFECT(S)	DOSING RANGE	COMMENT(S)
Dopamine	↑ Cardiac contractility Significant peripheral vasoconstriction at >10 μg/kg/min	3-20 μg/kg/min	↑ Risk of arrhythmias at high doses
Epinephrine	↑ Heart rate and ↑ cardiac contractility Potent vasoconstrictor	0.05-3.0 μg/kg/min	May ↓ renal perfusion at high doses ↑ Myocardial O_2 consumption Risk of arrhythmia at high doses
Dobutamine	↑ Cardiac contractility Peripheral vasodilator	1-10 μg/kg/min	—
Norepinephrine	Potent vasoconstriction No significant effect on cardiac contractility	0.05-1.5 μg/kg/min	↑ Blood pressure secondary to ↑ systemic vascular resistance ↑ Left ventricular afterload
Phenylephrine	Potent vasoconstriction	0.5-2.0 μg/kg/min	Can cause sudden hypertension ↑ O_2 consumption

Patients with **cardiogenic shock** have poor cardiac output secondary to systolic and/or diastolic myocardial depression, often with a compensatory elevation in SVR. These patients may show poor response to fluid resuscitation and may decompensate quickly when fluids are administered. Smaller boluses of fluid (5-10 mL/kg) should be given in cardiogenic shock to replace deficits and maintain preload. In any patient with shock whose clinical status deteriorates with fluid resuscitation, a cardiogenic etiology should be considered, and further administration of IV fluids should be provided judiciously. Early initiation of myocardial support with epinephrine or dopamine to improve cardiac output is important in this context, and early consideration should be given to administration of an inodilator, such as milrinone.

Despite adequate cardiac output with the support of inotropic agents, a high SVR with poor peripheral perfusion and acidosis may persist in cardiogenic shock. Therefore, if not already started, milrinone therapy may improve systolic function and decrease SVR without causing a significant increase in HR. Furthermore, this agent has the added benefit of enhancing diastolic relaxation. Dobutamine or other vasodilating agents, such as nitroprusside, may also be considered in this setting (Table 88.14). Titration of these agents should target clinical end-points, including increased urine output, improved peripheral perfusion, resolution of acidosis, and normalization of mental status. Even though they may be beneficial in other forms of shock, agents that improve BP by increasing SVR, such as norepinephrine and vasopressin, should generally be avoided in patients with cardiogenic shock. These agents may cause further decompensation and potentially precipitate cardiac arrest as a result of the increased afterload and additional work imposed on the myocardium. The combination of inotropic and vasoactive agents must be tailored to the pathophysiology of the individual patient with close and frequent reassessment of the patient's cardiovascular status.

Table 88.14

Vasodilators/Afterload Reducers in Treatment of Shock

DRUG	EFFECT(S)	DOSING RANGE	COMMENT(S)
Nitroprusside	Vasodilator (mainly arterial)	0.5-4.0 μg/kg/min	Rapid effect Risk of cyanide toxicity with prolonged use (>96 hr)
Nitroglycerin	Vasodilator (mainly venous)	1-20 μg/kg/min	Rapid effect Risk of increased intracranial pressure
Prostaglandin E_1	Vasodilator Maintains an open ductus arteriosus in the newborn with ductal-dependent congenital heart disease	0.01-0.2 μg/kg/min	Can lead to hypotension Risk of apnea
Milrinone	Increased cardiac contractility	Load 50 μg/kg over 15 min	Phosphodiesterase inhibitor—slows cyclic adenosine monophosphate breakdown
	Improves cardiac diastolic function Peripheral vasodilation	0.5-1.0 μg/kg/min	

For patients with **obstructive shock** , fluid resuscitation may be briefly temporizing in maintaining cardiac output, but the primary insult must be immediately addressed. Examples of lifesaving therapeutic interventions for such patients are pericardiocentesis for pericardial effusion, pleurocentesis or chest tube placement for pneumothorax, thrombectomy/thrombolysis for pulmonary embolism, and the initiation of a prostaglandin infusion for ductus-dependent cardiac lesions. There is often a *last-drop phenomenon* associated with some obstructive lesions, in that small additional amounts of intravascular volume depletion may lead to a rapid deterioration, including cardiac arrest, if the obstructive lesion is not corrected.

Regardless of the etiology of shock, metabolic status should be meticulously maintained (see Table 88.8). Electrolyte levels should be monitored closely and corrected as needed. Hypoglycemia is common and should be promptly treated. Neonates and infants in particular may have profound glucose dysregulation in association with shock. Glucose levels should be checked routinely and treated appropriately, especially early in the course of illness. Hypocalcemia, which may contribute to myocardial dysfunction, should be treated with a goal of normalizing the ionized calcium concentration. There is no evidence that supranormal calcium levels benefit the myocardium, and hypercalcemia may be associated with increased myocardial toxicity.

Adrenal function is another important consideration in shock, and hydrocortisone replacement may be beneficial. Up to 50% of critically ill patients may have absolute or relative adrenal insufficiency. Patients at risk for adrenal insufficiency include those with congenial adrenal hypoplasia, abnormalities of the hypothalamic-pituitary axis, and recent therapy with corticosteroids (including those with asthma, rheumatic diseases, malignancies, and inflammatory bowel disease). These patients are at high risk for adrenal dysfunction and should receive stress doses of hydrocortisone. *Corticosteroids may also be considered in patients with shock that is unresponsive to fluid resuscitation and catecholamines.* Although a subset of pediatric septic shock patients may benefit from treatment with hydrocortisone, currently available pediatric data do not demonstrate an overall survival benefit in patients with shock treated with hydrocortisone. Determination of baseline cortisol levels before corticosteroid administration may be beneficial in guiding therapy, although this approach remains controversial.

Considerations for Continued Therapy

After the 1st hr of therapy and attempts at early reversal of shock, focus on goal-directed end-points should continue in an intensive care setting (see Figs. 88.1 and 88.2 and Table 88.8). Clinical end-points serve as global markers for organ perfusion and oxygenation. Laboratory parameters such as SvO_2 (or $ScvO_2$), serum lactate concentration, cardiac index, and hemoglobin serve as adjunctive measures of tissue oxygen delivery. Hemoglobin should be generally maintained at 10 g/dL, SvO_2 (or $ScvO_2$) >70%, and cardiac index at 3.3-6.0 L/min/m^2 to optimize oxygen delivery in the acute phase of shock. It is important to note that cardiac index is rarely monitored in the clinical setting because of the limited use of pulmonary artery catheters and lack of accurate noninvasive cardiac output monitors for infants and children. Blood lactate levels and calculation of base deficit from arterial blood gas values are very useful markers for the adequacy of oxygen delivery. These traditional markers are indicators of global oxygen utilization and delivery. There is increasing use of measures of local tissue oxygenation, including near-infrared spectroscopy of the cerebrum, flank, or abdomen.

Respiratory support should be used as clinically appropriate. When shock leads to ARDS requiring mechanical ventilation, lung-protective strategies to keep plateau pressure <30 cm H_2O and maintain tidal volume at 6 mL/kg have been shown to improve mortality in adult patients (see Chapter 89). These data are extrapolated to pediatric patients because of the lack of definitive pediatric studies in this area. Additionally, after the initial shock state has been reversed, data demonstrate that judicious fluid administration, renal replacement therapy, and fluid removal may also be useful in children with anuria or oliguria and fluid overload (see Chapter 550). Other interventions include correction of coagulopathy with fresh-frozen plasma or cryoprecipitate and platelet transfusions as necessary, especially in the presence of active bleeding.

If shock remains refractory despite maximal therapeutic interventions, mechanical support with **extracorporeal membrane oxygenation** (ECMO) or a **ventricular assist device** (VAD) may be indicated. ECMO may be lifesaving in cases of refractory shock regardless of underlying etiology. Similarly, a VAD may be indicated for refractory cardiogenic shock in the setting of cardiomyopathy or recent cardiac surgery. Systemic anticoagulation, which is required while patients are receiving mechanical support, may be difficult, given the significant coagulopathy often encountered in refractory shock, especially when the underlying etiology is sepsis. Mechanical support in refractory shock poses substantial risks but can improve survival in specific populations of

patients.

Prognosis

In septic shock, mortality rates are as low as 3% in previously healthy children and 6–9% in children with chronic illness (compared with 25–30% in adults). With early recognition and therapy, the mortality rate for pediatric shock continues to improve, but shock and MODS remain one of the leading causes of death in infants and children. The risk of death involves a complex interaction of factors, including the underlying etiology, presence of chronic illness, host immune response, and timing of recognition and therapy.

CHAPTER 89

Respiratory Distress and Failure

Ashok P. Sarnaik, Jeff A. Clark, Sabrina M. Heidemann

The term *respiratory distress* is used to indicate signs and symptoms of abnormal respiratory pattern. A child with nasal flaring, tachypnea, chest wall retractions, stridor, grunting, dyspnea, and wheezing has respiratory distress. Taken together, the magnitude of these findings is used to judge clinical severity. Nasal flaring is nonspecific, but the other signs are useful in localizing the site of pathology (see Chapter 400). *Respiratory failure* is defined as inability of the lungs to provide sufficient oxygen (hypoxic respiratory failure) or remove carbon dioxide (ventilator failure) to meet metabolic demands. Therefore, whereas respiratory distress is determined by a clinical impression, the diagnosis of respiratory failure is indicated by inadequacy of oxygenation or of ventilation, or both. Respiratory distress can occur in patients without respiratory disease, and respiratory failure can occur in patients without respiratory distress.

Respiratory Distress

A careful physical examination must be performed when managing a child in respiratory distress. **Nasal flaring** , although nonspecific, is an extremely important sign of distress in infants. It may indicate discomfort, pain, fatigue, or breathing difficulty. The state of **responsiveness** is another crucial sign. Lethargy, disinterest in surroundings, and poor cry are suggestive of exhaustion, hypercarbia, and impending respiratory failure. Abnormalities of the rate and depth of **breathing** can occur with both pulmonary and nonpulmonary causes of respiratory distress. In diseases of decreased lung compliance, such as pneumonia and pulmonary edema, breathing is characteristically rapid and shallow (decreased tidal volume). In obstructive airway diseases, such as asthma and laryngotracheitis, breathing is deep with increased tidal volume, but less rapid. Rapid and deep breathing without other respiratory signs should alert the physician to possible nonpulmonary or nonthoracic causes of respiratory distress, such as response to metabolic acidosis (e.g., diabetic ketoacidosis, renal tubular acidosis) or stimulation of the respiratory center (e.g., encephalitis, ingestion of central nervous system stimulants). Chest wall, suprasternal, and subcostal **retractions** are manifestations of increased inspiratory effort, weak chest wall, or both. Inspiratory **stridor** indicates airway obstruction above the thoracic inlet, whereas expiratory wheezing results from airway obstruction below the thoracic inlet. **Grunting** is most commonly heard in diseases with decreased functional residual capacity (e.g., pneumonia, pulmonary edema) and peripheral airway obstruction (e.g., bronchiolitis).

Respiratory Disease Manifesting as Respiratory Distress

Clinical examination is important in localizing the site of pathology (see Chapter 400). Extrathoracic airway obstruction occurs anywhere above the thoracic inlet. Inspiratory stridor, suprasternal, chest wall, and subcostal retractions; and prolongation of inspiration are hallmarks of extrathoracic airway obstruction. By comparison, features of intrathoracic airway obstruction are prolongation of expiration and expiratory wheezing. Typical manifestations of alveolar interstitial pathology are rapid, shallow respirations, chest wall retractions, and grunting. The site of pathology can be localized and the differential diagnosis established on the basis of the clinical signs and symptoms (Tables 89.1 and 89.2).

Table 89.1

Typical Localizing Signs for Pulmonary Pathology

SITE OF PATHOLOGY	RESPIRATORY RATE	RETRACTIONS	AUDIBLE SOUNDS
Extrathoracic airway	↑	↑↑↑↑	Stridor
Intrathoracic extrapulmonary	↑	↑↑	Wheezing
Intrathoracic intrapulmonary	↑↑	↑↑	Wheezing
Alveolar interstitial	↑↑↑	↑↑↑	Grunting

Table 89.2

Examples of Anatomic Sites of Lesions Causing

Respiratory Failure

LUNG	**RESPIRATORY PUMP**
CENTRAL AIRWAY OBSTRUCTION	**THORACIC CAGE**

	NEUROMUSCULAR
	Phrenic nerve injury Birth trauma Infant botulism Guillain-Barré syndrome Muscular dystrophy Myasthenia gravis Organophosphate poisoning

ARDS, Acute respiratory distress syndrome; CNS, central nervous system.

Respiratory Distress Without Respiratory Disease

Although respiratory distress most frequently results from diseases of lungs, airways, and chest wall, pathology in other organ systems can manifest as respiratory distress and lead to misdiagnosis and inappropriate management (Table 89.3). Respiratory distress resulting from heart failure or diabetic ketoacidosis may be misdiagnosed as asthma and improperly treated with albuterol, resulting in worsened hemodynamic state or ketoacidosis. Careful history and physical examination provide essential clues in avoiding misdiagnosis.

Table 89.3

Nonpulmonary Causes of Respiratory Distress

SYSTEM	EXAMPLE(S)	MECHANISM(S)
Cardiovascular	Left-to-right shunt Congestive heart failure Cardiogenic shock	↑ Pulmonary blood/water content Metabolic acidosis Baroreceptor stimulation
Central nervous	Increased intracranial pressure Encephalitis Neurogenic pulmonary edema Toxic encephalopathy	Stimulation of brainstem respiratory centers
Metabolic	Diabetic ketoacidosis Organic acidemia Hyperammonemia	Stimulation of central and peripheral chemoreceptors
Renal	Renal tubular acidosis	Stimulation of central and peripheral chemoreceptors
	Hypertension	Left ventricular dysfunction → increased pulmonary blood/water content
Sepsis	Toxic shock syndrome Meningococcemia	Cytokine stimulation of respiratory centers Baroreceptor stimulation from shock Metabolic acidosis

Cardiovascular Disease Manifesting as Respiratory Distress

A child with cardiovascular pathology may present with respiratory distress caused by either *decreased lung compliance* or *cardiogenic shock* (Table 89.4). Diseases that result in increased pulmonary arterial blood flow (e.g., left-to-right shunts) or increased pulmonary venous pressure (e.g., left ventricular dysfunction from hypertension or myocarditis, obstructed total anomalous pulmonary venous return) cause an increase in pulmonary capillary pressure and transudation of fluid into the pulmonary interstitium and alveoli. The increased pulmonary blood and water content lead to decreased lung compliance and result in rapid shallow breathing.

Table 89.4

Cardiovascular Pathology Manifesting as

Respiratory Distress

- I. **Decreased lung compliance**
  - A. Left-to-right shunts
    - 1. Ventricular septal defect, atrial septal defect, patent ductus arteriosus, atrioventricular canal, truncus arteriosus
    - 2. Cerebral or hepatic arteriovenous fistula
  - B. Ventricular failure
    - 1. Left heart obstructive lesions
      - a. Aortic stenosis
      - b. Coarctation of the aorta
      - c. Mitral stenosis
      - d. Interrupted aortic arch
      - e. Hypoplastic left heart syndrome
    - 2. Myocardial infarction
      - a. Anomalous left coronary artery arising from the pulmonary artery
    - 3. Hypertension
      - a. Acute glomerulonephritis
    - 4. Inflammatory/infectious
      - a. Myocarditis
      - b. Pericardial effusion
    - 5. Idiopathic
      - a. Dilated cardiomyopathy
      - b. Hypertrophic obstructive cardiomyopathy
  - C. Pulmonary venous obstruction
    - 1. Total anomalous pulmonary venous return with obstruction
    - 2. Cor triatriatum
- II. **Shock resulting in metabolic acidosis**
  - A. Left heart obstructive lesions
  - B. Acute ventricular failure
    - 1. Myocarditis, myocardial infarction

It is important to recognize that interstitial lung edema cannot only manifest as alveolar fluid, but as small airway obstruction as well. **Wheezing** as a sign of congestive cardiac disease is common in infants and young children and should be recognized. Patients with cardiac lesions, resulting in low cardiac output, often present in shock. For example, obstructive lesions of left side of the heart and acquired or congenital cardiomyopathy result in decreased perfusion and metabolic acidosis, as well as respiratory distress because of chemoreceptor and baroreceptor stimulation. The likelihood of a particular cardiovascular illness manifesting as respiratory distress depends on age at presentation (Table 89.5).

Table 89.5

Typical Chronology of Heart Disease Presentation in Children

AGE	MECHANISM	DISEASE
Newborn (1-10 days)	↑ Arteriovenous pressure difference	Arteriovenous fistula (brain, liver)
	Ductal closure	Single ventricle lesions or severe ventricular outflow obstruction
	Independent pulmonary and systemic blood flow	Transposition of the great arteries
	Pulmonary venous obstruction	Total anomalous pulmonary venous return (TAPVR)
Young infant (1-6 mo)	↓ Pulmonary vascular resistance	Left-to-right shunt
	↓ Pulmonary artery pressure	Anomalous left coronary artery to the pulmonary artery
Any age	Rate disturbance	Tachy- or bradyarrhythmias
	Infection	Myocarditis, pericarditis
	Abnormal cardiac myocytes	Cardiomyopathy
	Excess afterload	hypertension

Neurologic Disease Manifesting as Respiratory Distress

Central nervous system (CNS) dysfunction can lead to alterations in respiratory patterns and manifest as respiratory distress. Increased intracranial pressure (ICP) may manifest as respiratory distress. Early rise in intracranial pressure (ICP) results in stimulation of respiratory centers, leading to increases in the rate (**tachypnea**) and depth (**hyperpnea**) of respiration. The resultant decrease in arterial blood partial pressure of carbon dioxide (Pa_{CO_2}) and elevation of cerebrospinal fluid (CSF) pH lead to cerebral vasoconstriction and amelioration of intracranial hypertension. Stereotypical respiratory patterns are associated with dysfunction at multiple levels of the brain. Cerebral hemisphere and midbrain lesions result in hyperpnea as well as tachypnea. In such situations, arterial blood gas (ABG) measurements typically show respiratory alkalosis without hypoxemia. Pathology affecting the pons and medulla manifests as irregular breathing patterns such as **apneustic breathing** (prolonged inspiration with brief expiratory periods), **Cheyne-Stokes breathing** (alternate periods of rapid and slow breathing), and irregular, ineffective breathing or apnea (Table 89.6). Along with respiratory changes, other manifestations of CNS dysfunction and increased ICP may be present, such as focal neurologic signs, pupillary changes, hypertension, and bradycardia (see Chapter 85). Occasionally, severe CNS dysfunction can result in **neurogenic pulmonary edema** and respiratory distress, which may follow excessive sympathetic discharge resulting in increased pulmonary venous hydrostatic pressure as well as increased pulmonary capillary permeability. **Central neurogenic hyperventilation** is characteristically observed in CNS involvement by illnesses such as urea cycle defects and encephalitis. **Bradycardia** and **apnea** may be caused by CNS-depressant medications, poisoning, prolonged hypoxia, trauma, or infection (see Table 89.2).

Table 89.6

Respiratory Patterns in Neurologic Disease

INJURY	PATTERN[*]	COMMENTS
Normal		Variable V_T with normal respiratory pauses and sighs
Cortex		Hyperpnea and tachypnea
Midbrain		*Cheyne-Stokes breathing* : Gradually increasing and decreasing V_T
Pons		*Apneustic breathing* : Prolonged inspiration followed by prolonged expiration
Medulla and pons		*Biot's breathing* : Rapid and irregular respirations with pauses

[*] Lung volume vs time.

VT , Tidal volume.

Toxic Metabolic States Manifesting as Respiratory Distress

Direct stimulation of respiratory centers resulting in respiratory alkalosis is encountered in intoxication involving agents such as salicylates and theophylline. Similarly, intoxication with general CNS stimulants, such as cocaine and amphetamines, may result in increased respiration. Presence of endogenous and exogenous toxins, such as organic acidemias, ingestion of methanol and ethylene glycol, and late stages of salicylism, cause metabolic acidosis and compensatory hyperventilation, which can manifest as respiratory distress. ABG measurements show decreased pH and compensatory hypocarbia with normal oxygenation. Metabolic disorders causing hyperammonemia, on the other hand, cause respiratory alkalosis (decreased $PaCO_2$ with increased pH) because ammonia stimulates the respiratory centers. Carbon monoxide and cyanide poisoning or methemoglobinemia may produce respiratory distress.

Other Nonpulmonary Entities Manifesting as Respiratory Distress

Sepsis and **septic shock** may cause an acute respiratory distress syndrome (ARDS) with hypovolemic stimulation of baroreceptors, cytokine stimulation of respiratory centers, and lactic acidosis. Other indirect causes of lung injury include systemic inflammatory conditions, trauma, transfusion-related acute lung injury, and pancreatitis. Similarly, renal disease may manifest as respiratory distress by causing metabolic acidosis (e.g., renal tubular acidosis or renal failure) or hypertensive left ventricular failure and fluid overload.

Respiratory Failure

Respiratory failure occurs when oxygenation and ventilation are insufficient to meet the metabolic demands of the body. Respiratory failure may result from an abnormality in (1) lung and airways, (2) chest wall and muscles of breathing, or (3) central and peripheral chemoreceptors. Clinical manifestations depend largely on the site of pathology. Although respiratory failure is traditionally defined as respiratory dysfunction resulting in arterial partial pressure of oxygen (PaO_2) <60 mm Hg when breathing room air and $PaCO_2$ >50 mm Hg resulting in acidosis, the patient's general state, respiratory effort, and potential for impending exhaustion are more important indicators than ABG values.

The Berlin definition of ARDS was once used to describe pediatric patients with ARDS, even though the pathophysiology is different between children and adults. The current pediatric definition differs in chest imaging findings, definition of oxygenation, consideration of both noninvasive and invasive mechanical ventilation, and consideration of special populations (Table 89.7 and Fig. 89.1).

Table 89.7

Pediatric Acute Respiratory Distress Syndrome (PARDS) Definition

	BERLIN DEFINITION	PARDS
Age	Adults and children	Excludes patients with perinatal-related lung disease
Timing	Within 1 wk of known clinical insult or new or worsening respiratory symptoms	Within 1 wk of a known clinical insult
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload. Need objective assessment (e.g., echocardiography) to exclude hydrostatic edema, even if no risk factor present.	Respiratory failure not fully explained by cardiac failure or fluid overload
Chest imaging [a]	Bilateral opacities not fully explained by effusions, lobar/lung collapse, or nodules. (Illustrative clinical cases and chest radiographs have been provided.)	Chest imaging findings of new infiltrate(s) consistent with acute pulmonary parenchymal disease
Oxygenation [b]		
Mild	200 mm Hg < $\mathrm{PaO_2/FIO_2} \leq 300$ mm Hg with PEEP, or CPAP ≥5 cm H_2O [c]	Noninvasive mechanical ventilation: PARDS (No severity stratification) Full face-mask bilevel ventilation or CPAP >5 cm H_2O [e] PF ratio <300 SF ratio <264 [d] Invasive mechanical ventilation [f]: Mild: 4 < OI <8, or 5 < OSI <7.5 [d] Moderate: 8 < OI <16, or 7.5 < OSI <12.3 [d] Severe: OI >16, or OSI >12.3 [d]
Moderate	100 mm Hg < $\mathrm{PaO_2/FIO_2} \leq 200$ mm Hg with PEEP ≥5 cm H_2O	
Severe	$\mathrm{PaO_2/FIO_2} < 100$ mm Hg with PEEP ≥5 cm H_2O	

[a] Chest radiograph or CT scan in Berlin criteria only.

[b] If altitude is >1,000 m, the correction factor should be calculated as follows: $\mathrm{PaO_2/FIO_2} \times$ Barometric pressure/760.

[c] This may be delivered noninvasively in the mild acute respiratory distress syndrome group.

[d] Use $\mathrm{PAO_2}$-based metric when available. If $\mathrm{PaO_2}$ not available, wean $\mathrm{FIO_2}$ to maintain $\mathrm{SpO_2}$ <97% to calculate OSI or SF ratio.

[e] For nonintubated patients treated with supplemental oxygen or nasal modes of noninvasive ventilation, refer to reference below for “At Risk Criteria.”

[f] ARDS severity groups stratified by OI or OSI should not be applied to children with chronic lung disease who normally receive invasive mechanical ventilation or children with cyanotic heart disease.

In addition to the above, the Pediatric Acute Lung Injury Consensus Conference Group added definitions for special populations, including cyanotic heart disease, chronic lung disease, and left ventricular function.

CPAP, Continuous positive airway pressure; FIO_2, fraction of inspired oxygen; PaO_2, partial pressure of arterial oxygen; PEEP, positive end-expiratory pressure. OI, oxygenation index; OSI, oxygen saturation index.

Adapted from Pediatric Acute Lung Injury Consensus Conference Group, Pediatric Acute Respiratory Distress Syndrome: Consensus recommendations from the Pediatric Acute Lung Injury Consensus Conference, Pediatr Crit Care Med 16;428–439, 2015.

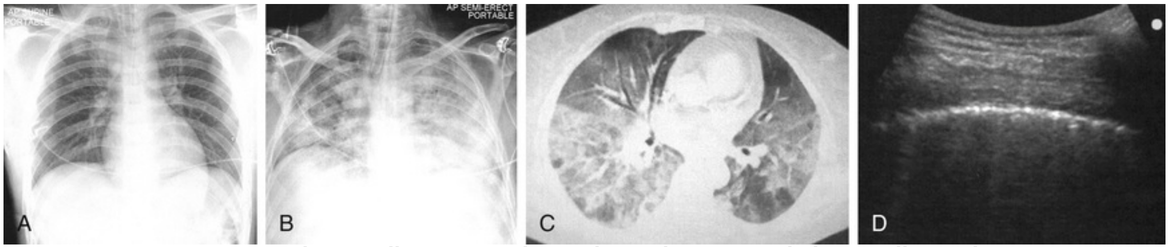

FIG. 89.1 **Acute respiratory distress syndrome (ARDS). A, Normal chest radiograph. B, Chest radiograph demonstrating bilateral alveolar infiltrates consistent with ARDS. (C, Chest CT showing bilateral pneumonitis and consolidation with air bronchograms consistent with ARDS, D, Lung ultrasonogram illustrating smooth pleural line, absence of horizontal A lines, and presence of vertical B lines suggestive of ARDS. (Modified from MacSweeney R, McAuley DF: Acute respiratory distress syndrome, *Lancet* 388:2416–2430, 2016, Fig 3.)**

Pathophysiology

Respiratory failure can be classified into *hypoxic* respiratory failure (failure of oxygenation) and *hypercarbic* respiratory failure (failure of ventilation). Systemic venous (pulmonary arterial) blood is arterialized after equilibration with alveolar gas in the pulmonary capillaries and is carried back to the heart by pulmonary veins. The ABG is influenced by the composition of inspired gas, effectiveness of alveolar ventilation, pulmonary capillary perfusion, and diffusion capacity of the alveolar capillary membrane. Abnormality in any of these steps can result in respiratory failure. **Hypoxic respiratory failure** results from intrapulmonary shunting and venous admixture or insufficient diffusion of oxygen from alveoli into pulmonary capillaries. This physiology can be caused by small airways obstruction, increased barriers to diffusion (e.g., interstitial edema, fibrosis), and conditions in which alveoli are collapsed or filled with fluid (e.g., ARDS, pneumonia, atelectasis, pulmonary edema). In most cases, hypoxic respiratory failure is associated with decreased functional residual capacity and can be managed by lung volume recruitment with positive pressure ventilation. **Hypercarbic respiratory failure** is caused by decreased minute ventilation (i.e., tidal volume multiplied by respiratory rate). This physiology can result from centrally mediated disorders of respiratory drive, increased dead space ventilation, or obstructive airways disease. *Hypoxic and hypercarbic respiratory failure may coexist as a combined failure of oxygenation and ventilation.*

Ventilation-Perfusion Mismatch

For exchange of O_2 and CO_2 to occur, alveolar gas must be exposed to blood in pulmonary capillaries. Both ventilation and perfusion are lower in nondependent areas of the lung and higher in dependent areas. The difference in perfusion ($\dot{Q}$) is greater than the difference in ventilation ($\dot{V}$). Perfusion in excess of ventilation results in incomplete arterialization of systemic venous (pulmonary arterial) blood and is referred to as **venous admixture** . Perfusion of unventilated areas is referred to as **intrapulmonary shunting** of systemic venous blood to systemic arterial circulation. Conversely, ventilation that is in excess of perfusion is wasted; that is, it does not contribute to gas exchange and is referred to as **dead space ventilation** . Dead space ventilation results in return of greater amounts of atmospheric gas (which has not participated in gas exchange and has negligible CO_2) back to the atmosphere during exhalation. The respiratory dead space is divided into the anatomic dead space and the alveolar dead space. The *anatomic dead space* includes the conducting airways from the nasopharynx to the terminal bronchioles, ends at the alveoli, and has no contact with the pulmonary capillary bed. The *alveolar dead space* refers to areas of the lung where alveoli are ventilated but not perfused. Under normal conditions, this physiology usually occurs in West zone I, where alveolar pressure is greater than pulmonary capillary pressure. Under clinical conditions, this physiology may result from dynamic hyperinflation, high levels of positive end-expiratory pressure (PEEP), or large tidal volume in ventilated patients. Additionally, decreased pulmonary artery perfusion from pulmonary embolism or decreased cardiac output and hypovolemia can result in alveolar dead space. The end result is a decrease in mixed expired CO_2 ($PECO_2$) and an increase in the $PaCO_2$ – $PECO_2$ gradient. Dea space as a fraction of tidal volume (VD /VT) is calculated as:

$$(PaCO_2 - PECO_2) \div PaCO_2$$

Normal VD /VT is approximately 0.33. Venous admixture and intrapulmonary shunting predominantly affect oxygenation, resulting in a alveolar oxygen (PAO_2) to PaO_2 (A-aO_2) gradient without elevation in $PaCO_2$. This physiology is caused by greater ventilation of perfused areas, which is sufficient to normalize $PaCO_2$ but not PaO_2 because of their respective dissociation curves. The relative straight-line relationship of the hemoglobin-CO_2 dissociation allows for averaging of capillary PCO_2 ($PcCO_2$) from hyperventilated and hypoventilated areas. Because the association between oxygen tension and hemoglobin saturation plateaus with increasing PaO_2, the decreased hemoglobin-O_2 saturation in poorly ventilated areas cannot be compensated for by well-ventilated areas where hemoglobin-O_2 saturation has already reached near-maximum. This physiology results in decreased arterial oxyhemoglobin saturation (SaO_2) and PaO_2. Elevation of $PaCO_2$ in such situations is indicative of coincident alveolar hypoventilation. Examples of diseases leading to venous admixture include asthma and aspiration pneumonia, and those of intrapulmonary shunt include lobar pneumonia and ARDS.

Diffusion

Even if ventilation and perfusion are matched, gas exchange requires diffusion across the interstitial space between alveoli and pulmonary capillaries. Under normal conditions, there is sufficient time for the pulmonary capillary blood to equilibrate with alveolar gas across the interstitial space. When the interstitial space is filled with inflammatory cells or fluid, diffusion is impaired. Because the diffusion capacity of CO_2 is 20 times greater than that of O_2, diffusion defects manifest as hypoxemia rather than hypercarbia. Even with the administration of 100% oxygen, PAO_2 increases to approximately 660 mm Hg from 100 mm Hg at sea level, and the concentration gradient for diffusion of O_2 is increased by only 6.6 times. Therefore, with diffusion defects, lethal hypoxemia will set in before clinically significant CO_2 retention results. In fact, in such situations, Pa_{CO_2} is often decreased because of the hyperventilation that accompanies hypoxemia. Presence of hypercarbia in diseases that impair diffusion is indicative of alveolar hypoventilation from coexisting airway obstruction, exhaustion, or CNS depression. Examples of disease that impair diffusion are interstitial pneumonia, ARDS, scleroderma, and pulmonary lymphangiectasia.

Monitoring a Child in Respiratory Distress and Respiratory Failure

Clinical Examination

It cannot be overemphasized that clinical observation is the most important component of monitoring. The presence and magnitude of abnormal clinical findings, their progression with time, and their temporal relation to therapeutic interventions serve as guides to diagnosis and management (see Chapter 400). As much as possible, the child with respiratory distress or failure should be observed in the position of greatest comfort and in the least threatening environment.

Pulse oximetry is the most commonly used technique to monitor oxygenation. Noninvasive and safe, it is the standard of care in bedside monitoring of children during transport, procedural sedation, surgery, and critical illness. It indirectly measures arterial hemoglobin-O_2 saturation by differentiating oxyhemoglobin from deoxygenated hemoglobin using their respective light absorption at wavelengths of 660 nm (red) and 940 nm (infrared). A pulsatile circulation is required to enable detection of oxygenated blood entering the capillary bed. Percentage of arterial oxyhemoglobin is reported as Sa_{O_2} ; however, the correct description is *oxyhemoglobin saturation as measured by pulse oximetry* (Sp_{O_2}). Such precision is needed because Sp_{O_2} may not always reflect Sa_{O_2} . It is important to be familiar with the hemoglobin-O_2 dissociation curve (see Chapter 400) to estimate Pa_{O_2} at a given oxyhemoglobin saturation. Because of the shape of the hemoglobin-O_2 dissociation curve, changes in Pa_{O_2} above 70 mm Hg are not readily identified by pulse oximetry. Also, at the same Pa_{O_2} , there may be significant change in Sp_{O_2} at a different blood pH value. In most situations, Sp_{O_2} >95% is a reasonable goal, especially in emergency care. In some adult studies of ARDS, the recommended saturation is 94–96% to avoid oxygen toxicity. There are exceptions, such as in patients with single-ventricle cardiac lesions, in whom the pulmonary and systemic circulations are receiving blood flow from the same ventricle (e.g., after Norwood procedure for hypoplastic left heart syndrome), or with large left-to-right shunts (e.g., ventricular septal defect, patent ductus arteriosus). In these types of pathophysiologic situations, a lower SpO_2 is desired to avoid excessive blood flow to the lungs and pulmonary edema from the pulmonary vasodilatory effects of oxygen, in the patient with a single ventricle, diverting blood flow away from the systemic circulation. Because most commercially available pulse oximeters recognize all types of hemoglobin as either oxyhemoglobin or deoxygenated hemoglobin, they provide inaccurate information in the presence of carboxyhemoglobin and methemoglobin. In carbon monoxide poisoning, **carboxyhemoglobin** absorbs light in the same (red) wavelength as oxyhemoglobin, leading to overestimation of oxygen saturation. **Methemoglobin** absorbs light in both the oxygenated and deoxygenated wavelengths, which can cause either an overestimation or underestimation of oxygen saturation. Data suggest that increasing methemoglobin concentrations tend to drive SpO_2 toward 85%, no matter the actual percent of oxyhemoglobin. At lower methemoglobin levels, the pulse oximetry reading is falsely low, whereas high levels lead to a falsely high pulse oximetry reading. Newer pulse oximeters may have the ability to distinguish dyshemoglobinemias and to prevent false readings, but these are not currently in widespread use. It should be recognized that dangerous levels of hypercarbia may exist in patients with ventilatory failure, who have satisfactory SpO_2 if they are receiving supplementa oxygen. Pulse oximetry should not be the only monitoring method in patients with primary ventilatory failure, such as neuromuscular weakness and CNS depression. It is also unreliable in patients with poor perfusion and poor pulsatile flow to the extremities. Despite these limitations, pulse oximetry is a noninvasive, easily applicable, and effective means of evaluating the percentage of oxyhemoglobin in most patients.

Volumetric capnography (end-tidal CO_2 [$PetCO_2$] measurement) is helpful in non-invasively determining the effectiveness of ventilation and pulmonary circulation. The $PetCO_2$ can be used to determine the alveolar dead space fraction and is calculated as follows: [($PaCO_2$ − $PetCO_2$)/$PaCO_2$]. Changes in the alveola dead space fraction usually correlate well with changes in the gradient of $PaCO_2$

and $PetCO_2$ ($PaCO_2 – PetCO_2$). Thus a change in $PaCO_2 – PetCO_2$ can be used as an index of changes in alveolar dead space. In healthy children the gradient is smaller than in adults and is usually <3 mm Hg. Diseases resulting in increased alveolar dead space (e.g., dynamic hyperinflation) or decreased pulmonary blood flow (e.g., pulmonary embolism, low cardiac output) lead to decreases in $PetCO_2$ and an increase in $PaCO_2 – PetCO_2$. $PetCO_2$ alone may overestimate adequacy of ventilation.

Blood Gas Abnormalities

Arterial blood gas analysis offers valuable assistance in diagnosis, monitoring, and management of a child in respiratory distress and failure. Because of technical difficulties in obtaining an arterial sample in children, a *capillary blood gas* (CBG) sample is most often obtained in emergency situations. A properly arterialized CBG sample obtained by warming the digit and obtaining free-flowing blood is acceptable. The blood sample needs to be processed without delay. CBG provides a good estimate of $PaCO_2$ and arterial pH, but less so for PaO_2. In patients who mainly require monitoring of ventilation (especially those whose oxygenation is being monitored with pulse oximetry) a *venous blood gas* sample provides reliable estimate of arterial pH and $PaCO_2$ values, provided tissue perfusion is reasonably adequate. Venous PCO_2 ($PvCO_2$) is approximately 6 mm Hg higher and pH approximately 0.03 lower than the arterial values. PvO_2 has a poor correlation with PaO_2. Mixed venous O_2 saturation obtained from a central venous catheter in the right atrium is an excellent marker of the balance between oxygen delivery and oxygen consumption. In patients with a constant arterial O_2 content and O_2 consumption, mixed venous O_2 saturation offers valuable information about cardiac output.

Blood gas analysis is important not only for determining the adequacy of oxygenation and ventilation but also for determining site of respiratory pathology and planning treatment (see Chapter 400). Briefly, in the presence of pure alveolar hypoventilation (e.g., airway obstruction above carina, decreased CO_2 responsiveness, neuromuscular weakness), the blood gas will show respiratory acidosis with an elevated $PaCO_2$ but a relative sparing of oxygenation $V/\dot{Q}$ mismatch (peripheral airway obstruction, bronchopneumonia) will be reflected in increasing hypoxemia and variable levels of $PaCO_2$ (low, normal, high) depending on severity of disease. Intrapulmonary right-to-left shunting and diffusion defects (alveolar-interstitial diseases such as pulmonary edema, ARDS) will be associated with a large A-aO_2 gradient and hypoxemia with relative sparing of CO_2 elimination, unless there is coincident fatigue or CNS depression.

Acid-Base Abnormalities

It is crucial to analyze the magnitude and appropriateness of changes in pH, $PaCO_2$, and bicarbonate concentration ($[HCO_3^-]$) because they provide useful clues to the underlying pathophysiology and presence of more than 1 disorder. To do so, it is useful to assume baseline values of pH 7.40, $PaCO_2$ 40 mm Hg, and $[HCO_3^-]$ 24 mEq/L. Newborns have lower renal threshold for bicarbonate and therefore have slightly different baseline values of pH 7.38, $PaCO_2$ 35 mm Hg, and $[HCO_3^-]$ 20 mEq/L.

Metabolic Acidosis With Respiratory Compensation

Patients with metabolic acidosis have decreased pH resulting from decreased serum $[HCO_3^-]$. Chemoreceptor stimulation results in hyperventilation and respiratory compensation that may clinically manifest as respiratory distress. Normal compensation does not completely correct the pH but rather minimizes a change in pH that would otherwise occur without compensation. The adequacy of respiratory compensation is judged by the extent of the decline in $PaCO_2$ in response to the decline in $[HCO_3^-]$ or pH. A normal compensation for metabolic acidosis results in a fall in $PaCO_2$ by 1.2 mm Hg for every 1 mEq/L fall in $[HCO_3^-]$. The most commonly used method to analyze the adequacy of respiratory compensation is Winter's formula:

$$PaCO_2 = ([HCO_3^-] \times 1.5) + 8 \pm 2$$

A quick method is to look at the last 2 digits of pH (provided it is not <7.10), which should be within 2 mm Hg of $PaCO_2$. For example, pH 7.27, $PaCO_2$ 26 mm Hg, and $[HCO_3^-]$ 12 mEq/L represents metabolic acidosis with a normal respiratory compensation response. On the other hand, pH 7.15, Pa_{CO_2} 30 mm Hg, and $[HCO_3^-]$ 10 mEq/L constitutes metabolic acidosis with inadequate respiratory compensation. The reasons for inadequate compensation include decreased CO_2 responsiveness (e.g., narcotic poisoning, cerebral edema), abnormalities of lungs and airways, or neuromuscular weakness. A decrease in Pa_{CO_2} that is greater than what could be expected as a normal compensatory response to metabolic acidosis is indicative of a mixed disorder. A pH 7.20, Pa_{CO_2} 15 mm Hg, and $[HCO_3^-]$ 7.5 mEq/L represents metabolic acidosis with a concomitant respiratory alkalosis because the decline in Pa_{CO_2} is greater than what can be expected as normal compensation. Combination of metabolic acidosis and respiratory alkalosis is often encountered in serious conditions such as cardiogenic shock (e.g., anxiety, stimulation of baroreceptors), sepsis, or toxic-metabolic states (e.g., salicylates, organic acidemia).

Respiratory Acidosis With Metabolic Compensation

Patients with respiratory acidosis have decreased pH as a result of elevated Pa_{CO_2}. An acute increase in Pa_{CO_2} of 10 mm Hg results in a decrease in pH by 0.08. Thus a child with severe status asthmaticus and a Pa_{CO_2} of 60 mm Hg will have blood pH of approximately 7.24. Chronically elevated (>3-5 days) Pa_{CO_2} is accompanied by renal compensation and increase in serum $[HCO_3^-]$, limiting the fall in pH to 0.03 for every 10 mm Hg rise in Pa_{CO_2}. Thus an infant with bronchopulmonary dysplasia who has a basal Pa_{CO_2} of 60 mm Hg will have blood pH of approximately 7.34. These findings are helpful in distinguishing acute from chronic changes in Pa_{CO_2}. Also, for a given level of CO_2 accumulation, a decrease in pH that is greater than expected is indicative of concomitant metabolic acidosis, and a decline in pH that is less than expected is caused by accompanying metabolic alkalosis.

Assessment of Oxygenation and Ventilation Deficits

For standardizing management, following clinical progress, and determining prognosis for patients with defects in oxygenation or ventilation, the following indicators have been proposed, each with its strengths and limitations:

A-aO$_2$ gradient is calculated by the subtraction, PAO$_2$ − PaO$_2$. For the comparison to be valid, both values must be taken at the same time and with the same fraction of oxygen in the inspired gas (FIO$_2$).

PaO$_2$/FIO$_2$ ratio (P/F) is calculated by dividing PaO$_2$ by FIO$_2$. In hypoxic respiratory failure, a PaO$_2$/FIO$_2$ value <300 mm Hg is consistent with acute lung injury, and a value <200 mm Hg is consistent with ARDS. Although the intent is to measure $V/\dot{Q}$ mismatch, intrapulmonary shunt, and diffusion defect, the status of alveolar hypoventilation could have a significant impact on PaO$_2$/FIO$_2$.

SpO$_2$/FIO$_2$ ratio is a surrogate measure of oxygenation when PaO$_2$ is not available. It is calculated by dividing the pulse oximeter saturation by the FIO$_2$. P/F ratios of 200 mm Hg and 300 mm Hg correlate approximately with S/F ratios of 235 and 315 respectively. This relationship is most valid for SpO$_2$ values between 80% and 97%.

PaO$_2$/PAO$_2$ ratio is determined by dividing PaO$_2$ by PAO$_2$. The level of alveolar ventilation is accounted for in the calculation of PaO$_2$. Therefore, PaO$_2$/PAO$_2$ is more indicative of $V/\dot{Q}$ mismatch and alveolar capillary integrity.

Oxygenation index (OI) is aimed at standardizing oxygenation to the level of therapeutic interventions, such as mean airway pressure (MAP) and FIO$_2$ used during mechanical ventilation, which are directed toward improving oxygenation. None of the indicators of oxygenation mentioned above takes into account the degree of positive pressure respiratory support.

$$\mathrm{OI} = (\mathrm{MAP} \times \mathrm{FIO_2} \times 100) \div \mathrm{PaO_2}$$

The limitation of OI is that level of ventilation is not accounted for in the assessment.

Ventilation index (VI) is aimed at standardizing alveolar ventilation to the level of therapeutic interventions, such as peak inspiratory pressure (PIP), positive end-expiratory pressure (PEEP), and ventilator rate ([R) directed toward lowering PaCO$_2$.

$$VI = [R \times (PIP - PEEP) \times PaCO_2] \div 1000$$

Management

The goal of management for respiratory distress and respiratory failure is to ensure a patent airway and provide necessary support for adequate oxygenation of the blood and removal of CO_2 . Compared with hypercapnia, **hypoxemia** is a life-threatening condition; therefore initial therapy for respiratory failure should be aimed at ensuring adequate oxygenation.

Oxygen Administration

Supplemental oxygen administration is the least invasive and most easily tolerated therapy for hypoxemic respiratory failure. **Nasal cannula** oxygen provides low levels of oxygen supplementation and is easy to administer. Oxygen is humidified in a bubble humidifier and delivered via nasal prongs inserted in to the nares. In children, a flow rate <5 L/min is most often used because of increasing nasal irritation with higher flow rates. A common formula for an estimation of the FIO_2 during use of a nasal cannula in older children and adults follows:

$$FIO_2 \text{ (as percentage)} = 21\% + [(\text{Nasal cannula flow (L/min)} \times 3)]$$

The typical FIO_2 value (expressed as percentage rather than fraction of 1) using this method is between 23% and 40%, although the FIO_2 varies according to the size of the child, the respiratory rate, and the volume of air moved with each breath. In a young child, because typical nasal cannula flow rates are a greater percentage of total minute ventilation, significantly higher FIO_2 may be provided. Alternately, a **simple mask** may be used, which consists of a mask with open side ports and a valveless oxygen source. Variable amounts of room air are entrained through the ports and around the side of the mask, depending on the fit, size, and minute volume of the child. Oxygen flow rates vary from 5-10 L/min, yielding typical FIO_2 values (expressed as percentage rather than fraction of 1) between 30% and 65%. If more precise delivery of oxygen is desired, other mask devices should be used.

A **Venturi mask** provides preset FIO_2 through a mask and reservoir system by entraining precise flow rates of room air into the reservoir along with high-flow oxygen. The adapter at the end of each mask reservoir determines the flow rate of entrained room air and the subsequent FIO_2 . (Adapters provide FIO_2 of 0.30-0.50.) Oxygen flow rates of 5-10 L/min are recommended to achieve the desired FIO_2 and to prevent rebreathing. Partial rebreather and non-rebreather masks use a reservoir bag attached to a mask to provide higher FIO_2 . **Partial rebreather masks** have 2 open exhalation ports and contain a valveless oxygen reservoir bag. Some exhaled gas can mix with reservoir gas, although most exhaled gas exits the mask via the exhalation ports. Through these same ports, room air is entrained, and the partial rebreather mask can provide FIO_2 up to 0.60, for as long as oxygen flow is adequate to keep the bag from collapsing (typically 10-15 L/ min). As with nasal cannulas, smaller children with smaller tidal volumes entrain less room air, and their Fio_2 values will be higher. **Non-rebreather masks** include 2 one-way valves, 1 between the oxygen reservoir bag and the mask and the other on 1 of the 2 exhalation ports. This arrangement minimizes mixing of exhaled and fresh gas and entrainment of room air during inspiration. The 2nd exhalation port has no valve, a safeguard to allow some room air to enter the mask in the event of disconnection from the oxygen source. A non-rebreather mask can provide FIO_2 up to 0.95. The use of a non-rebreather mask in conjunction with an oxygen blender allows delivery of FIO_2 between 0.50 and 0.95 (Table 89.8). When supplemental oxygen alone is inadequate to improve oxygenation, or when ventilation problems coexist, additional therapies may be necessary.

Table 89.8

Approximate Oxygen Delivery According to Device and Flow Rates in Infants and Older Children*

DEVICE	FLOW (L/min)	FIO_2 DELIVERED
Nasal cannula	0.1-6	0.21-0.4
Simple face mask	5-10	0.4-0.6
Partial rebreather	6-15	0.55-0.7
Non-rebreather	6-15	0.7-0.95
Venturi mask	5-10	0.25-0.5

Hood/tent	7-12	0.21-1.0

[*] Individual delivery varies and depends on the patient's size, respiratory rate, and volume moved with every breath.

Airway Adjuncts

Maintenance of a patent airway is a critical step in maintaining adequate oxygenation and ventilation. Artificial pharyngeal airways may be useful in patients with oropharyngeal or nasopharyngeal airway obstruction and in those with neuromuscular weakness in whom inherent extrathoracic airway resistance contributes to respiratory compromise. An **oropharyngeal airway** is a stiff plastic spacer with grooves along each side that can be placed in the mouth to run from the teeth along the tongue to its base just above the vallecula. The spacer prevents the tongue from opposing the posterior pharynx and occluding the airway. Because the tip sits at the base of the tongue, it is usually not tolerated by patients who are awake or whose gag reflex is strong. The **nasopharyngeal airway** , or *nasal trumpet* , is a flexible tube that can be inserted into the nose to run from the nasal opening along the top of the hard and soft palate with the tip ending in the hypopharynx. It is useful in bypassing obstruction from enlarged adenoids or from contact of the soft palate with the posterior nasopharynx. Because it is inserted past the adenoids, a nasopharyngeal airway should be used with caution in patients with bleeding tendencies.

Inhaled Gases

Helium-oxygen mixture (heliox) is useful in overcoming airway obstruction and improving ventilation. Helium is much less dense and slightly more viscous than nitrogen. When substituted for nitrogen, helium helps maintain laminar flow across an obstructed airway, decreases airway resistance, and improves ventilation. It is especially helpful in diseases of large airways obstruction in which turbulent airflow is more common, such as acute laryngotracheobronchitis, subglottic stenosis, and vascular ring. It is also used in patients with severe status asthmaticus. To be effective, helium should be administered in concentrations of at least 60%, so associated hypoxemia may limit its use in patients requiring >40% oxygen.

Inhaled nitric oxide (iNO) is a powerful inhaled pulmonary vasodilator. Its use may improve pulmonary blood flow and $\dot{V}/\dot{Q}$ mismatch in patients with diseases that elevate pulmonary vascular resistance, such as occurs in persistent pulmonary hypertension of the newborn, primary pulmonary hypertension, and secondary pulmonary hypertension as a result of chronic excess pulmonary blood flow (e.g., ventriculoseptal defect) or collagen vascular diseases. iNO is administered in doses ranging from 5 to 20 parts per million of inspired gas. Although administration of iNO to unintubated patients is possible, it is usually administered to patients undergoing mechanical ventilation via an endotracheal tube, because of the need for precision in iNO dosing.

Positive Pressure Respiratory Support

Noninvasive positive pressure respiratory support is useful in treating both hypoxemic and hypoventilatory respiratory failure. Positive airway pressure helps with aeration of partially atelectatic or filled alveoli, prevention of alveolar collapse at end-exhalation, and increase in functional residual capacity (FRC). These actions improve pulmonary compliance and hypoxemia, as well as decrease intrapulmonary shunt. In addition, positive pressure ventilation is useful in preventing collapse of extrathoracic airways by maintaining positive airway pressure during inspiration. Improving compliance and overcoming airway resistance also improves tidal volume and therefore ventilation. A **high-flow nasal cannula** delivers gas flow at 4-16 L/min and up to 60 L/min, with newer systems for older children and adolescents, capable of providing significant **continuous positive airway pressure (CPAP)** . In this setting, the amount of CPAP provided is not quantifiable and varies with each patient, depending on the percentage of total inspiratory flow that is delivered from the cannula, airway anatomy, and degree of mouth breathing. In small children the relative amount of CPAP for a given flow is usually greater than in older children and may provide significant positive pressure. The F_{IO_2} can be adjusted by provision of gas flow through an oxygen blender. Another benefit of a high-flow nasal cannula system is the washout of CO_2 from the nasopharynx, which decreases rebreathing of CO_2 and dead space ventilation. When delivering high-flow air or oxygen, adequate humidification is essential, by using a separate heated humidification chamber. CPAP can also be provided through snugly fitting nasal prongs or a tight-fitting face mask attached to a mechanical ventilator or other positive pressure device. Noninvasive CPAP is most useful in diseases of mildly decreased lung compliance and low FRC, such as atelectasis and pneumonia. Patients with diseases of extrathoracic airway obstruction, in which extrathoracic negative airway pressures during inspiration lead to airway narrowing (e.g., laryngotracheitis, obstructive sleep apnea, postextubation airway edema), may also benefit from CPAP. Potential risks include nasal irritation, hyperinflation from excessive CPAP in smaller patients, and abdominal distention from swallowed air.

Noninvasive positive airway pressure ventilation (NIPPV) provides positive airway pressure during exhalation, and bilevel modes can apply additional positive pressure during inspiration (see Chapter 89.1).

Endotracheal Intubation and Mechanical Ventilation

When hypoxemia or significant hypoventilation persists despite the interventions already described, endotracheal intubation and mechanical ventilation are indicated. Additional indications for intubation include maintaining airway patency in patients who have the potential for airway compromise, such as those with actual or potential neurologic deterioration, and in patients with hemodynamic instability.

Proper monitoring is essential to ensuring a safe and successful endotracheal intubation. Pulse oximetry, heart rate, and blood pressure monitoring are mandatory and should be forgone only in situations calling for emergency intubation. All necessary equipment, including bag-mask ventilation device, laryngoscope, endotracheal tube (ETT) with stylet, and suction equipment, must be available and working properly before the procedure of intubation. The proper internal diameter (ID) for the ETT can be estimated using the following formula:

$$\mathrm{ID} = (\mathrm{Age}\ [\mathrm{yr}]/4) + 4$$

Table 89.9 provides average values for age, size, and depth of insertion for tracheal tubes. Preoxygenation of the patient with high $F\mathrm{IO}_2$ is essential and will allow maximum procedure time before the onset of hypoxemia. Although intubation can be accomplished without sedation and pharmacologic paralysis in selected patients, the physiologic benefits of these measures to the patient as well as to the facilitation of the intubation usually far outweigh the risks. Administration of a sedative and analgesic followed by a paralytic agent is a common pharmacologic regimen for facilitating intubation. In fact, sedation and paralysis with neuromuscular blocking agents should be considered standard unless contraindicated. The particular type and dose of each agent often depends on the underlying disease and clinician preference. Table 89.10 lists commonly used agents. *Dexmedetomidine* has been a standard sedating agent for maintenance during mechanical ventilation. An alternative to this pharmacologic approach is **rapid sequence intubation** , used when endotracheal intubation is urgent, or the patient is suspected of having a full stomach and at increased risk of aspiration (see Chapter 81).

Table 89.9

Average Size and Depth Dimensions for Tracheal Tubes

Cisatracurium	0.1 mg/kg IV	2-3	25-30	Histamine release Nonrenal elimination

BP, Blood pressure; HR, heart rate; ICP, intracranial pressure; IM, intramuscularly; IV, intravenously.

Once adequate sedation and/or paralysis have been achieved, ventilation should be assisted with a **bag-mask device** . After optimal preoxygenation, intubation can be performed. The clinician uses the dominant hand to open the patient's mouth and insert the laryngoscope blade gently along the tongue to its base. The airway opening can be visualized by applying lift up-and-away from the clinician, along the axis of the laryngoscope handle. When a *straight* (Miller) laryngoscope blade is used to visualize the glottis, the tip of the blade lifts the epiglottis anteriorly. When a *curved* (Macintosh) blade is used to visualize the glottis, the tip of the blade should be advanced into the vallecula and then lifted. Secretions often obscure visualizations at this step and should be suctioned clear. Once clear visualization of the vocal cords is accomplished, the ETT can be placed through the vocal cords. Rapid confirmation of ETT placement is essential and should be assessed by as many of the following steps as possible: presence of PetCO_2 determined by a monitor attached in-line with ETT; auscultation of both lung fields as well as the epigastrium for equal breath sounds; and, good air movement and evaluation of the abdomen for increasing distention. Adequate, bilateral chest expansion and misting inside the ETT with each breath confirm proper tube placement. An increasing heart rate, if heart rate has decreased during the attempt, and a rising or normal SpO_2 reading are suggestive of successful tube placement. Preoxygenation may significantly delay any drop in SpO_2 with improper tube placement, leading to a significant delay in its recognition. Confirmation of exhaled PetCO_2 is mandatory, using a disposable colorimetric CO_2 detector or with capnography. In situations of very low pulmonary perfusion, such as cardiac arrest, PetCO_2 may not be detected. A chest radiograph should also be obtained to confirm proper placement of the ETT, which should lie with the tip about halfway between the glottis and the carina (see Chapter 81).

Transient Manual Ventilation in Immediate Preintubation and Postintubation Periods

Establishment of supportive ventilation via bag-mask or bag-ETT is required before transport of the patient to a setting of continued critical care. The technique of manual ventilation should take into account the underlying pathology. Mechanical ventilation of patients with diseases characterized by low FRC (e.g., pneumonia, pulmonary edema, ARDS) should include the application of PEEP to prevent alveolar derecruitment. Lung volume recruitment can be accomplished with a PEEP valve on a self-inflating ventilation bag or by careful manipulation of exhaust gas using an anesthesia bag. Such diseases are also characterized by a short time constant for lung deflation and therefore are best managed with relatively small tidal volumes and high ventilation rates.

In contrast, diseases characterized by airway obstruction have prolonged deflation time constants and are therefore best managed with relatively slow rates and high tidal volumes.

The decision to institute support with mechanical ventilation is based mainly on the need to assist lung function; supporting left ventricular (LV) performance and treating intracranial hypertension are additional indications. Although there are no absolute criteria for derangement of gas exchange, Pa_{O_2} <60 mm Hg while breathing >60% oxygen, Pa_{CO_2} >60 mm Hg, and pH <7.25 are often reasons to initiate mechanical ventilation. Clinical impressions of fatigue and impending exhaustion are also indications for ventilatory support, even in the presence of adequate gas exchange. Positive pressure ventilation is a powerful means of decreasing LV afterload, and it is used for this purpose in patients with cardiogenic shock resulting from LV dysfunction. Mechanical ventilation is also used in patients whose breathing is unreliable (e.g., unconscious patients, those with neuromuscular dysfunction) and when deliberate hyperventilation is desired, such as in patients with intracranial hypertension.

Mechanical ventilation is not intended to normalize gas exchange, nor is it a cure. The goals are to maintain sufficient oxygenation and ventilation to ensure tissue viability until the disease process that has compromised the patient's lung function has resolved, while minimizing any complications. Thus, Pa_{O_2} , Pa_{CO_2} and pH levels are maintained in ranges that provide a safe environment for the patient, while protecting the lungs from damage caused by oxygen toxicity, pressure (**barotrauma**), tidal volume overdistention (**volutrauma**), **atelectrauma** , and cytokine release (**biotrauma**) (Figs. 89.2 and 89.3).

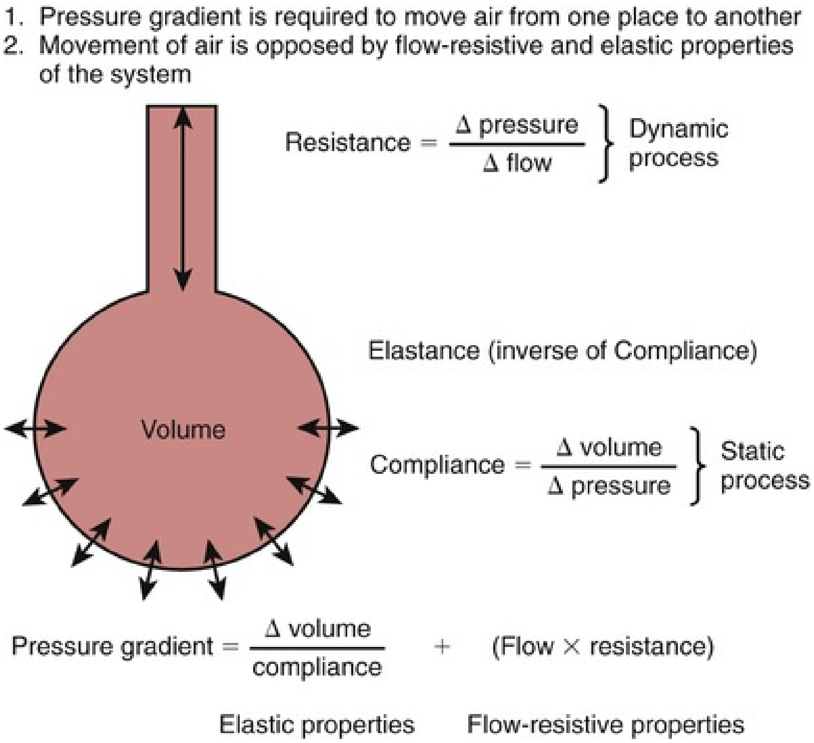
FIG. 89.3 Pulmonary pressure-volume relation in a patient with acute lung injury. Top, The lower inflection point is typically 12-18 cm H_2O, and the upper inflection point 26-32 cm H_2O. Bottom, Specific protective ventilation strategies require that positive end-expiratory pressure (PEEP) is set just above the lower inflection point and the pressure limit (P_{max}) just below the upper inflection point. Thus the lung is ventilated in the safe zone between the zone of recruitment and derecruitment and the zone of overdistention, and both high-volume and low-volume injuries are avoided. (From Pinhu L, Whitehead T, Evans T, et al: Ventilator-associated lung injury, *Lancet* 361:332–340, 2003.)

Basic Concepts of Ventilator Management

Equation of Motion

A pressure gradient is required for air to move from one place to another. During natural spontaneous ventilation, inspiration results from generation of negative intrapleural pressure from contraction of the diaphragm and intercostal muscles, drawing air from the atmosphere across the airways into the alveoli. During mechanical ventilation, inspiration results from positive pressure created by compressed gases through the ventilator, which pushes air across the airways into alveoli. In both spontaneous and mechanical ventilation, exhalation results from alveolar pressure generated by the elastic recoil of the lung and the chest wall. Pressure necessary to move a given amount of air into the lung is determined by 2 factors: lung and chest wall elastance and airway resistance. Fig. 89.4 describes the relationship in pressure gradient, compliance, and resistance. *Elastance* —defined as the change in pressure (ΔP) divided by the change in volume (ΔV)—refers to the property of a substance to oppose deformation. It is opposite of *compliance* (ΔV ÷ ΔP), the property of a substance to allow distention or lengthening when subjected to pressure. Compliance (C) is therefore expressed as 1/elastance.



1. Pressure gradient is required to move air from one place to another
2. Movement of air is opposed by flow-resistive and elastic properties of the system
Resistance = Δ pressure / Δ flow
Dynamic process
Elastance (inverse of Compliance)
Volume
Compliance = Δ volume / Δ pressure
Static process
Pressure gradient = Δ volume / compliance + (Flow × resistance)
Elastic properties
Flow-resistive properties

FIG. 89.4 **Equation of motion. A pressure gradient is required to move air from one**

place to another. In the lungs, the required pressure gradient must overcome the lung and chest wall elastance (static component) and the flow-resistive properties (dynamic component). The static component is increased in alveolar interstitial diseases and stiff chest wall, whereas the dynamic component is increased with airway obstruction.

The pressure needed to overcome tissue elastance is measured in conditions in which there is no flow (at end-inspiration and end-expiration) and is therefore a reflection of static conditions in the lung. It is influenced by tidal volume (V_T) and compliance ($P = \Delta V \div C$). It is increased with high V_T and low compliance. This pressure gradient is used to calculate the static compliance of the respiratory system (C_{STAT}).

Resistance (R) refers to the opposition to generation of flow. It is measured as the amount of pressure needed to generate a unit of flow ($\Delta P \div \Delta$Flow). Pressure needed to overcome airway resistance is calculated as flow multiplied by resistance. Because this pressure is needed only when the flow is occurring through the airways, it is referred to as the *dynamic component* . Pressure to overcome flow-resistive properties is measured when there is maximum flow and is therefore under dynamic conditions. It is increased in conditions with greater airway resistance and flow rate. Flow rate depends on the time allowed for inspiration and expiration. At higher respiratory rates, there is less time available for each inspiration and expiration, necessitating higher flows; therefore higher pressure is required to overcome flow-resistive properties. The pressure gradient necessary to move air from one place to another is the sum of pressure needed to overcome the elastic and flow-resistive properties of the lung. This pressure gradient is taken into account to calculate the dynamic compliance of the respiratory system (C_{DYN}). The difference in change in pressure between static conditions and dynamic conditions is attributable to airway resistance.

Functional Residual Capacity

During inspiration, oxygen-enriched gas enters alveoli. During exhalation, oxygen continues to be removed by the pulmonary capillary circulation. FRC is the volume of gas left in the alveoli at end-expiration. It is the only source of gas available for gas exchange during exhalation. In diseases with decreased FRC (e.g., ARDS, pulmonary edema), P_{AO_2} declines sharply throughout expiration, resulting in hypoxemia. Two ventilator strategies used to improve oxygenation in such situations are the application of PEEP and increasing the *inspiratory time* (T_I) (Fig. 89.5). PEEP increases FRC, whereas a longer T_I allows longer exposure of pulmonary capillary blood to a higher concentration of O_2 during inspiration. (See also Chapter 400 .)

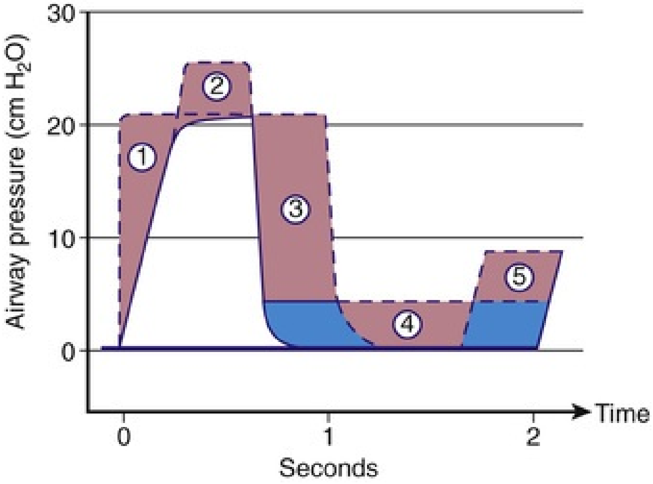


FIG. 89.5 **Five different ways to increase mean airway pressure.** ***(1)*** **Increase the respiratory flow rate, producing a square wave inspiratory pattern;** ***(2)*** **increase the peak inspiratory pressure;** ***(3)*** **reverse the inspiratory-expiratory ratio or prolong the inspiratory time without changing the rate;** ***(4)*** **increase positive end-expiratory pressure; and** ***(5)*** **increase the ventilatory rate by reducing the expiratory time without changing the inspiratory time. (From Harris TR, Wood BR: Physiologic principles. In Goldsmith JP, Karotkin EH, editors:** ***Assisted ventilation of the neonate,*** **ed 3, Philadelphia, 1996, Saunders.)**

Time Constant

At the beginning of inspiration, the atmospheric pressure is higher than the pressure in the alveoli, resulting in movement of air into the alveoli. During mechanical ventilation, the ventilator circuit serves as the patient's atmosphere. As alveoli expand with air, the alveolar pressure rises throughout inspiration until it equilibrates with the ventilator pressure, at which time airflow ceases. Expiration starts when the ventilator pressure falls below the alveolar pressure. Alveolar pressure decreases throughout expiration until it reaches the ventilator pressure, at which time no further egress of air from the alveoli occurs. If inspiration or expiration is terminated before pressure equilibration between alveoli and the ventilator is allowed to occur, alveolar expansion during inspiration or alveolar emptying during expiration is incomplete. Incomplete inspiration results in delivery of decreased V_T , whereas incomplete expiration is associated with air trapping and the presence of residual PEEP in the alveoli that is greater than the ventilator pressure, referred to as **auto-PEEP** . Some time is required for pressure equilibration to occur between alveoli and the atmosphere, which is reflected in the *time constant* (TC). It takes 3 TCs for 95% (and 5 TCs for 99%) of pressure equilibration to occur. The TC depends on compliance (C) and resistance (R), and their relationship is depicted in Fig. 89.6 . TC is calculated as compliance multiplied by resistance (C × R) and is measured in seconds.

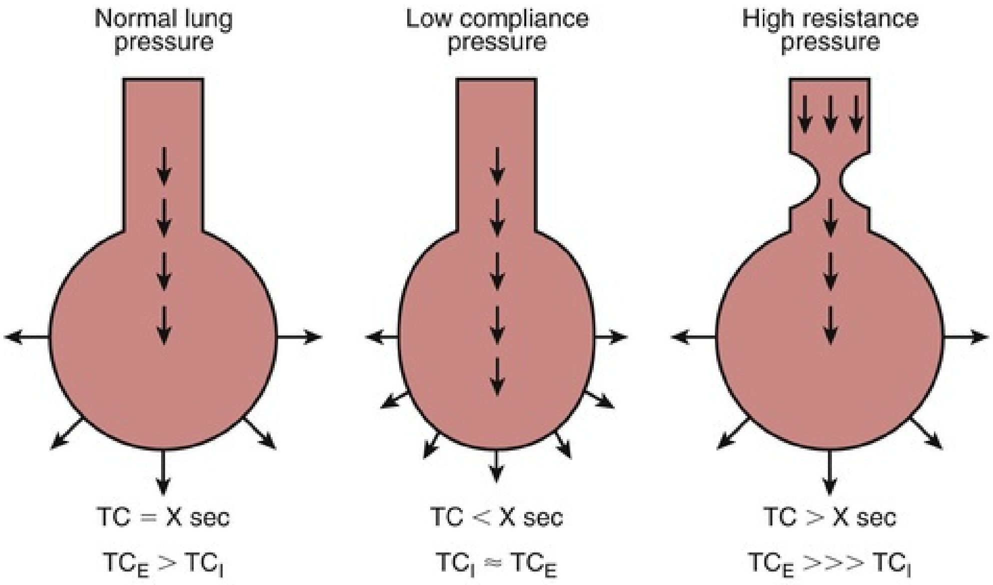

FIG. 89.6 **Time constant (TC). A certain amount of time is necessary for pressure equilibration (and therefore completion of delivery of gas) to occur between proximal airway and alveoli. TC, a reflection of time required for pressure equilibration, is a product of compliance and resistance. In diseases of decreased lung compliance, less time is needed for pressure equilibration to occur, whereas in diseases of increased airway resistance, more time is required. Expiratory TC is increased much more than inspiratory TC in obstructive airway diseases, because airway narrowing is exaggerated during expiration.**

Diseases with decreased compliance (increased elastance) are characterized by high elastic recoil pressure, which results in more rapid equilibration of alveolar and ventilator pressures, thereby decreasing TC. Diseases with increased airway resistance are associated with slower flow rates, require longer time for movement of air from one place to another, and therefore have increased TC. Airways expand during inspiration and narrow during expiration. Therefore, expiratory time constant (TC_E) is longer than inspiratory time constant (TC_I). In intrathoracic airway obstruction (e.g., asthma, bronchiolitis, aspiration syndromes), airway narrowing is much more pronounced during expiration.

Therefore, although both TC_E and TC_I are prolonged in such diseases, TC_E is much more prolonged than TC_I . Patients with such diseases therefore are best ventilated with slower rates, higher V_T , and longer expiratory time than inspiratory time. In diseases characterized by decreased compliance, both TC_E and TC_I are short; however, the TC_E is closer to TC_I than in normal lungs because of the stiffer alveoli recoil with greater force. Patients with these diseases are best ventilated with small V_T to prevent ventilator-induced lung injury and with a relatively longer inspiratory time in each breath to improve oxygenation.

Critical Opening Pressure

Collapsed or atelectatic alveoli require a considerable amount of pressure to open. Once open, the alveoli require relatively less pressure for continued expansion. The process of opening atelectatic alveoli is called **recruitment** . In a normal lung, alveoli remain open at end-expiration, and therefore the lung requires relatively less pressure to receive its V_T . In a disease process in which the alveoli collapse at end-expiration (e.g., ARDS), a substantial amount of pressure is required to open the alveoli during inspiration. This pressure causes ventilator-induced lung injury by 2 mechanisms: *barotrauma* at the terminal airway–alveolar junction and *volutrauma* as a result of overdistention of alveoli that are already open (see Figs. 89.2 and 89.3). Although a pulmonary parenchymal disease process is rarely uniform, and each of the millions of alveoli may have its own mechanical characteristics, a composite volume-pressure relationship could be conceptualized for the whole lung (Fig. 89.7).

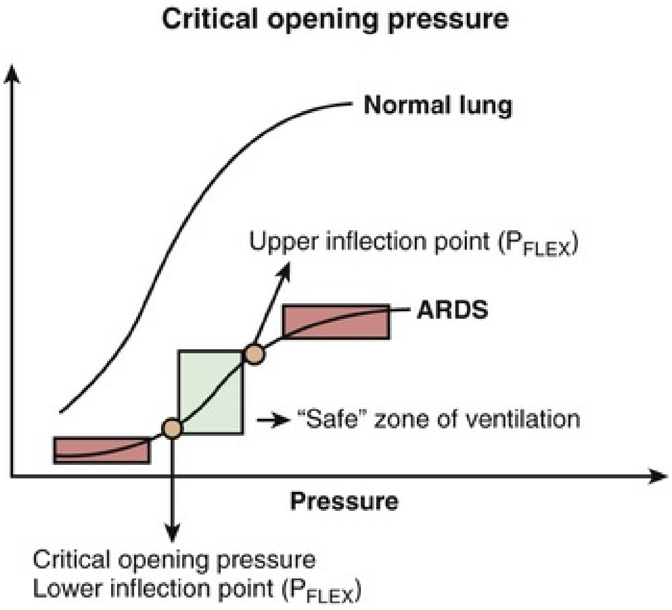

FIG. 89.7 **Volume-pressure relationship in normal lung and in acute respiratory distress syndrome. In ARDS, atelectatic alveoli require a considerable amount of pressure to open. Critical opening pressure, also referred to as lower P_{FLEX} , is the airway pressure above which further alveolar expansion occurs with relatively less pressure. Upper P_{FLEX} is the airway pressure above which further increase in pressure results in less alveolar expansion; this is the area of alveolar overdistention. Keeping tidal volume between upper and lower P_{FLEX} values is considered less injurious to the lung.**

In these situations, the lower and upper portions of the curve are relatively horizontal, and the middle portion is more vertical. At the beginning of inspiration, atelectatic alveoli are being recruited, requiring high pressure for a relatively small increase in volume. Once they are recruited, further increase in volume requires relatively less pressure. The pressure at which most alveoli are open is called *critical opening pressure* ; this point is also referred to as the *lower inflection point* (lower P_{FLEX}). After the lower P_{FLEX} , greater volume can be delivered for relatively less pressure until the upper P_{FLEX} is reached, at which the volume-pressure curve again becomes relatively horizontal. The goal of mechanical ventilation in alveolar interstitial pathology is to deliver a VT between the lower and upper inflection points, the so-called safe zone of ventilation. If VT is delivered with a change in inflation pressure that includes the lower P_{FLEX} , alveoli are likely to open *and* close during every breath, a process termed **tidal recruitment** that is injurious to the lung, especially at the terminal airway–alveolar junction. If VT is delivered with a change of pressure that includes the upper P_{FLEX} , overdistention of alveoli is likely to occur, resulting in volutrauma and barotrauma. Keeping tidal ventilation between the upper and lower P_{FLEX} values is accomplished by maintaining a level of PEEP to produce baseline alveolar recruitment and delivering a relatively small (6 mL/kg) V_T . Called “open lung” strategy, this approach has proved to be beneficial in alveolar interstitial diseases such as ARDS.

Mechanical ventilation may be delivered either noninvasively with a patient-machine interface other than an ETT or invasively after endotracheal intubation.

Noninvasive Mechanical Ventilation

Delivering positive pressure mechanical respiratory support without the use of endotracheal intubation is called noninvasive positive pressure ventilation (**NIPPV**). This type of respiratory support has been increasingly used in the pediatric intensive care setting.

The most common techniques applied are continuous positive airway pressure (**CPAP**) or biphasic (inspiratory and expiratory) positive airway pressure (**BiPAP**). A variety of devices with increasing sophistication has been developed in recent years, and different interfaces are available, such as nasal prongs, nasal and full-face masks, as well as helmets. Especially in the pediatric population a comfortable interface is critical for the successful application of NIPPV. NIPPV has been successfully used in acute and chronic hypoxic and/or hypercarbic respiratory failure. Indications range from acute lower airway obstruction such as asthma or acute upper airway obstruction including postextubation airway swelling, to parenchymal lung diseases such as pneumonia and ARDS. Acute and chronic respiratory failure, from neuromuscular weakness and chest wall deformities, has been the classic indication for its use. NIPPV can also be used to help prevent reintubation after prolonged mechanical ventilation.

BiPAP provides positive airway pressure during exhalation and additional positive pressure during inspiration. These pressures can be adjusted independently to suit individual needs and comfort, and a respiratory rate can be delivered. The additional positive pressure during inspiration helps improve alveolar ventilation in low compliance and obstructive lung disease. During exhalation, expiratory positive airway pressure can decrease the effects of airway closure by raising intraluminal pressure and ameliorating intrathoracic airway collapse. During inspiration, inspiratory positive airway pressure can unload inspiratory muscle work.

These mechanics may explain many of the physiological benefits of NIPPV including an increase in lung compliance and FRC, a decrease of dynamic airway narrowing (“stenting” of the airway), augmentation of VT and alveolar ventilation, and decreased work of breathing. Physiologic benefits of NIPPV in obstructive (e.g., asthma) and restrictive (e.g., ARDS) lung disease are schematically presented in Figs. 89.8 and 89.9 . Additional benefits result from improving cardiopulmonary interactions, especially LV afterload reduction, thereby improving cardiac output in patients with acute or chronic LV dysfunction.

FIG. 89.8 **Work of breathing (WOB) in status asthmaticus with and without noninvasive positive pressure ventilation. In the expiratory limb of the respiratory cycle, the equal pressure point is displaced distally, causing airways to begin to close at a higher lung volume (increased closing capacity), leading to dynamic hyperinflation, and auto–positive end-expiratory pressure (auto-PEEP) *(A).* Application of expiratory positive airway pressure (EPAP) stents the airways, reducing intrathoracic airway collapse, dynamic hyperinflation, auto-PEEP *(B),* and WOB. In the inspiratory limb, the patient needs to generate less negative pressure to initiate inspiration because of lower auto-PEEP. Inspiratory muscles are further unloaded by inspiratory positive airway pressure (IPAP) throughout inspiration for the given tidal volume. Both expiratory and inspiratory WOB are thus reduced by application of noninvasive positive pressure ventilation. P-V, Pressure-volume. (From Sarnaik AA, Sarnaik AP: Noninvasive ventilation in pediatric status asthmaticus: sound physiologic rationale but is it really safe, effective, and cost-efficient? *Pediatr Crit Care Med* 13:484–485, 2012.)**

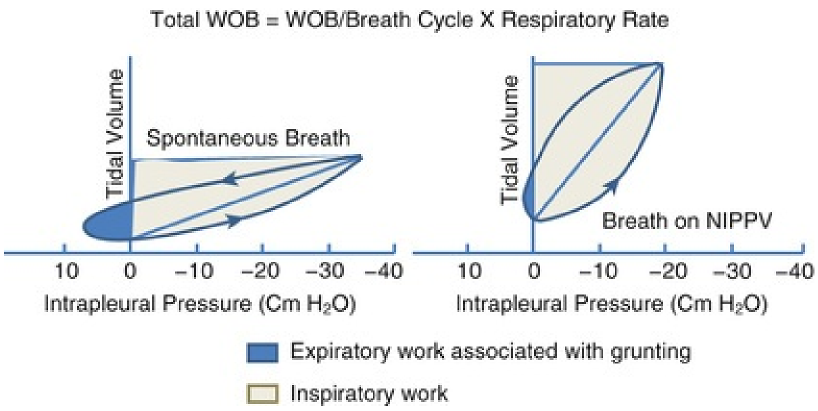

FIG. 89.9 **Beneficial physiologic pulmonary effects of noninvasive positive pressure ventilation (NIPPV) in restrictive lung disease (e.g., ARDS). Left, Without NIPPV, the slope of pressure-volume relationship is flatter, resulting in lower tidal volume for a given inflation pressure and necessitating in increased respiratory rate to maintain required minute alveolar ventilation. Start of inspiration is at a lower lung volume, indicating decreased functional residual capacity (FRC). Expiration is active toward the end as a result of grunting aimed at increasing FRC. Right, On institution of NIPPV, the slope of pressure-volume relationship is increased, resulting in greater tidal volume for a given inflation pressure, with a subsequent decrease in respiratory rate and inspiratory work of breathing (WOB). FRC is increased because of expiratory positive airway pressure (EPAP), resulting in improved oxygenation and decreased expiratory work associated with grunting.**

NIPPV is usually well tolerated and safer than invasive mechanical ventilation. Airway trauma from endotracheal intubation can be avoided, and less sedation is required. Breaks can be given for the application of oral medications and clearance of respiratory secretions, and selected stable patients can be fed by mouth. The number of nosocomial infections, ventilator-associated pneumonia, and ventilator-induced lung injury is expected to decrease as well. In addition, aerosol therapy driven by NIPPV, appears to be more effective.

Complications of NIPPV may include upper airway mucosal irritation, pulmonary hyperinflation with resulting interstitial emphysema and pneumothorax, abdominal distention, aspiration, and feeding intolerance. Patients initiated on NIPPV need close cardiorespiratory monitoring because the respiratory failure may progress, leading to the need for endotracheal intubation.

Some authorities have suggested independent predictors of NIPPV failure. Patients with more severe respiratory distress and those who do not show improvement of respiratory indices (i.e., respiratory rate, reduction in F_{IO_2}) within 2 hr of initiation are more likely to fail. Underlying severe systemic diseases such as sepsis, multiorgan dysfunction, and malignancies are less likely to respond favorably to NIPPV. Absolute contraindications include loss of airway reflexes, acute severe neurologic insults, cardiorespiratory arrest, and severe hemodynamic instability. Patients with mid-face abnormalities or facial trauma and burns should not be considered as candidates for NIPPV. Other contraindications include the immediate postoperative period after facial and upper airway surgery, recent gastrointestinal surgery, or patients with bowel obstruction and vomiting. Patients who are severely agitated and confused should not be initiated on NIPPV. NIPPV has been shown to decrease intubation rates, as well as reintubation rates, and is increasingly used to treat acute or chronic respiratory failure in pediatric patients.

Invasive Mechanical Ventilation

Mechanical ventilation involves considering the four phases of the respiratory cycle: (1) initiation of respiration and a variable that is controlled, often referred to as *mode* ; (2) inspiratory phase characteristics, which determine the duration of inspiration and how the pressure or volume is delivered; (3) termination of inspiration, often referred to as *cycle* ; and (4) expiratory phase characteristics. Ideally, mechanical ventilation should not completely take over the work of breathing, but rather should assist the patient's own respiratory effort. In the absence of any patient effort, respiratory muscle deconditioning may occur, making weaning from mechanical ventilation more difficult.

Initiation of Inspiration and the Control Variable (Mode)

The initiation of inspiration may be set to occur at a predetermined rate and interval regardless of patient effort, or it could be timed in response to patient effort. Once inspiration is initiated, the ventilator breath either is controlled entirely by the ventilator (*control mode*) or supports the patient's inspiratory effort to a predetermined inspiratory volume or pressure target (*support mode*). Advances in technology allow for greater patient-ventilator synchrony to occur. The ventilator may be set to be *triggered* by the signal it receives as a result of patient effort. This feature may be in the form of lowering of either pressure (*pressure trigger*) or airflow (*flow trigger*) in the ventilator circuit generated by the patient's inspiratory effort. If no such signal is received because of lack of patient effort, the ventilator delivers a breath at an interval selected by the operator.

Control Modes

Intermittent Mandatory Ventilation Mode.

In intermittent mandatory ventilation (**IMV**), the inspiration is initiated at a set frequency with a timing mechanism independent of patient effort. In between machine-delivered breaths, the patient can breathe spontaneously from a fresh source of gas. IMV allows for adjustment of ventilator support according to the patient's needs, making it useful in the weaning process. Lack of synchrony between machine-delivered breaths and patient efforts may result in ineffective ventilation and patient discomfort, especially when IMV is delivered at a high rate. In such cases the patient may require sedation and pharmacologic neuromuscular blockade for efficient delivery of V_T . To obviate this problem, **synchronized** IMV (**SIMV**) is used, whereby the machine-delivered breaths are triggered by the patient's inspiratory efforts (Fig. 89.10). In between the machine-delivered breaths, a fresh source of gas is available for spontaneous patient breaths. In the absence of patient effort, the patient receives a backup rate, as in IMV mode. Even with SIMV, ventilator-patient asynchrony can occur, because V_T , inflation pressure, and inspiratory time are determined by the ventilator alone.

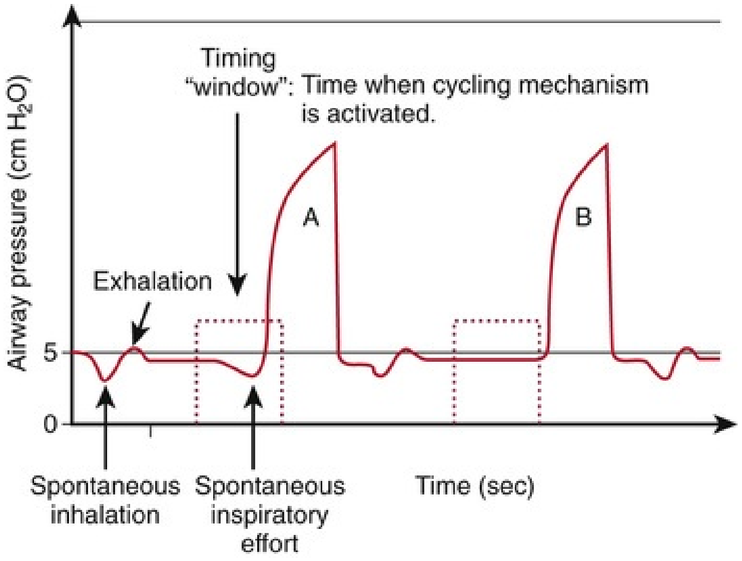

FIG. 89.10 Synchronized intermittent mandatory ventilation. At set intervals, the ventilator's timing circuit becomes activated and a timing "window" appears *(dotted line area)* . If the patient initiates a breath in the timing window, the ventilator delivers a mandatory breath *(A)* . If no spontaneous effort occurs, the ventilator delivers a mandatory breath at a fixed time after the timing window *(B)* . (From Banner MJ,

Gallagher TJ: Respiratory failure in the adult: ventilatory support. In Kirby RR, Smith RA, Desautels DA, editors: *Mechanical ventilation* , New York, 1985, Churchill Livingstone.)

Assist-Control Mode.

In assist-control (AC) mode, every patient breath is triggered by pressure or flow generated by patient inspiratory effort and “assisted” with either preselected inspiratory pressure or volume. The rate of respirations is therefore determined by the patient's inherent rate. A backup total (patient and ventilator) obligatory rate is set to deliver a minimum number of breaths. On AC mode, with a backup rate of 20 breaths/min and a patient's inherent rate of 15 breaths/min; the ventilator will assist all the patient's breaths, and the patient will receive 5 additional breaths/min. On the other hand, a patient with an inherent rate of 25 breaths/min will receive all 25 breaths assisted. Although useful in some patients, the AC mode cannot be used in the weaning process, which involves gradual decrease in ventilator support.

Control Variable

Once initiated, either the VT or the pressure delivered by the machine can be controlled. The machine-delivered breath is thus referred to as either volume controlled or pressure controlled (Table 89.11). With **volume-controlled ventilation (VCV)** , machine-delivered volume is the primary control, and the inflation pressure generated depends on the respiratory system's compliance and resistance. Changes in respiratory system compliance and resistance are therefore easily detected from changes observed in inflation pressure. In **pressure-controlled ventilation (PCV)** the pressure change above the baseline is the primary control, and the Vt delivered to the lungs depends on the respiratory system's C and R. Changes in respiratory system C and R do not affect inflation pressure and may therefore go undetected unless the exhaled Vt is monitored.

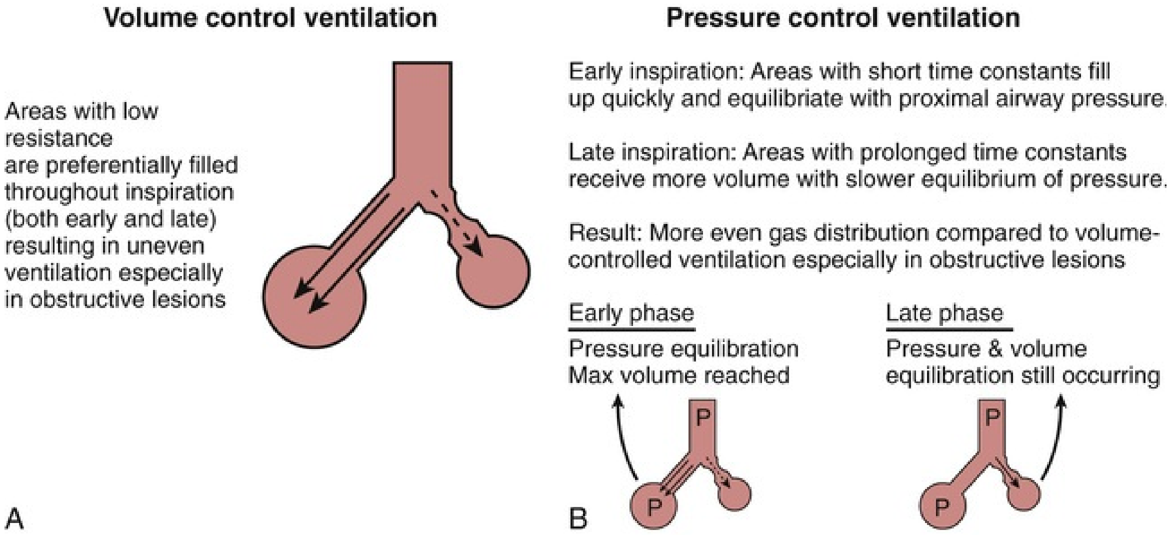
Table 89.11

Characteristics of Pressure-Controlled and Volume-Controlled Methods of Ventilation

	PRESSURE-CONTROLLED VENTILATION	VOLUME-CONTROLLED VENTILATION
Control setting(s)	Inflation pressure	Tidal volume

	Inspiratory time Rise time	Flow rate Inspiratory flow pattern (constant vs decelerating)
Machine-delivered volume	Depends on respiratory system compliance and resistance	Constant
Inflation pressure	Constant	Depends on respiratory system compliance and resistance
Endotracheal tube leak	Somewhat compensated	Leaked volume part of tidal volume
Distribution of ventilation	More uniform in lungs with varying time constant units	Less uniform in lungs with varying time constant units
Patient comfort	Possibly compromised	Possibly enhanced
Weaning	Inflation pressure adjustment required to deliver desired tidal volume	Tidal volume remains constant; inflation pressure automatically weaned

VCV and PCV have their own advantages and disadvantages (Table 89.11). Generally speaking, PCV is more efficient than VCV in terms of amount of V_T delivered for a given inflation pressure during ventilation of a lung that has nonuniform TC, as in asthma. In VCV, relatively less-obstructed airways are likely to receive more of the machine-delivered volume throughout inspiration than relatively more-obstructed airways with longer TC (Fig. 89.11 *A*). This situation would result in uneven ventilation, higher peak inspiratory pressure (PIP), and a decrease in C_{DYN} . In PCV, because of a constant inflation pressure that is held throughout inspiration, relatively less-obstructed lung units with shorter TC would achieve pressure equilibration earlier during inspiration than the relatively more-obstructed areas. Thus, units with shorter TCs would attain their final volume earlier in inspiration, and those with longer TCs would continue to receive additional volume later in inspiration (Fig. 89.11 *B*). This situation would result in more even distribution of inspired gas, delivery of more V_T for the same inflation pressure, and improved C_{DYN} compared with VCV.



Volume control ventilation
Areas with low resistance are preferentially filled throughout inspiration (both early and late) resulting in uneven ventilation especially in obstructive lesions
A
Pressure control ventilation
Early inspiration: Areas with short time constants fill up quickly and equilibriate with proximal airway pressure.
Late inspiration: Areas with prolonged time constants receive more volume with slower equilibrium of pressure.
Result: More even gas distribution compared to volume-controlled ventilation especially in obstructive lesions
Early phase
Pressure equilibration
Max volume reached
Late phase
Pressure & volume equilibration still occurring
P
P
P
P
B

FIG. 89.11 **A,** In volume-controlled ventilation (VCV), tidal volume (VT) is delivered to the less-obstructed areas throughout inspiration. Obstructed areas of the lung therefore receive a lower proportion of VT , resulting in uneven ventilation. **B,** In pressure-controlled ventilation (PCV), less-obstructed areas equilibrate with inflation pressure and therefore receive most of their VT early during inspiration. More-obstructed areas, with prolonged time constants, require longer time for pressure equilibration and therefore continue to receive a portion of their VT later during inspiration. The entire VT is more evenly distributed than with volume-cycled ventilation.

Pressure-regulated volume control (PRVC) combines the advantages of VCV and PCV. In this mode, the VT and TI are controlled as primary variables, but the ventilator determines the amount of pressure needed to deliver the desired VT . Inflation pressure is thus adjusted to deliver the prescribed VT over the TI , depending on the patient's respiratory C and R.

Support Modes

Pressure-support ventilation (PSV) and **volume-support ventilation (VSV)** are designed to support the patient's spontaneous respirations. With PSV, initiation of inspiration is triggered by the patient's spontaneous breath, which is then "supported" by a rapid rise in ventilator pressure to a preselected level. The inspiration is continued until the inspiratory flow rate falls to a set level (generally 25% of peak flow rate) as the patient's lungs fill up. Thus, TI is controlled by the patient's own efforts. PSV can be combined with SIMV so that any breath above the SIMV rate is supported by PSV. Allowing the patient to control as much of the rate, VT , and inspiratory time as possible is considered a gentler form of mechanical ventilation than SIMV, in which the VT (or inflation pressure) and TI are preset. PSV as the sole source of mechanical ventilator support is often not adequate for patients with severe lung disease. However, PSV is especially useful in patients being weaned and in those who require mechanical ventilation for relatively minor lung disease or for neuromuscular weakness.

VSV is similar to PSV, in that all the spontaneous breaths are supported. In VSV, inspiratory pressure to support spontaneous breaths is adjusted to guarantee a preset VT . If there is a change in respiratory mechanics or patient effort, the inspiratory pressure to support the breath initiated by patient effort is automatically adjusted to deliver the set VT .

Inspiratory Phase Characteristics

TI , inspiratory flow waveform, and pressure rise time can be adjusted in the inspiratory phase to suit the patient's respiratory mechanics.

In PCV the duration of TI is directly set in seconds. In VCV the TI can be adjusted by adjusting the inspiratory flow (volume/time). The choice of TI value depends on the respiratory rate, which determines the total duration of each breath, and on the estimation of inspiratory and expiratory TCs. Decreasing the flow rate delivery increases TI , and vice versa. With an increase in TI , the pulmonary capillary blood is exposed to a higher level of PAO$_2$ for a longer time. This feature is beneficial in diseases with decreased FRC, such as ARDS and pulmonary edema. An increase in TI also increases VT without increasing inflation pressure in PCV if inspiratory flow is still occurring at end-expiration. It must be recognized that at a given ventilator rate, an increase in TI decreases expiratory time (TE). Therefore, any strategy that employs an increase in the inspiratory component of the respiratory cycle should ensure that the decreased TE is still sufficient for complete exhalation.

Inspiratory flow waveform can be adjusted in VCV mode as either a constant flow (square waveform) or a decelerating flow (descending ramp waveform). With a square waveform, flow is held constant throughout inspiration. In a descending ramp waveform, flow is maximal at the start of inspiration and declines throughout its duration. It is debatable which flow pattern is better for a given disease.

In PCV and PSV, the prescribed PIP is reached through delivery of airflow. *Pressure rise time* reflects the time required for the ventilator to reach PIP and can be adjusted by control of flow at the beginning of the inspiratory phase. The inspiratory flow rise time is adjusted to provide comfort for a patient who is awake and also to prevent an extremely rapid rise in inspiratory pressure, which might result in barotrauma.

Termination of Inspiration (Cycle)

The 2 most commonly used inspiratory terminating mechanisms in control modes are time-cycled and volume-cycled. With a **time-cycled** mechanical breath, inspiration is terminated after a preselected TI has elapsed, whereas with **volume-cycled** breath the inspiration ends after a preselected volume has been delivered by the machine into the ventilator circuit. A time-cycled breath is almost always pressure-limited, with the PIP held constant for the duration of inspiration. A volume-cycled breath can be pressure-limited as a safety mechanism to avoid barotrauma. The inspiration-terminating mechanism is set somewhat differently in support modes. In PSV the inspiration is set to end after the inspiratory flow decreases below a certain percentage (usually 25%) of peak inspiratory flow. This happens when the patient no longer desires to receive additional VT . Such a breath can be termed **flow-cycled** . In VSV the inspiration is terminated when the patient has received the desired VT .

Expiratory Phase Maneuvers

The most useful expiratory phase maneuver is the application of PEEP, which is applied to both the control breath and the assisted breath. The most important clinical benefits of PEEP are to recruit atelectatic alveoli and to increase FRC in patients with alveolar-interstitial diseases and thereby improve oxygenation. There is growing recognition that even a brief disconnection from a ventilator, and therefore having zero end-expiratory pressure (ZEEP), can result in significant alveolar **derecruitment** and decline in oxygenation. In patients with obstructive lesions in which insufficient exhalation results in air trapping and auto-PEEP, extrinsic PEEP (that applied through a mechanical device) can prevent airway closure during expiration and improve ventilation. Other salutary effects of PEEP include redistribution of extravascular lung water away from gas-exchanging areas, improved V̇/Q̇ relationship, and stabilization of the chest wall. The effect of PEEP on lung C is variable, depending on the level of PEEP provided and the patient's pulmonary mechanics. By shifting the VT ventilation to a more favorable part of the pressure-volume curve, PEEP may recruit more alveoli, delay airway closure, and improve lung C. Excessive PEEP, on the other hand, may lead to overdistention of alveoli and reduced C. The effect of PEEP in individual patients can be ascertained by measuring exhaled V_T and calculating C_{DYN} . Other deleterious effects of PEEP include decreased venous return, increased pulmonary vascular resistance, and decreased cardiac output.

Additional Ventilatory Modalities

Airway Pressure Release Ventilation

Airway pressure release ventilation (**APRV**) improves oxygenation in patients with severe hypoxemic respiratory failure resulting from alveolar-interstitial disease. This modality applies a CPAP, designated $CPAP_{HIGH}$, to recruit and maintain FRC with brief intermittent release phases of $CPAP_{LOW}$ to allow alveolar gas to escape. $CPAP_{HIGH}$ is analogous to PIP, and $CPAP_{LOW}$ is similar to setting PEEP. In contrast to the patient receiving conventional mechanical ventilation, a patient receiving APRV spends the majority of time in the $CPAP_{HIGH}$ phase, which may last as long as 3-5 sec with a brief (0.3-0.5 sec) time in the $CPAP_{LOW}$ phase. These atypically long T_I s are tolerated because of a floating expiratory valve in the ventilator circuit that permits spontaneous breathing during $CPAP_{HIGH}$ phase. Therefore, even if the $CPAP_{HIGH}$ phase can be considered “inspiratory” and the $CPAP_{LOW}$ phase “expiratory” in regard to the ventilator, the patient is able to breathe spontaneously during both these phases. The longer ventilator T_I recruits lung units, and the ability to breathe spontaneously during this phase allows distribution of gas flow to atelectatic lung regions. The outcome benefit of APRV in pediatric hypoxemic respiratory failure has not been proved.

High-Frequency Ventilation

Mechanical ventilation at supraphysiologic rates and low V_T , known as high-frequency ventilation (**HFV**), improves gas exchange in a select group of patients who show no response to traditional ventilatory modalities. The mechanism of alveolar ventilation in HFV is very different from that in conventional ventilation, in that HFV is less dependent on V_T and more dependent on asymmetric velocities and convective dispersion of inspired gas.

Patients with severe persistent hypoxic failure are most likely to benefit from HFV. HFV is also helpful in patients with bronchopleural fistula and persistent air leaks. The main tenet of HFV is to recruit lung volume with a high MAP and produce smaller fluctuations in alveolar pressure during inspiration and expiration, thus maintaining a satisfactory FRC and reducing alveolar stretch. The 2 most investigated techniques of HFV are HFO and HFJV.

The most commonly used HFV modality is **high-frequency oscillation (HFO)** , which employs a mechanism to generate to-and-fro air movement. Additional air is drawn in (entrained) through a parallel circuit via a Venturi effect. Air is pushed in during inspiration and actively sucked out during expiration. The main determinants of oxygenation are FIO_2 and MAP, whereas ventilation is determined by changes in pressure (amplitude) from the MAP. Commonly used respiratory frequency varies from 5 Hz (300 breaths/min) in adults and older children, to 6-8 Hz (360-480 breaths/min) in young children, 8-10 Hz (480-600 breaths/min) in infants, and 10-12 Hz (600-720 breaths/min) in newborn and premature infants.

In **high-frequency jet ventilation (HFJV)** , a high-frequency interrupter is interposed between a high-pressure gas source and a small cannula that is incorporated in the ETT. The cannula propels tiny amounts of gas (jets) at high velocity and high frequency through the ETT. An additional amount of gas is entrained from a parallel circuit. Unlike in HFO, expiration occurs passively in HFJV as a result of elastic recoil of the lung and the chest wall. PEEP is set through the parallel circuit by a conventional ventilator in line. Respiratory rate is generally set at 420 breaths/min. Major determinants of oxygenation are Fio_2 and PEEP, and the major determinant of ventilation is PIP.

Conventional Ventilator Settings

Fraction of Inspired Oxygen

The shape of the hemoglobin-O_2 dissociation curve dictates that oxygen content in the blood is not linearly related to PaO_2 . A PaO_2 value that results in an oxyhemoglobin saturation of 94% is reasonable in most situations, because a higher PaO_2 would cause minimal increase in arterial oxygen content, and a modest (10 mm Hg) drop in PaO_2 would result in minimal decrease in oxyhemoglobin saturation. In most cases, a PaO_2 value of 70-75 mm Hg is a reasonable goal. F_{IO_2} values that are higher than those necessary to attain oxyhemoglobin saturations of approximately 95% expose the patient to unnecessary oxygen toxicity. Whenever possible, F_{IO_2} values should be decreased to a level ≤0.40 as long as oxyhemoglobin saturation remains ≥95%.

Mode

The choice of mode of ventilation depends on how much ventilator-patient interaction is desired and the disease entity that is being treated. SIMV or AC is chosen as the control mode; PCV, VCV, or PRVC as the variable that is to be controlled; and pressure support and volume support are the choices for support modes.

Tidal Volume and Rate

As previously discussed, alveolar ventilation, the chief determinant of Pa_{CO_2}, is calculated using V_T, respiratory rate, and V_D. A change in V_T results in a corresponding change in alveolar ventilation without affecting V_D-ventilation. A change in respiratory rate will affect alveolar ventilation as well as the V_D-ventilation. Choice of V_T and rate depends on the TC. In a patient with relatively normal lungs, an age-appropriate ventilator rate and a V_T of 7-10 mL/kg would be appropriate initial settings. Diseases associated with decreased TC (decreased static compliance; e.g., ARDS, pneumonia, pulmonary edema) are best treated with small (6 mL/kg) V_T and relatively rapid rates (e.g., 25-40 breaths/min). Diseases associated with prolonged TCs (increased airway resistance; e.g., asthma, bronchiolitis) are best treated with relatively slow rates and higher (10-12 mL/kg) V_T. In PCV the delivered V_T depends on the C and R of the patient's respiratory system and needs to be monitored to ensure the appropriate amount for a given situation. An inflation pressure of 15-35 cm H_2O is sufficient for most patients, but it may need adjustment, depending on the volume of exhaled V_T. It should be emphasized that achieving a *normal* Pa_{CO_2} value is not a goal of mechanical ventilation. Mild hypercapnia (permissive hypercapnia) should be acceptable, especially when one is attempting to limit injurious inflation pressures or V_Ts.

Inspiratory Time and Expiratory Time

TI and TE are adjusted by setting inspiratory flow rate in VCV and by setting the precise TI in PCV. Increasing the TI results in increased MAP, improved oxygenation in diseases with decreased FRC, and better distribution of VT in obstructive lung disease. Sufficient expiratory time must be provided to ensure adequate emptying of the alveoli.

Positive End-Expiratory Pressure

The best level of PEEP depends on the disease entity that is being treated, and it may change in the same patient from time to time. Decisions are often based on the PaO_2/FIO_2 ratio and the measurement of C_{DYN}.

Patient-Ventilator Asynchrony

Patient-ventilator asynchrony occurs when the patient's respiratory pattern does not match that of the ventilator. This can occur during all phases of respiration. Adverse effects of patient-ventilator asynchrony include wasted effort, ineffective delivery of desired VT , excessive generation of intrathoracic pressure resulting in barotrauma and adverse effects on cardiac output, increased work of breathing, and patient discomfort. Although several mechanisms exist to facilitate patient-ventilator asynchrony, a certain amount of asynchrony is inevitable unless the patient is pharmacologically sedated and paralyzed.

Triggering the Ventilator

The patient must be able to trigger the ventilator without excessive effort. Ventilators can be pressure-triggered or flow-triggered. With **pressure triggering** , the inspiratory valve opens and flow is delivered when a set negative pressure is generated within the patient-ventilator circuit during inspiration. The amount of pressure required to trigger an inspiration depends on the pressure trigger sensitivity. In **flow triggering** the ventilator provides a base flow of gas through the ventilator-patient circuit. When a flow sensor on the expiratory limb of the patient-ventilator circuit detects a decrease in flow as a result of the patient's inspiratory effort, the inspiratory valve opens and a ventilator breath is delivered. The degree of change in flow required to trigger an inspiration depends on the flow trigger sensitivity. Flow triggering is considered to be more comfortable, primarily because the patient receives some flow before triggering the ventilator, in contrast to pressure triggering, in which no flow is provided until the ventilator breath is triggered. Increasing the trigger sensitivity by decreasing the change in either pressure or flow needed to trigger an inspiration decreases the work of breathing. However, reducing the required pressure or flow excessively could result in accidental triggering and unwanted breaths by turbulence, caused by condensation in the ventilator circuit, ETT air leaks, or cardiac oscillations.

Selection of Appropriate Inspiratory Time

The duration of T_I should match the patient's own inspiratory phase. If T_I is too long, the patient's drive to exhale may begin before the ventilator breath has cycled off. When this occurs, exhalation occurs against inspiratory flow and a closed exhalation valve, resulting in increased work of breathing, excessive rise in intrathoracic pressure, and discomfort. If T_I is too short, the patient may be still inhaling without respirator support. In general terms, T_I is usually initiated at 0.5-0.7 sec for neonates, 0.8-1 sec in older children, and 1-1.2 sec for adolescents and adults. Adjustments need to be made through individual patient observations and according to the type of lung disease present. In patients with severe lung disease (both obstructive and restrictive), unnatural T_I and T_E values may have to be selected, as discussed earlier. In such situations, adequate analgesia, sedation, and in extreme cases neuromuscular blockade may be needed.

Selection of Inspiratory Flow Pattern

In VCV, inappropriate flow may be another source of patient-ventilator dyssynchrony. After initiation of inspiration, if the set amount of flow is inadequate to meet patient demand, a state of **flow starvation** occurs, resulting in excessive work of breathing and discomfort. Such patients may require a decelerating inspiratory flow pattern, in which a higher flow is provided in the beginning of inspiration and less toward the end as the lungs fill up. On the other hand, such a pattern may be uncomfortable for a patient who desires more gradual alveolar filling. The selection of inspiratory flow pattern should be based on the individual patient's respiratory mechanics. In PCV and PSV, the inspiratory rise time determines the manner in which the airway pressure is raised and V_T delivered. Considerations for choosing the appropriate rise time in

PCV and PSV are similar to those for choosing the inspiratory flow pattern in VCV.

Use of Support Modes

A conscious patient should be allowed to have spontaneous breaths that are supported by either PSV or VSV. This approach minimizes the mandatory breaths generated by the ventilator that are beyond the patient's control to modulate. Therefore, continued assessments should be made to determine whether the patient is able to maintain ventilatory requirements more in support modes and less in control modes.

Use of Sedation and Pharmacologic Neuromuscular Blockade

Having a conscious but comfortable patient is a desirable goal during mechanical ventilation. Spontaneous breaths with good muscle tone and presence of cough are important for adequate clearance of tracheobronchial secretions. The patient's ability to indicate distress is also important in identifying and preventing potential injurious factors. In certain situations, management of patient-ventilator asynchrony assumes much greater importance when the asynchrony is causing unacceptable derangement of gas exchange and ventilator-induced lung injury. Both alveolar interstitial lung pathology and obstructive airway diseases may necessitate unnatural and uncomfortable settings for respiratory rate, T_I , and inflation pressures. In such patients, deep sedation is often necessary; dexmedetomidine, benzodiazepines, and opiates are the agents most commonly used for this purpose. In extreme situations, pharmacologic neuromuscular blockade with a nondepolarizing agent, such as vecuronium, is required to abolish any patient effort and respiratory muscle tone. When such pharmacologic paralysis is used, deep sedation must be ensured so that the patient does not sense pain and discomfort. Pharmacologic sedation and paralysis can ensure total control of the patient's ventilation by mechanical means and may result in lifesaving improvement in gas exchange with reduction in inflation pressures. However, long-term use of such agents may be associated with undesirable consequences and higher morbidity. The risk of inadequate tracheobronchial secretions and atelectasis is potentially greater. Long-term use of pharmacologic sedation may be associated with chemical dependency and withdrawal manifestations, and prolonged neuromuscular blockade is associated with neuromyopathy in critically ill patients. The benefits of sedation and pharmacologic paralysis therefore should be carefully balanced with the risks, and periodic assessments should be made to determine the need for their continuation.

Cardiopulmonary Interactions

Mechanical ventilation can have salutary as well as adverse effects on cardiac performance. By decreasing oxygen consumption necessary for work of breathing, oxygen supply to vital organs is improved. Positive pressure breathing decreases LV afterload, thus enhancing stroke volume and cardiac output in patients with failing myocardium (e.g., myocarditis). On the other hand, the decreased systemic venous return may further compromise stroke volume in hypovolemic patients. Such patients will require intravascular fluid loading. Also, an increase in pulmonary vascular resistance (PVR) caused by positive intrathoracic pressure may result in further decompensation of a poorly performing right ventricle. PVR is at its lowest value at an optimum FRC. When FRC is too low or too high, PVR (and therefore the right ventricular afterload) is increased. Both desirable and undesirable effects of cardiopulmonary interactions may coexist and require ongoing assessment and necessary interventions (Table 89.12).

Table 89.12

Suggested Mechanical Ventilation Strategies in Various Clinical Situations

SITUATION	DISEASE	STRATEGY
Low compliance, normal resistance	ARDS	PCV, APRV, HFO, HFJV
Normal compliance, high resistance	Asthma	PVC, PRVC
Normal compliance, normal resistance, for weaning	Head trauma, drug overdose, subglottic stenosis	VCV

APRV, Airway pressure release ventilation; ARDS, acute respiratory distress syndrome; HFO, high-frequency oscillation; HFJV, high-frequency jet ventilation; PCV, pressure-controlled ventilation; PRVC, pressure-regulated volume control; VCV, volume-controlled ventilation.

Monitoring Respiratory Mechanics

Exhaled Tidal Volume

Exhaled tidal volume (VTE) is measured by a pneumotachometer in the ventilator circuit during exhalation. In VCV, part of the machine-delivered volume may leak out during inspiration and therefore never reach the patient. Measurement of VTE more accurately describes the VT that is contributing to the patient's alveolar ventilation. In PCV the VTE depends on the patient's respiratory system compliance and resistance and therefore offers valuable diagnostic clues. A decrease in VTE during PCV is indicative of either decrease in compliance or increase in resistance and is helpful in directing the clinician to appropriate investigation and management. An increase in VTE is indicative of improvement and may require weaning of inflation pressures to adjust the VTE .

Peak Inspiratory Pressure

In VCV and PRVC, the PIP is the secondary variable determined by the patient's respiratory system compliance and resistance. An increase in PIP in these modes is indicative of decreased C (e.g., atelectasis, pulmonary edema, pneumothorax) or increased R (e.g., bronchospasm, obstructed ET). During VCV and PRVC, decreasing the respiratory rate or prolonging the TI will result in a lower PIP in patients with prolonged TCs because more time will be available for alveoli to fill. In such patients, a decrease in PIP suggests increased C or decreased R of the respiratory system.

Respiratory System Dynamic Compliance and Static Compliance

The changes in PIP during VCV and PRVC, and in VTE during PCV, are determined by C_{DYN} of the respiratory system (lung and chest wall). C_{DYN} is calculated as follows:

$$C_{DYN} = \mathrm{VTE} \div (\mathrm{PIP} - \mathrm{PEEP})$$

C_{DYN} takes into account both the flow-resistive and the elastic properties of the respiratory system. Changes in C_{DYN} can be used to assess effects of different levels of PEEP as tidal ventilation is shifted along the slope of the volume-pressure curve (see Fig. 89.7). An increase in PEEP in alveolar-interstitial diseases (increased elastance), resulting in an increase in C_{DYN} suggests alveolar recruitment, whereas a decrease in C_{DYN} may indicate overdistention. Similarly, in obstructive diseases (increased R), adjustment in PEEP levels to ameliorate airway collapse during exhalation can be guided by monitoring C_{DYN} . To assess only the elastic recoil of the lung, measurement of C_{STAT} when there is no airflow is required. This measurement is performed by using an inspiratory hold maneuver with the patient under neuromuscular blockade and observing pressure-time and flow-time waveforms (Fig. 89.12). During this maneuver, inspiratory flow ceases while the expiratory valve continues to remain closed, thus allowing pressure to equilibrate throughout the ventilator circuit and the patient's lungs. This pressure, referred to as the *plateau pressure* (P_{plat}), reflects alveolar pressure. C_{STAT} is calculated as follows:

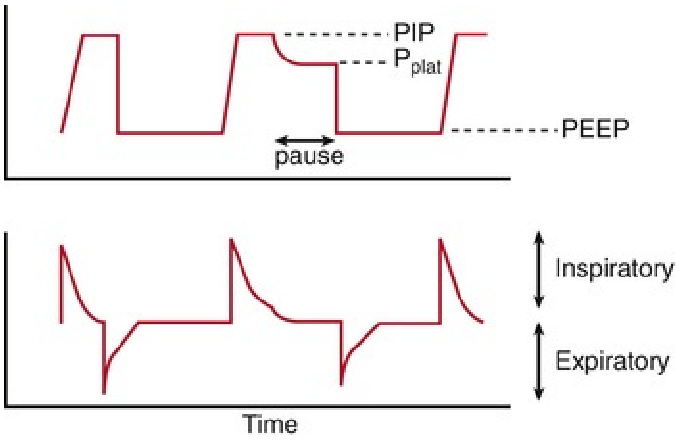


FIG. 89.12 Alveolar pressure is best determined by measurement of plateau pressure (P_{plat}). Inspiration is paused for an extended period, and alveolar gas pressure is allowed to equilibrate with the ventilator circuit pressure. Airway pressure at the end of the inspiratory pause is P_{plat} . The difference between peak inspiratory pressure (PIP) and P_{plat} is meant to overcome flow-resistive properties of the lung, whereas P_{plat} reflects the pressure needed to overcome elastic properties of lung and chest wall. PEEP, Positive end-expiratory pressure.

$$C_{STAT} = VTE \div (P_{plat} - PEEP)$$

The difference between C_{DYN} and C_{STAT} is attributable to airway resistance. This difference is minimal in alveolar-interstitial diseases but substantial in airway obstruction.

Assessment of Auto-PEEP

Auto-PEEP is assessed with the use of an expiratory pause maneuver in which inspiration is delayed and alveolar pressure is allowed to equilibrate with the airway. In diseases with airway obstruction, insufficient alveolar emptying may occur if exhalation time is not adequate. The alveolar pressure in excess of the set PEEP at the completion of the expiratory pause is measured as auto-PEEP or intrinsic PEEP. Auto-PEEP can have adverse effects on ventilation and hemodynamic status. It can be managed by decreasing the respiratory rate or T_I and thus allowing longer time for exhalation. Auto-PEEP may also be managed by increasing the set PEEP (*extrinsic* PEEP), thereby delaying airway closure during exhalation and improving alveolar emptying.

Assessment of Dead Space Ventilation

Positive pressure ventilation and application of PEEP may result in a decrease in venous return, cardiac output, and therefore pulmonary perfusion as well. Ventilation of poorly perfused alveoli results in dead space ventilation, which does not contribute to gas exchange. The V_D/V_T fraction can be calculated (see Chapter 89). Normal V_D/V_T is 0.33. Increased V_D/V_T is indicative of poorly perfused alveoli. Patients with increased V_D/V_T may require intravascular volume infusion or other means of augmenting the cardiac output to improve pulmonary perfusion. The V_D/V_T fraction is calculated and displayed by commercially available capnographs, which measure endotracheal P_{ETCO_2} continuously.

Ventilator-Induced Lung Injury

As with most medical therapies, mechanical ventilation can be harmful. Pathophysiology of ventilator-induced lung injury can be multifactorial. Large lung volumes and high pressures delivered with increased frequency cause cyclic strain, which may lead to disruption of the tight junctions between the alveolar epithelial and capillary endothelial cells, with intracapillary blebs resulting in alveolar and interstitial edema. This **biotrauma** may cause the release of proinflammatory cytokines that further injure the lung and travel in the blood outside the lung, leading to multiorgan failure. Evidence shows that in patients with ARDS, avoidance of $V_T \geq 10$ mL/kg and $P_{plat} \geq 30$ cm H_2O limits diffuse alveolar damage.

Atelectrauma is shear stress on the alveolar walls caused by cyclic opening and closing of the alveoli. PEEP can be used to prevent collapse and keep alveoli open. It is important that alveolar units are neither overdistended nor collapsed. Careful adjustments of PEEP may also permit the clinician to wean a patient from a high F_{IO_2}, another potential source of lung injury (**oxytrauma**). Although most patients receive an F_{IO_2} of 1.00 during endotracheal intubation and at the beginning of mechanical ventilation, increasing PEEP to recruit alveoli without overdistention should be quickly instituted to improve oxygenation and permit weaning of the F_{IO_2}. Although the F_{IO_2} value below which there is no risk of oxygen toxicity is unknown, most clinicians aim for a value <0.6. Regional mechanics may play a role in lung injury.

Ventilator-Associated Pneumonia

The pathophysiology of ventilator-associated pneumonia (VAP) is multifactorial. Aspiration of oral and/or gastric secretions, colonization of ETTs, and suppression of cough reflexes with sedation all play a role. New-onset fever and leukocytosis accompanied by demonstration of an infiltrative process on chest radiography are consistent with a diagnosis of VAP. This complication can lead to worsened gas exchange, increased duration of ventilation, and even death. Elevation of the head of the bed to 30 degrees after initiation of mechanical ventilation and use of a protocol for oral decontamination during mechanical ventilation are 2 means of reducing the risk for VAP. The most effective strategy to minimize any of the aforementioned complications is regular assessment of extubation readiness and liberation from mechanical ventilation as soon as clinically possible.

Weaning

Weaning from mechanical ventilation should be considered as a patient's respiratory insufficiency begins to improve. Most pediatricians favor gradual weaning from ventilator support. With SIMV, the ventilator rate is slowly reduced, allowing the patient's spontaneous breaths (typically assisted with pressure or volume support) to assume a larger proportion of the minute ventilation. When the ventilator rate is low (<5 breaths/min) such that its contribution to minute ventilation is minimal, assessment of extubation readiness is performed. An alternative method of gradual weaning is transition to PSV. In this mode, no ventilator rate is set, allowing all triggered breaths to be assisted with pressure support. The clinician reduces the pressure support slowly to a low value (<5-10 cm H_2O), at which point assessment of extubation readiness is performed. During either technique, weaning should be halted if tachypnea, increased work of breathing, hypoxemia, hypercapnia, acidosis, diaphoresis, tachycardia, or hypotension occurs.

The most objective means of assessing extubation readiness is a **spontaneous breathing trial (SBT)** . Before performance of an SBT, a patient should be awake with intact airway reflexes, capable of handling oropharyngeal secretions, and with stable hemodynamic status. In addition, gas exchange should be adequate, defined as Pa_{O_2} >60 mm Hg while receiving F_{IO_2} <0.4 and PEEP ≤5 cm H_2O. If these criteria are present, a patient should be started on CPAP with minimal or no pressure support (≤5 cm H_2O). If this SBT is tolerated with no episodes of respiratory or cardiovascular decompensation, successful extubation is likely.

Some neonates and small children cannot be calmed or consoled long enough to complete the SBT. In this situation, extubation readiness must be assessed on a low level of ventilator support. Data suggest a low risk of extubation failure if the patient is comfortable and has stable hemodynamic status, with adequate gas exchange and spontaneous V_T >6.5 mL/kg, while receiving <20% of total minute ventilation from the ventilator. Certain patient populations are at increased risk for extubation failure, such as young infants, children mechanically ventilated for >7 days, and patients with chronic respiratory or neurologic conditions. These children often benefit from transition to a noninvasive form of positive pressure ventilation (e.g., high-flow nasal cannula, CPAP, or BiPAP) delivered via nasal prongs or face mask to increase the odds of successful extubation.

The likelihood of **postextubation upper airway obstruction** , the most common cause of extubation failure in children, cannot be predicted on the basis of an SBT result or bedside measurements of physiologic variables. Traumatic endotracheal intubation and subglottic swelling from ETT irritation, especially in patients who exhibit agitation while receiving mechanical ventilation, are common causes of airway narrowing after extubation. Administration of intravenous corticosteroids (dexamethasone, 0.5 mg/kg every 6 hr for 4 doses before extubation) has been shown to minimize the incidence of postextubation airway obstruction. In patients in whom postextubation airway obstruction develops, the need for reintubation may be obviated by administration of nebulized racemic epinephrine and heliox.

CHAPTER 90

Altitude-Associated Illness in Children (Acute Mountain Sickness)

Christian A. Otto

High-altitude illness represents a spectrum of clinical entities with neurologic and pulmonary manifestations that overlap in their presentations and share common elements of pathophysiology. **Acute mountain sickness (AMS)** is the relatively benign and self-limited presentation, whereas **high-altitude pulmonary edema (HAPE)** and **high-altitude cerebral edema (HACE)** have potentially life-threatening manifestations.

Often overlooked by travelers as high-altitude destinations are cities such as La Paz, Bolivia (3,700 meters, approximately 12,100 feet), Lhasa, Tibet (3,600 m, ~11,800 ft), Cusco, Peru (3,400 m, ~11,200 ft), and Quito, Ecuador (2,850 m, ~9,350 ft), which reside at an elevation where altitude illness is likely to develop. In 2014, >15 million people visited Lhasa, a 6-fold increase over 8 yr since the opening of the Qinghai-Tibet Railway. In the western United States, 35 million people visit alpine resorts each year. Over 40% of those who stay above 3,300 m (~11,000 ft) have been found to suffer from AMS. In Colorado alone, approximately 150,000 children <12 yr old visit the mountains annually on ski holidays with their families. In 2014, AMS symptoms were severe enough to result in 1,350 visits to emergency departments (EDs) throughout Colorado. Because of the increasing family travel to high altitude, thousands of children are likely to develop AMS symptoms.

Etiology

The altitude threshold where clinical illness may begin to occur is 1,500 m (~4,900 ft). At this altitude a mild impairment in oxygen transport begins, although altitude illness is relatively rare until higher elevations are reached. Children with underlying medical problems that impair oxygen transport may be predisposed to developing altitude illness at these lower levels. At *moderate high altitude,* 2,500-3,500 m (~8,000-11,500 ft), arterial oxygen saturation (SaO_2) is generally well maintained; however, mild tissue hypoxia may occur as a result of low arterial oxygen partial pressure (PaO_2), and altitude illness becomes common after rapid ascent above 2,500 m (~8,200 ft). This is the altitude range that most people visit and the elevation of many popular U.S. ski resorts and thus the most common range to find the greatest number of altitude illness cases. *Very high altitude,* 3,500-5,500 m (~11,500-18,000 ft), is associated with the most serious altitude illness; SaO_2 falls below 90%, on the steep portion of the oxyhemoglobin dissociation curve, and marked desaturation may occur with relatively small increases in altitude. At these heights, severe hypoxemia is seen with sleep, exercise, and illness. HAPE and HACE are most common in this environment. *Extreme high altitude,* above 5,500 m (~18,000 ft), generally results in severe altitude illness during acute ascent without supplemental oxygen. Acclimatization at intermediate altitudes is required to reach extreme altitudes. Complete acclimatization is not possible, and long visits result in progressive deterioration.

General Effects of Hypobaric Hypoxia

The partial pressure of oxygen (PO_2) in the atmosphere decreases logarithmically as geographic altitude rises, but oxygen remains a constant 20.93% of the barometric pressure. SaO_2 falls with increasing altitude, eventually triggering central chemoreceptor responses to produce hyperventilation in an attempt to normalize SaO_2; relative hypoventilation exacerbates the hypoxemia of high-altitude exposure. During sleep, periodic breathing associated with high-altitude exposure may result in periods of apnea, causing further arterial oxygen desaturation. Fluid homeostasis often shifts at altitude, resulting in a generalized fluid retention and redistribution into intracellular and interstitial spaces, manifested by peripheral edema, decreased urine output, and impaired gas exchange.

Acclimatization

Gradual ascents allowing for acclimatization over several weeks have allowed successful summiting of many of the world's highest peaks without supplemental oxygen. Without this gradual approach, rapid exposure to extreme altitude results in loss of consciousness and asphyxia in minutes. Children acclimatize as well as, if not better than, adults when comparing heart rate and SaO_2 of 7-9 yr olds to their parents during a slow ascent.

Some of the responses to hypoxia are mediated at the molecular level by *hypoxia-inducible factor* (HIF). This transcriptional activator orchestrates the expression of hundreds of genes in response to both acute and chronic hypoxic conditions. Acclimatization begins at the altitude that causes SaO_2 to fall below sea-level values. Most healthy, unacclimatized visitors to high altitude will not experience a significant drop in SaO_2 (<90%) until they reach elevations above 2,500 m (~8,200 ft). Children with preexisting conditions that reduce oxygen transport may have altitude intolerance and hypoxic stress at lower levels. Of particular importance are both acute and chronic cardiac and respiratory illnesses. An individual's inherent ability to acclimatize is also important. Previous successful acclimatization may be predictive of future responses for adults in similar conditions but may not be the case for children. Some acclimatize easily without developing clinical symptoms; others may transiently develop AMS during acclimatization; and a few have marked reactions to altitude exposure, fail to acclimatize, and develop severe altitude illness.

The most important response to acute hypoxia is an increase in minute ventilation. Peripheral chemoreceptors in the carotid bodies respond to hypoxia by signaling the respiratory control center in the medulla to increase ventilation. This decreases alveolar carbon dioxide partial pressure ($PACO_2$), resulting in a corresponding increase of PAO_2 and arterial oxygenation. This increased ventilation, known as the **hypoxic ventilatory response (HVR)** , varies in magnitude among individuals, may be genetically predetermined, and is related to the ability to acclimatize. Changes in the HVR and the onset of AMS with ascent to high altitude have been found to be remarkably similar between children and their fathers. Additional research has demonstrated that familial clustering of AMS accounts for up to 50% of the variability of AMS onset among children. A low HVR and relative hypoventilation are implicated in the pathogenesis of both AMS and HAPE, whereas a strong HVR enhances acclimatization. As ventilation increases, a respiratory alkalosis occurs, exerting negative feedback on central respiratory control and limiting further ventilation increase. The kidneys excrete bicarbonate in an effort to compensate for the alkalosis. As the pH normalizes, ventilation rises slowly, reaching a maximum after 4-7 days. *This process is enhanced by acetazolamide, which induces a bicarbonate diuresis.*

Increased sympathetic activity and catecholamine release on ascent result in elevation of heart rate, blood pressure, cardiac output, and venous tone. Except at extreme altitudes, acclimatization results in the resting heart rate gradually returning to near sea-level values. *Resting relative tachycardia is evidence of poor acclimatization.*

Hematopoietic acclimatization consists of an increase in hemoglobin (Hb) and red blood cells (RBCs) and in 2,3-diphosphoglycerate (DPG). After acute ascent, an early increase of up to 15% occurs in Hb concentration primarily from fluid shifting into the extravascular space. Acclimatization leads to an increase in plasma volume and total blood volume. Erythropoietin is secreted in a HIF-mediated response to hypoxemia within hours of ascent, stimulating the production of new RBCs, which begin to appear in the circulation in 4 or 5 days. Hypoxemia also increases 2,3-DPG, resulting in a rightward shift of the oxyhemoglobin dissociation curve, favoring release of oxygen from the blood to the tissues. This is counteracted by the leftward shift of the curve caused by the respiratory alkalosis from hyperventilation. The result is a net null change in the oxyhemoglobin dissociation curve and an increase in O_2 -Hb binding in the lung, raising Sa_{O_2} . Climbers at extreme altitude respond with marked hyperventilation, alkalosis, and a leftward shift that favors oxygen loading in a hypoxic environment and increases Sa_{O_2} .

Acute Mountain Sickness

Epidemiology and Risk Factors

The incidence of high-altitude illness depends on several variables, including the rate of ascent, previous altitude exposure, and individual genetic susceptibility. Sleeping altitude, final altitude reached, and duration of stay at altitude are also clear risk factors for AMS development. AMS is very common with **rapid ascent** . Climbers around the world who ascend quickly (1 or 2 days) from sea level to altitudes of about 4,300-6100 m (14,000-20,000 ft) have a very high incidence of AMS (27–83%). The rapid ascent profile associated with air travel to high-altitude locations also results in high AMS attack rates. Trekkers who fly into the Khumbu region to explore the Mt. Everest area have a higher incidence of AMS (47%) compared with those who walk (23%). Skiers who visit resorts in the western United States from sea level generally fly or drive to the region but sleep at relatively moderate altitudes (2,000-3,000 m, 6,300-9,700 ft). Among this population, AMS occurs in approximately 25%.

Children have the same incidence of AMS as adults. Individual (genetic) susceptibility for the development of AMS plays a significant role in risk assessment. Most individuals with a previous history of AMS after acute ascent are likely to experience similar symptoms with repeated visits to altitude. Gender does not affect the incidence of AMS.

Pathophysiology

The symptoms of AMS develop several hours after arrival at high altitude, whereas the development of HAPE and HACE generally requires several days of altitude exposure. Because hypoxemia occurs within minutes of arrival, it cannot be the direct cause of high-altitude illness, but rather the initiating factor.

The clinical manifestations of AMS/HACE are primarily the result of central nervous system (CNS) dysfunction caused by hemodynamic mechanical factors and biochemical mediators of permeability. The CNS vasodilatory response to hypoxemia causes an increase in cerebral blood flow and volume. Significant elevation of brain volume is observed in moderate to severe AMS and HACE but has not been demonstrated in mild AMS. Hypoxic alteration of CNS vascular autoregulation and hypertension from exercise may increase pressure transmission to the brain's capillary beds, resulting in transcapillary leakage and vasogenic edema. HIF-mediated vascular endothelial growth factor, the inducible form of nitric oxide synthase, reactive cytokines, and free radical formation may increase permeability. Both mechanical and biochemical activation of the trigeminovascular system have been proposed as the cause of **high-altitude headache** , the primary symptom of AMS. Vasogenic edema has been implicated in severe AMS and HACE, but MRI reveals signal changes in persons with and without clinical AMS. It has been well established that adults can have changes in cognitive function with acute exposure to high altitude. Investigation of cognitive dysfunction in healthy, lowlander European children found significant impairment in verbal short-term memory, episodic memory, and executive functions 24 hr after arrival at 3,450 m (11,400 ft). These impairments were attributed to hypoxia-induced dysfunction of the cerebral white matter. The neuropsychological changes were found to be reversible, since cognitive function returned to baseline on reevaluation 3 mo after returning to sea level.

Many of the responses to hypoxia and altitude exposure occur in both individuals who develop symptoms and those who remain free of AMS. To address the discrepancy in symptomatic illness, the “tight fit” hypothesis was proposed. This theory suggests that the development of AMS/HACE is the result of a lack of intracranial space to accommodate increasing volume from brain swelling and edema that develop at altitude. The adequacy of the intracranial and intraspinal space to buffer changes in brain and cerebrospinal fluid (CSF) volume is the central concept. Buffering occurs as the intracranial CSF is displaced by the foramen magnum into the space available in the spinal canal, followed by increased CSF absorption and decreased CSF production. Individuals with less CSF buffering capacity have less compliance and are hypothesized to become more symptomatic (develop AMS).

Prevention

A comprehensive approach to travel to high altitude with children should focus on 3 phases: planning the ascent and assessment of risk, recognition and management of altitude-associated illness, and follow-up of any illness relative to future travel or diagnostic testing necessary.

Planning for travel to high altitude with children should consider rate of ascent, formulation of an emergency plan for communication and evacuation, and availability of medical care at the high-altitude destination. The availability of medical care and evacuation from altitude will influence the degree of personal preparation necessary. *Slow ascent with time for acclimatization is the best prevention for all forms of altitude illness* . Residing for a few days at moderate altitudes (2,000-3,100 m, 6,600-10,200 ft) followed by graded ascent before arriving at high altitude. One extra night of acclimatization (at the same sleeping altitude) should be taken for every 1,000 m (~3,300 ft) gained. Rapid ascent by air may be avoidable through alternate routes or alternate means of transportation. Exposure to hypobaric hypoxia (reduced barometric pressure with maintained O_2 of 20.9%) decreases end-tidal CO_2 and AMS score, while increasing SaO_2 and exercise endurance on exposure to higher altitude. Staying over in Denver, Colorado, for 1 or 2 days before traveling to higher alpine destinations is an example of such a strategy and has been an effective technique of acclimatization; it has the advantage of reducing the likelihood of developing AMS, HACE, or HAPE. A similar trend in preacclimatization was found with preexposure to *normobaric* hypoxia (maintained barometric pressure with O_2 <20.9%) using commercially available low-O_2 tents or hypoxia breathing masks, although not as effective as preacclimatization with *hypobaric* hypoxia. Slow, gradual ascent is another effective means of acclimatization. The altitude at which someone sleeps is considered more important than the highest altitude reached during waking hours. Guidelines recommend that *above 3,000 m (~9,800 ft), one should not increase sleeping elevation by >500 m (1,600 ft) per day and should include a rest day every 3-4 days with no ascent to a higher sleeping elevation.* Acclimatization and slow ascent are by far the best ways to avoid AMS. The first few days at altitude, individuals should limit their activity and maintain adequate hydration.

Medical risk assessment encompasses consideration of age, previous altitude-associated illness, and possible predisposing circumstances to altitude illness. Very young infants (<4-6 wk) may not have completed the postnatal circulatory transition and may be more vulnerable to altitude-associated desaturation with periodic breathing, right-to-left shunting across the foramen ovale, and hypoxic pulmonary vasoconstriction. Infants who required supplemental oxygen during the neonatal period, especially for pulmonary hypertension, may be at risk for hypoxemia with prolonged altitude exposure. History and physical examination are useful to identify conditions predisposing to HAPE, including recent viral infections, cardiac malformations, or obstructive sleep apnea. Children are known to have greater pulmonary vascular reactivity than adults. Thus, respiratory illnesses such as otitis media, pneumonia, or bronchiolitis that cause release of inflammatory mediators will increase capillary permeability; although normally tolerated at sea level, when superimposed on hypoxia at high elevations, it may predispose children to serious altitude illness. If a child has had a recent upper or lower respiratory infection or otitis media, careful consideration should be given to rapid ascent above 2,000 m (~6,600 ft).

Children with chronic lung disease (e.g., cystic fibrosis, bronchopulmonary dysplasia) and obstructive sleep apnea (OSA) are at increased risk of hypoxia at altitude and development of HAPE. Therefore they should undergo S_{O_2} monitoring during altitude travel. Similarly, children with cardiac lesions involving an increase in pulmonary blood flow or pulmonary hypertension are at greater risk of developing HAPE. Children with trisomy 21 have increased pulmonary vascular reactivity and a higher risk of pulmonary hypertension, and are also more likely to have OSA and hypoventilation. *Children with sickle cell anemia who live at sea level should reconsider travel to altitude, or else ascend carefully because sickle cell crisis may occur at as low as 1,500 m (~5,000 ft).* Those with sickle cell trait may become symptomatic at altitudes above 2,500 m (~8,200 ft).

Acetazolamide is commonly prescribed as prophylaxis against AMS because of its ability to stimulate respiration and increase alveolar and arterial oxygenation. It acts as a carbonic anhydrase inhibitor that induces a renal bicarbonate diuresis, causing a metabolic acidosis that increases ventilation and arterial oxygenation. However, prophylactic pharmacologic therapy with acetazolamide in children is generally not recommended because preacclimatization with slow ascent achieves the same effect. Exceptions include children with previous susceptibility to AMS and an unavoidably rapid ascent, such as flying to La Paz, Bolivia (3,700 m, 12,100 ft), or Cusco, Peru (3,400 m, 11,200 ft), from sea level. The pediatric dose of acetazolamide is 2.5 mg/kg (maximum, 125 mg/dose) every 12 hr (Table 90.1). In adults, it is recommended that prophylaxis begin 24 hr before arriving at altitude and be continued for 48 hr at altitude, or until the final destination high altitude is reached. The respiratory stimulation caused by acetazolamide also improves sleep by eradicating periodic breathing. Side effects are common and include paresthesias, polyuria, lightheadedness, dry mouth, and metallic taste with carbonated beverages. Acetazolamide is a nonbacteriostatic sulfonamide drug, so a history of anaphylactic reaction to sulfa medications is a contraindication to its use. Acetazolamide should be avoided in breastfeeding mothers and pregnant women. **Dexamethasone** is another agent that has been used for AMS prophylaxis in the adult population. However, it should not be used for prophylaxis in children because of the potential for side effects; pancreatitis, pseudotumor cerebri, and interference with normal growth. Low-risk children should not need medications for prophylaxis and should use gradual ascent to prevent illness.

Table 90.1

Medications for Treatment of Altitude-Associated Illness in Children (No Studies in Children for High-Altitude Indications)

MEDICATION	CLASSIFICATION	INDICATION	DOSE AND ROUTE	ADVERSE EFFECTS
Acetazolamide	Carbonic anhydrase inhibitor	AMS prevention[*]	2.5 mg/kg PO every 12 hr; max 125 mg/dose	Collateral effects include paresthesias and taste alteration
		AMS treatment	2.5 mg/kg PO every 12 hr; max 250 mg/dose	
Dexamethasone	Steroid	AMS prevention [†]		Risk of adverse effects precludes prophylactic use
		AMS HACE treatment [‡]	0.15 mg/kg PO/IM/IV every 6 hr; max 4 mg/dose	Hypertension, gastrointestinal hemorrhage, pancreatitis, growth inhibition
Nifedipine	Calcium channel blocker	HAPE treatment (small children) [§]	0.5 mg/kg PO every 4-8 hr; max 20 mg/dose	Hypotension
		HAPE treatment (>60 kg) [§]	30 mg SR PO every 12 hr or 20 mg SR PO every 8 hr	
		Reentry HAPE prevention	Same dose as HAPE treatment	
Sildenafil	Phosphodiesterase-5 inhibitor	HAPE [¶]	0.5 mg/kg/dose PO every 4-8 hr; max 50 mg/dose every 8 hr	

[*] AMS prophylaxis is not routinely recommended in children. It is indicated when rapid ascent profile is unavoidable or with previous altitude illness in child about to undergo similar ascent profile. Doses as low as 1.25 mg/kg every 12 hr have been successful in some children.

[†] Use not warranted due to risk of adverse effects. Use slow, graded ascent or acetazolamide.

[‡] Oxygen and descent are the treatment of choice for severe AMS. If acetazolamide is not tolerated, dexamethasone may be used. Oxygen, descent, and dexamethasone should be used in HACE.

[§] In emergency settings where oxygen and descent are not an option, nifedipine is indicated.

[¶] In emergency settings where oxygen and descent are not an option, if nifedipine is not well tolerated, sildenafil may provide an alternative.

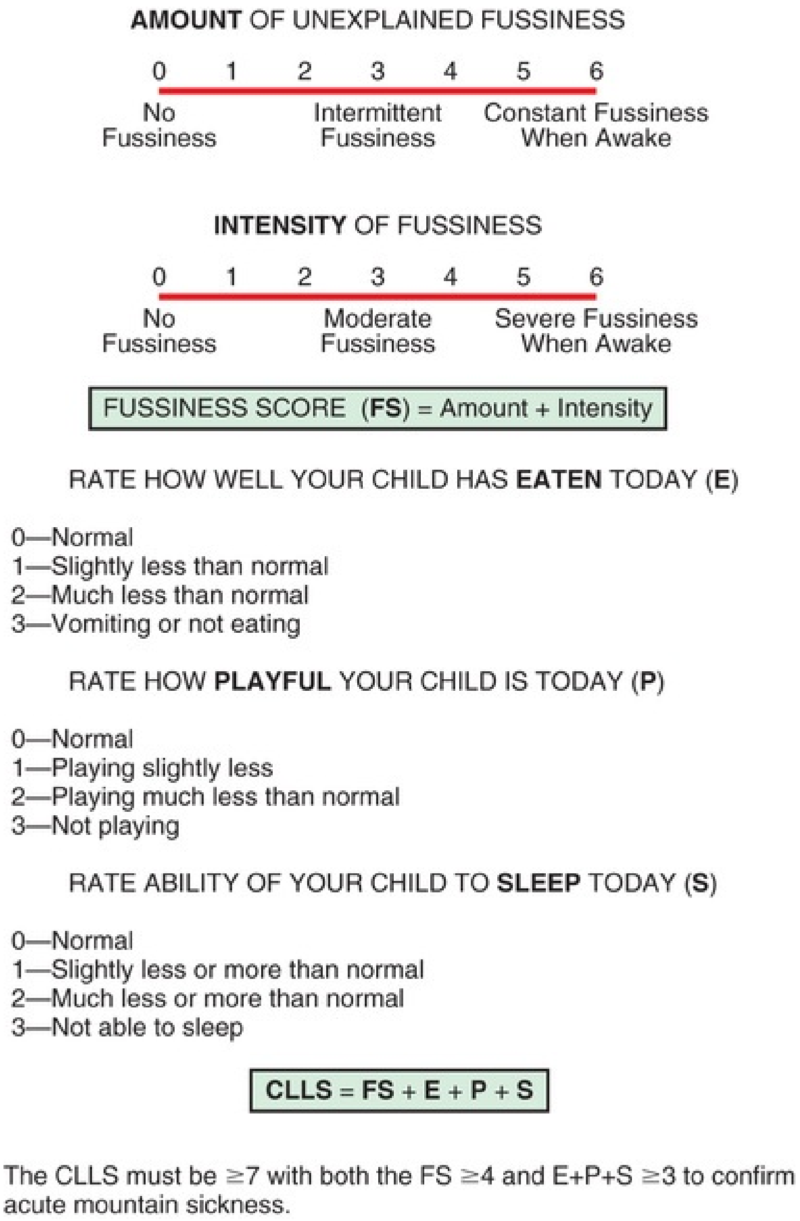
AMS, Acute mountain sickness; HACE, high-altitude cerebral edema; HAPE, high-altitude pulmonary edema, IM, intramuscularly; IV, intravenously; PO, orally; SR, sustained release.

Diagnosis

AMS is easily identified in older children and adolescents using the **Self-Report Lake Louise AMS Scoring System** . The criteria require that the individual be in the setting of a recent gain in altitude, be at the new altitude for at least several hours, and report a headache *plus* at least 1 of the following symptoms: gastrointestinal (GI) upset (anorexia, nausea, or vomiting), general weakness or fatigue, dizziness or lightheadedness, or difficulty sleeping. Shortness of breath on exertion may also be a part of the clinical picture, although if occurring at rest, the presence of HAPE should be considered in the absence of other causes. The headache may vary from mild to severe; anorexia and nausea, with or without vomiting, are common. Sleep disturbance caused by periodic breathing is common in all visitors to high altitudes but is exacerbated in the setting of AMS. All the symptoms of AMS can range in severity from mild to incapacitating. Symptoms develop within a few hours after ascent and generally reach maximum severity between 24 and 48 hr, followed by gradual resolution. Most adults become symptom free by the 3rd or 4th day. The vague nature of this presentation has resulted in many misdiagnoses and morbidity among adults. In the setting of recent altitude exposure, these symptoms warrant a presumptive diagnosis of AMS and limitation of further ascent. Any evidence of CNS dysfunction, such as mild ataxia or altered mentation, is early evidence of HACE.

In nonverbal young children and infants, recognition of AMS symptoms is more challenging. AMS is often a diagnosis of exclusion and is characterized by nonspecific signs: fussiness, lack of playfulness, anorexia, nausea, vomiting, and disordered sleep. In most cases of AMS in nonverbal young children and infants, all these symptoms are present. *Fussiness* is defined as a state of irritability that is not easily explained by a cause, such as tiredness, wet diaper, hunger, teething, or pain from an injury. Fussy behavior may include crying, restlessness, or muscular tension. Decreased playfulness may be profound. Alterations of appetite may progress to frank vomiting. Sleep disturbance can manifest with either increased or decreased sleep compared to normal patterns. Most often, decreased sleep and the inability to nap are noted.

The **Children's Lake Louise Score (CLLS)** has been successfully tested in preverbal children <4 yr old by parents briefed on the use of the scoring system. The CLLS combines a score for the amount and intensity of unexplained fussiness with a symptom score of how well the child has eaten, played, and slept in the past 24 hr. Evaluating for headache is done by asking if the head hurts or by using a “faces” pain scale. GI symptoms are evaluated by asking children if they are “hungry” rather than trying to evaluate their appetite. A combined score of ≥7 is indicative of AMS (Fig. 90.1). Many of the symptoms manifested by AMS in children may also result from the disruption of normal routine with travel. A change in environment, sleeping accommodation, or eating options can result in a fussy child. The threshold scores for AMS diagnostic criteria are modified to account for these baseline variations. Supplemental oxygen may serve as a diagnostic aid; 2-4 L/min by nasal cannula (27–33% O_2) for 15-20 min should significantly improve headache and other symptoms.



AMOUNT OF UNEXPLAINED FUSSINESS

0 1 2 3 4 5 6

No Fussiness — Intermittent Fussiness — Constant Fussiness When Awake

INTENSITY OF FUSSINESS

0 1 2 3 4 5 6

No Fussiness — Moderate Fussiness — Severe Fussiness When Awake

FUSSINESS SCORE (**FS**) = Amount + Intensity

RATE HOW WELL YOUR CHILD HAS **EATEN** TODAY (**E**)

0—Normal
1—Slightly less than normal
2—Much less than normal
3—Vomiting or not eating

RATE HOW **PLAYFUL** YOUR CHILD IS TODAY (**P**)

0—Normal
1—Playing slightly less
2—Playing much less than normal
3—Not playing

RATE ABILITY OF YOUR CHILD TO **SLEEP** TODAY (**S**)

0—Normal
1—Slightly less or more than normal
2—Much less or more than normal
3—Not able to sleep

CLLS = FS + E + P + S

The CLLS must be ≥7 with both the FS ≥4 and E+P+S ≥3 to confirm acute mountain sickness.

FIG. 90.1 Children's Lake Louise Score (CLLS). ***Fussiness*** **is defined as a state of irritability that is not easily explained by a cause, such as tiredness, hunger, teething, or pain from an injury. Fussy behavior may include crying, restlessness, or muscular tension. Please rate your child's typical fussy behavior** ***during the last 24 hr*** **without the benefit of your intervention.**

If symptoms occur >2 days after arrival at altitude and headache and dyspnea at rest are absent, and if the child fails to improve with supplemental oxygen, an alternative diagnosis should be sought. It must be emphasized that altered mental status, neurologic abnormalities, breathing difficulty, or cyanosis are *not* part of uncomplicated AMS. **Any of these signs warrants immediate medical attention.** If serious bacterial illness, a surgical condition, or another problem meriting specific intervention is suspected in a child, descent to lower altitude is recommended to eliminate the confounding variable of altitude illness.

Periodic Breathing

Periodic breathing at altitude is common at all ages during sleep, resulting in brief, repeated episodes of oxyhemoglobin desaturation. Prepubertal children (9-12 yr old) have similar nighttime oxygen desaturation as their parents but have somewhat more stable breathing patterns with less periodicity. Periodic breathing is not a sign of AMS, but the exacerbation of hypoxia during sleep plays a role in AMS development. Newborn infants normally have periodicity in their respiratory pattern, which is increased by high-altitude exposure and sleep. $\mathrm{Sa}_{\mathrm{O}_2}$ of awake neonates born in Colorado at 3,100 m ranges from 88–91%. During sleep with increased periodic breathing, $\mathrm{Sa}_{\mathrm{O}_2}$ may drop to 81% during the 1st wk of life. The amount and magnitude of respiratory periodicity decrease as the child matures, and $\mathrm{Sa}_{\mathrm{O}_2}$ during sleep increases to 86% after 2 mo. A stable, mature pattern is usually reached by 6 mo of age. Preterm babies may demonstrate marked periodicity with prolonged desaturation as a result of their immaturity. Acute ascent with a child born preterm is best delayed until maturity, when normal pulmonary function and respiratory drive can be demonstrated. Parents of normal healthy babies may become distressed by the marked periodic breathing pattern in their child after ascent to moderate altitude. Clinicians can reassure parents that this is generally not a precursor of true apnea; however, desaturation can occur with periodic breathing in sleep, especially at higher altitudes.

Management

The management of AMS must include strict adherence to the principle that further ascent to a higher sleeping altitude is contraindicated after the symptoms of altitude illness occur. Halting ascent or activity to allow further acclimatization may reverse the symptoms. However, the ascent exacerbates the underlying pathologic processes and may lead to disastrous results. Stopping further ascent and waiting for acclimatization treats most AMS in 1-4 days. Mild cases of AMS may be treated without descent if monitoring by a reliable caregiver is available. Conservative treatment may be provided, including rest, analgesics for headache, and antiemetics for nausea. Ibuprofen and acetaminophen are useful for the treatment of high-altitude headache; for nausea and vomiting, ondansetron dissolving tablets may be used.

More moderate symptoms may require acetazolamide and/or oxygen when conservative measures have proved inadequate. Oxygen is effective in the treatment of moderate AMS, titrated to maintain Sao_2 >94%. Although no studies have formally assessed its use in pediatric patients, anecdotal reports have demonstrated efficacy of acetazolamide in treating mild AMS in this population. AMS that becomes worse or does not respond to maintenance of altitude, rest, and pharmacologic intervention after 48 hr mandates descent. Descent (500-1,000 m, ~1,600-3,300 ft) is effective treatment for all forms of altitude illness and should be tailored to the individual response. *The presence of neurologic abnormalities (ataxia or altered mentation) or evidence of pulmonary edema (dyspnea at rest) mandates descent because these signs indicate a progression of AMS to severe altitude illness.*

High-Altitude Cerebral Edema

The incidence of HACE is very low and practically unheard of below 4,000 m (~13,100 ft), but it is rapidly fatal if unrecognized. Generally seen in adults with prolonged stays above 4,000 m, HACE is usually associated with concurrent AMS or HAPE but can occur on its own.

HACE is regarded as the extreme expression of the same pathophysiology underlying AMS. The etiology is believed to be secondary to increased cerebral blood flow leading to increased intracranial pressure (ICP). Cerebral venous congestion caused by compression and/or elevated central venous pressure may be an underappreciated mechanism of the increased ICP. In patients with HACE, MRI reveals white matter changes consistent with vasogenic edema that correlate with symptoms; evidence of cytotoxic edema has also been described.

HACE is frequently preceded by AMS, but it is differentiated from severe AMS by the presence of **neurologic signs** , most often ataxia and altered mental status, including confusion, progressive decrease in responsiveness, and eventually coma. Less common signs are focal cranial nerve palsies, motor and sensory deficits, and seizures. The CT scan is consistent with edema and increased ICP. MRI shows a high T2 signal in the white matter, specifically in the splenium of the corpus callosum, with diffusion-weighted technique.

Descent remains the most effective treatment for HACE. If available, supplemental oxygen is useful, especially when descent is not possible or delayed. Portable hyperbaric treatment is beneficial, but its use should not delay descent. Dexamethasone should be administered at a dose of 0.15 mg/kg orally every 6 hr. The few children reported with mild cases of HACE have recovered with dexamethasone and descent.

High-Altitude Pulmonary Edema

Epidemiology and Risk Factors

HAPE is a **noncardiogenic pulmonary edema** caused by intense pulmonary vasoconstriction and subsequent high capillary pressure, secondary to hypoxia, resulting in altered permeability of the alveolocapillary membrane and the extravasation of intravascular fluid into the extravascular space of the lung. *HAPE is the deadliest of the high-altitude illnesses* ; its reported incidence is 0.5%, without an underlying predisposition, and typically requires recent ascent above 3,000 m. The development of HAPE depends on genetic factors typically affecting pulmonary vasoreactivity, rate of ascent, altitude achieved, and time spent at that altitude. Among children, HAPE occurs in 2 distinct settings. **Type I** HAPE (or simply HAPE) occurs in a child who resides at low altitude who travels to high altitude. **Type II** HAPE (also termed **reentry** or **reascent** HAPE) affects children who reside at high altitude but become ill on their return home after descent to lower altitudes. HAPE may also occur in children who develop acute respiratory illnesses that exacerbate hypoxia at high altitude. Fatal outcomes of HAPE in children have been reported. Most mild and moderate cases resolve without difficulty; however, if unrecognized and untreated, rapid progression to death can occur, especially when infection or cardiac conditions complicate the illness.

HAPE affects male and female children more equally than adults, among whom the observed male predominance appears to result from strenuous sport activities and military assignments. The occurrence and even the pathophysiology of HAPE may vary by population and genetic background. Individuals of Tibetan ancestry, resident on the Himalayan plateau and having minimal admixture with other populations, represent the extreme of adaptation to high altitude and rarely experience HAPE. Other native populations residing at high altitude, such as Andeans, do not appear to be protected from HAPE, and certain populations may have genetic polymorphisms associated with pulmonary edema.

A number of conditions may predispose a child to HAPE (Table 90.2). Preexisting viral respiratory infections have been linked to HAPE, especially in children. Cardiorespiratory conditions associated with pulmonary hypertension, such as atrial and ventricular septal defects, pulmonary vein stenosis, congenital absence of a pulmonary artery, and OSA, also predispose to HAPE. Down syndrome is a risk factor for HAPE development, as are previously repaired congenital heart defects and the presence of hypoplastic lungs. Undiagnosed structural cardiopulmonary abnormalities may result in severe hypoxia and/or altitude illness once ascent occurs.

Table 90.2

Conditions Associated With Increased Risk of High-Altitude Pulmonary Edema (HAPE)

Environmental

- Ascent above 2,500 m (~8,200 ft)
- Rapid rate of ascent (generally >1,000 m [~3,300 ft] per day)
- Cold exposure

Cardiac

- Anomalies causing increased pulmonary blood flow or increased pulmonary artery pressure
- Ventricular septal defect, atrial septal defect, patent foramen ovale, patent ductus arteriosus
- Anomalous pulmonary venous return or pulmonary vein stenosis
- Unilateral absent pulmonary artery or isolated pulmonary artery of ductal origin
- Coarctation of the aorta
- Congestive heart failure

Pulmonary

- Chronic lung disease
  - Bronchopulmonary dysplasia
  - Pulmonary hypoplasia
  - Supplemental oxygen requirement at sea level
- Pulmonary hypertension
- Perinatal respiratory distress
  - Persistent pulmonary hypertension of the newborn
  - Perinatal asphyxia or depression
- Sleep apnea

Infectious

- Upper respiratory tract infection
- Bronchitis/bronchiolitis
- Pneumonitis
- Otitis media

Pharmacologic

- Any medication causing central nervous system and respiratory depression
- Alcohol
- Sympathomimetics

Systemic

- Down syndrome (trisomy 21)
- History of premature birth or low birthweight

Pathophysiology

Alveolar hypoxia results in vasoconstriction of pulmonary arterioles just proximal to the alveolar capillary bed. Hypoxic pulmonary vasoconstriction is a normal physiologic response to optimize ventilation/perfusion (V̇/Q̇) matching by redistributing regional pulmonary blood flow to areas of highest ventilation, thereby optimizing arterial oxygenation. Under conditions that result in widespread alveolar hypoxia, extensive pulmonary vasoconstriction will lead to significant elevations in pulmonary arterial pressure; uneven pulmonary vasoconstriction can result in localized overperfusion, increased capillary pressures, distention, and leakage in the remaining vessels. This explains the patchy and heterogeneous edema that is classically observed in HAPE. The combination of pulmonary hypertension and uneven pulmonary vasoconstriction appears to be necessary in the pathogenesis of HAPE. Children and adolescents acutely exposed to high-altitude hypoxia demonstrated pulmonary hypertension, with increases in pulmonary artery pressure inversely related to age. Once the vascular leak occurs and alveolar fluid accumulates, a defect in transepithelial sodium transport impairs the clearance of alveolar fluid and contributes to HAPE.

Diagnosis

The diagnosis of HAPE is based on clinical findings and their evolution in the context of recent ascent from lower elevation. There is no single diagnostic test or constellation of laboratory findings. Symptoms usually develop within 24-96 hr, with onset of symptoms the 1st or 2nd night at altitude, when hypoxia may be exacerbated during sleep. HAPE generally is not observed beyond 5 days after ascent to altitude (unless additional ascent occurs) because pulmonary vascular remodeling and acclimatization have taken place. The minimum criteria to diagnose HAPE include recent exposure to altitude, dyspnea at rest, radiographic evidence of alveolar infiltrates, and near-complete resolution of both clinical and radiographic signs within 48 hr after descent or institution of oxygen therapy. Portable ultrasound is useful to diagnose HAPE through the finding of *comet tails* , artifacts created by microreflections of the ultrasound beam within interlobular septa thickened by interstitial and alveolar edema.

Frequently, patients first exhibit general malaise that may progress to more specific signs of dyspnea at rest, then cardiopulmonary distress. In preverbal toddlers and infants, HAPE may manifest as worsening respiratory distress over 1-2 days, pallor, depressed consciousness, increased fussiness, decreased playfulness, crying, decreased appetite, poor sleep, and sometimes vomiting. Young children may show agitation and general debility. Older children and adolescents may complain of headache and orthopnea and present with cough, dyspnea not relieved by rest or out of proportion to effort, and production of frothy, rust-colored sputum. Physical exam findings include tachypnea, cyanosis, elevated jugular venous pressure, and diffuse crackles on lung auscultation. Dyspnea at rest, orthopnea, cyanosis, tachycardia, and chest pain herald worsening compromise, which may advance within hours to production of pink-tinged sputum.

Findings on physical examination frequently are less severe than the patient's chest radiograph and hypoxemia on pulse oximetry would predict. Children often appear pale, with or without visible cyanosis. Low-grade fever (<38.5°C [101.3°F]) is common, and respiratory rate is generally increased. Auscultation typically reveals rales, usually greater in the right lung than the left on presentation. Chest radiograph reveals diffuse interstitial changes typical of noncardiogenic pulmonary edema, with central interstitial edema associated with peribronchial cuffing, poorly defined vessels, enlargement of the pulmonary artery silhouette with dilation of more peripheral pulmonary arteries, and patchy air space consolidation; Kerley lines may be present. In severe cases, air space consolidation may become confluent and involve the entire lung (Fig. 90.2). Often the right lung shows more radiographic changes of edema than the left. Cardiomegaly is an uncommon finding, but enlargement of the pulmonary artery is a frequent finding. Significant arterial oxygen desaturation, as measured by pulse oximetry, is a consistent finding, with SpO_2 frequently below 75%. A complete blood count often reveals a leukocytosis with a left shift of the granulocyte series.

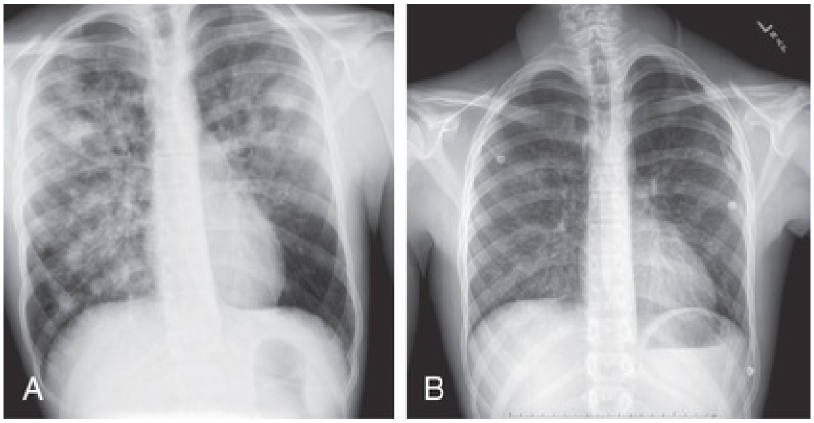


FIG. 90.2 **Acute mountain sickness (AMS) and high-altitude pulmonary edema (HAPE). A healthy 15 yr old boy flew from Buffalo, NY, to Denver, CO, and immediately drove with his school group from the airport to a ski resort at 9,300 ft in the Rocky Mountains. The following day he felt dizzy and complained of headache. Symptoms of headache**

and dizziness continued along with emesis daily for 2 days. A snowboarding coach brought the patient to the local emergency facility the next day because of dyspnea, cough, headache, emesis, and fatigue. Pulse oximetry showed an arterial oxygen saturation of 51%. Chest radiograph showed diffuse pulmonary edema (A). The patient was transported to Denver (5,280 ft) by ambulance with 15 L/min oxygen via a non-rebreathing mask. SaO_2 improved with descent and was 94% on arrival at the Children's Hospital Colorado emergency department. Breath sounds remained coarse, and the patient was tachycardic and tachypneic. Oxygen flow was weaned to 1 L/min shortly after admission. Two days after presentation, lung exam was improved, without crackles. Repeat chest radiograph showed clearing of edema pattern (B). The patient maintained adequate SaO_2 without supplemental oxygen and was discharged. (Courtesy of the Department of Radiology, Children's Hospital of Colorado.)

The **differential diagnosis** of HAPE includes pneumonia, bronchitis/bronchiolitis, asthma, and other forms of cardiogenic and noncardiogenic pulmonary edema, as well as pulmonary embolism. HAPE is most frequently misdiagnosed as pneumonia or a viral respiratory illness, especially when suspicion of altitude-associated pathology is not appropriately high. The presenting signs of cough, dyspnea, and orthopnea, followed by sputum production, can easily be misinterpreted as pneumonia, an impression reinforced by the frequent low-grade fever. Respiratory viral infections increase the risk of developing HAPE, which may lead to further confusion in diagnosis.

Complications of HAPE in children often relate to underlying, sometimes undiagnosed, cardiopulmonary pathology or coexisting viral infections that potentiate the severity of pulmonary edema and pulmonary hypertension. Acute altitude exposure in such circumstances may lead to severe presentations that progress rapidly to extreme hypoxemia or cardiac failure and death. Children with trisomy 21, with or without structural cardiac anomalies, show increased susceptibility to HAPE and rapid symptom progression. Neonatal respiratory distress with pulmonary hypertension has been linked to exaggerated hypoxic pulmonary vasoreactivity in early adulthood and thereby a theoretical predisposition to HAPE. Other conditions related to pulmonary overcirculation, small cross-sectional area of the pulmonary vascular bed, obstruction to pulmonary venous return, or left-sided obstruction potentiate HAPE. Inflammatory processes, such as viral infection, predispose to HAPE and may worsen hypoxemia.

Management

Descent with supplemental oxygen is the treatment of choice for HAPE in children. Unlike AMS, HAPE does not respond to rest and oxygen alone. When feasible, or in the absence of medical care, rapid descent of at least 1,000 m

(~3,300 ft) usually results in rapid recovery. As with all altitude illness, the magnitude of the descent is tailored to the resolution of symptoms. Those affected should exert themselves as little as possible on descent and prevent exposure to cold, to avoid exacerbation of pulmonary artery pressure and pulmonary edema. Oxygen and bed rest without descent can be safe and effective treatment for mild HAPE in children where careful medical observation is available. Mild HAPE in children and young adults at 3,750 m (~12,300 ft) has been treated with bed rest alone, although clinical recovery may be slower than with supplemental oxygen therapy.

Supplemental oxygen at altitude is administered at 2-6 L/min by nasal cannula for 48-72 hr to maintain an SaO_2 of at least 90%. Oxygen flow can be weaned with improvement in symptoms and SaO_2; at flow rates <2-4 L/min, children may be sufficiently stable and comfortable to continue treatment at home under family monitoring. Most children experience complete resolution of mild HAPE within 24-72 hr of oxygen therapy when treated at the altitude of symptom onset.

Pharmacotherapy for pediatric HAPE is rarely needed since oxygen and descent are so effective. However, in emergency situations without the option of descent or oxygen, pharmacotherapy should be considered for treatment of HAPE. In adults, nifedipine, a calcium channel blocker, is the preferred drug. Although its use has not been studied in children for treatment of HAPE, **nifedipine** is indicated for treatment of pulmonary hypertension. Extrapolated dosing for children is 0.5 mg/kg orally every 4-8 hr and titrated to response (maximum, 10 mg/dose). Liquid-filled capsules of nifedipine (10 mg/0.34 mL) can be punctured to obtain doses for children <20 kg. Patients should be monitored for hypotension during nifedipine administration. Alternatively, diltiazem can be given at 0.5-1.0 mg/kg/dose every 8 hr in tablet form or compounded oral suspension (12 mg/mL). Phosphodiesterase-5 inhibitors reduce pulmonary pressure at high altitude in adults through vasodilation and may be used if a calcium channel blocker is not available or poorly tolerated. However, concurrent use of multiple pulmonary vasodilators is not recommended. Pulmonary hypertension guidelines for children cite level I evidence for sildenafil in treatment of pulmonary hypertension.

β-Adrenergic agonists upregulate the clearance of alveolar fluid through transepithelial sodium transport and therefore could have a positive effect on HAPE. A single randomized controlled study in adults susceptible to HAPE exposed to very high altitude found that those receiving inhaled salmeterol had a 50% decreased incidence of HAPE compared to those who received placebo.

Prevention of pulmonary edema using salmeterol was not associated with a decrease in pulmonary pressure, underscoring the clearance of alveolar fluid and improved hypoxia, which is believed to have accounted for the improved AMS score in these patients compared with the placebo group.

Special Considerations

Reentry HAPE

Children residing at high altitude may also experience HAPE of the type termed *reentry* or *reascent* HAPE. Reentry HAPE occurs on reascent to the altitude of residence after a sojourn to low altitude. Most cases occur after several days at lower altitude, and probability of recurrence may justify pharmacologic prophylaxis.

Travel With Young Infants

Newborn infants retain some of the circulatory characteristics of recent fetal life, and these can pose a unique risk for altitude exposure. The fetal circulation has high pulmonary resistance, low pulmonary blood flow, and both intra- and extracardiac shunts that optimize oxygenation through the placenta rather than the fetal lungs. After birth, a transition begins that closes fetal shunts and establishes normal pulmonary circulation and oxygen transport. *Exposure to marked hypoxia (3,000-5,000 m) can result in reversion to fetal shunting patterns despite the absence of a placenta.* Therefore, prolonged exposure to high altitude should be avoided for infants <6 mo old who normally live at low altitude, or whose gestation occurred at low altitude. Normal infants at sea level complete these changes in 4-6 wk, although for infants born at moderate or high altitude, changes may last ≥3 mo. Travel to high altitude with young infants is generally safe after 4-6 wk, when circulatory changes have occurred, breastfeeding is established, and congenital abnormalities may have been detected. Infants between 6 wk and 1 yr of age may have a higher incidence of pulmonary hypertension with hypoxia, patent ductus arteriosus (PDA), and patent foramen ovale (PFO) with prolonged exposure to high altitudes. Hypoxic exposure induces medial hypertrophy of pulmonary arteries and pulmonary arterioles, together with dilation of the pulmonary trunk and impressive hypertrophy and dilation of the right ventricle.

Infants residing at an altitude above 2,400 m (~8,000 ft) are at an increased risk of **sudden infant death syndrome (SIDS)** , possibly from greater hypoxia. Altitude may be an independent risk factor for SIDS. Similar to low altitude, infants should be placed on their backs for sleeping, and parents should be counseled on the potential elevated risk of SIDS at altitude.

Sickle Trait and Sickle Cell Disease

Children with sickle cell disease or sickle trait should avoid travel to altitude, because hypoxemia may trigger sickling and painful crises, including splenic crises. Up to 20% of pediatric patients with sickle cell and sickle-thalassemia disease may experience a vasoocclusive crisis at moderate altitude. Although the majority of children with sickle trait remain asymptomatic, children can experience splenic ischemia or infarction, with severe left upper quadrant pain.

CHAPTER 91

Drowning and Submersion Injury

Anita A. Thomas, Derya Caglar

Drowning is one of the leading causes of childhood morbidity and mortality in the world. Prevention is the most important step to reducing the impact of drowning injury, followed by early initiation of cardiopulmonary resuscitation (CPR) at the scene.

Etiology

Children are at risk of drowning when they are exposed to a water hazard in their environment. The World Congress of Drowning definition of drowning is “the process of experiencing respiratory impairment from submersion/immersion in liquid.” The term *drowning* does not imply the final outcome—death or survival; the outcome should be denoted as *fatal* or *nonfatal* drowning. Use of this terminology should improve consistency in reporting and research; the use of confusing descriptive terms such as “near,” “wet,” “dry,” “secondary,” “silent,” “passive,” and “active” should be abandoned. The injury following a drowning event is *hypoxia* .

Epidemiology

From 2005 to 2014, an average 3,536 people per year were victims of **fatal drowning** , and an estimated 6,776 persons per year were treated in U.S. hospital emergency departments (EDs) for **nonfatal drowning** . Compared with other types of injuries, drowning has one of the highest case fatality rates and is in the top-10 causes of death related to unintentional injuries for all pediatric age-groups. From 2010 to 2015, the highest drowning death rates were seen in children age 1-4 yr and 15-19 yr (crude rates of 2.56 and 1.2 per 100,000, respectively). In children age 1-4 yr, drowning was the number-one cause of death from *unintentional injury* in the United States in 2014. Pediatric hospitalization rates associated with drowning ranged from 4.7 to 2.4 per 100,000 between 1993 and 2008. Rates of fatal drowning hospitalization declined from 0.5 to 0.3 deaths per 100,000 during the same period. Morbidity following nonfatal drowning is poorly studied.

The risk of drowning and the circumstances leading to it vary by age (Fig. 91.1). Drowning risk also relates to other host factors, including male gender, alcohol use, a history of seizures, and swimming lessons. Environmental risk factors include exposure to water and varying supervision. These factors are embedded in the context of geography, climate, socioeconomic status, and culture.

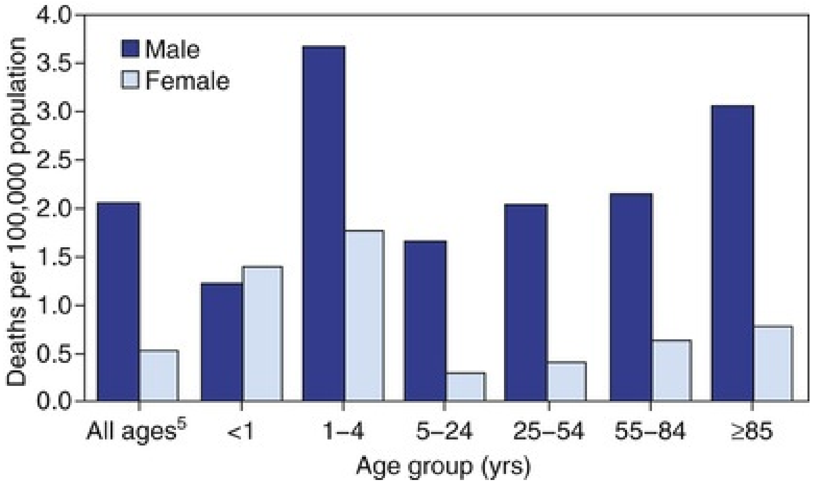

FIG. 91.1 Death rates from unintentional drowning* by age-group and sex—United States,[†] 2011. A total of 3,961 deaths from unintentional drowning were reported in the United States in 2011; the overall death rate for males was 2.05 per 100,000 population, almost 4 times the rate for females (0.52). In each age-group except for infants (i.e., those age <1 yr), the drowning death rate was higher for males. Males age 1-4 yr had the highest rate (3.67); for males and females, death rates increased with age after age 5-24 yr. *Unintentional drowning as the underlying cause of death includes codes for accidental drowning and submersion (W65-74), watercraft causing drowning and submersion (V90), and water-transport–related drowning and submersion without accident to watercraft (V92) in the *International Classification of Diseases, 10th Revision* . [†] U.S. residents only. [§] Includes decedents whose ages were not reported. (From National Vital Statistics System: Mortality public use data file for 2011. http://www.cdc.gov/nchs/data_access/vitalstatsonline.htm .)

Children <1 Yr Old

Most (71%) drowning deaths in children younger than 1 yr occur in the **bathtub** , when an infant is left alone or with an older sibling. Infant tub seats or rings may exacerbate the risk by giving caregivers a false sense of security that the child is safe in the tub. The next major risk to children <1 yr is the large (5-gallon) household bucket, implicated in 16% of infant drowning deaths. These buckets are approximately 30 cm (1 ft) tall and designed not to tip over when half-full. The average 9 mo old child tends to be top-heavy and thus can easily fall headfirst into a half-full bucket, become stuck, and drown within minutes.

Children 1-4 Yr Old

Drowning rates are consistently highest in 1-4 yr old children, likely because of their curious but unaware nature, coupled with the rapid progression of their physical capabilities. From 1999 to 2015, U.S. rates are highest in the southern regions, in some areas as high as 3.8 per 100,000. A common factor in many of these deaths is a lapse in adult supervision, often reportedly <5 min. Most U.S. drownings occur in residential **swimming pools** . Usually, the child is in the child's own home, and the caregiver does not expect the child to be near the pool.

In rural areas, children 1-4 yr old often drown in irrigation ditches or nearby ponds and rivers. The circumstances are similar to those noted previously, in a body of water that is near the house. Drowning is one of the leading causes of *farm injury–related deaths* in children.

School-Age Children

School-age children are at increased risk of drowning in natural bodies of water such as lakes, ponds, rivers, and canals. Although swimming pools account for most nonfatal drownings across all ages, **natural waterways** account for a higher death rate in children 10-19 yr old. Unlike for preschool children, swimming or boating activities are important factors in drowning injuries in school-age children.

Adolescents

The 2nd major peak in drowning death rates occurs in older adolescents, age 15-19 yr. Almost 90% drown in open water. In this age-group particularly, striking disparities in drowning deaths exist in gender and race. From 1999 to 2015, adolescent males fatally drowned at a rate of 2.4/100,000 compared to 0.3/100,000 in adolescent females. The gender disparity may likely be related to males' greater risk-taking behavior, greater alcohol use, less perception about risks associated with drowning, and greater confidence in their swimming ability than females.

Dangerous underwater breath-holding behaviors (DUBBs) are often performed by experienced healthy swimmers or fitness enthusiasts (hypoxic training) or when teenagers hold breath-holding contests during horseplay. DUBBs have been primarily reported in regulated swimming facilities. Behaviors include intentional hyperventilation before submersion, static apnea, and extended periods of underwater distance swimming or breathhold intervals. Swimmers are found motionless and submerged; resuscitation is often unsuccessful.

There is also significant racial disparity seen across drowning rates and causes. In 2015, as in previous years, drowning rates for black males age 15-19 yr were double those for white males of the same age. Non-Caucasian children are 4 times more likely to have a nonfatal drowning across all age-groups through 19 yr old. Black children are more likely to drown in unguarded public or apartment pools; white children are more likely to drown in private residential pools. Hispanic and foreign-born children have lower rates of drowning than their white counterparts. Those with private insurance have lower rates of nonfatal drowning. Other factors include differences in exposure to swimming lessons, cultural attitudes, and fears about swimming, as well as experience around water, all of which may contribute to overall drowning risk.

Underlying Conditions

Several underlying medical conditions are associated with drowning at all ages. A number of studies have found an increased risk, up to 19-fold, in individuals with **epilepsy** . Drowning risk for children with seizures is greatest in bathtubs and swimming pools. Cardiac etiologies, including arrhythmias, myocarditis, and prolonged QT syndromes, have been found in some children who die suddenly in the water, particularly in those with a family history of syncope, cardiac arrest, prior drowning, or QT prolongation. Some children with long QT syndrome are misdiagnosed as having seizures (see Chapter 462.5).

Drowning may also be an **intentional injury** . A history of the event that changes or is inconsistent with the child's developmental stage is the key to recognition of intentional drowning. Physical examination and other physical injuries rarely provide clues. **Child abuse** is more often recognized in bathtub-related drownings. **Suicide** usually occurs in lone swimmers in open water.

Alcohol Use

The use of alcohol and drugs greatly increases the risk of drowning. Of teenagers and adults who die, up to 70% are associated with alcohol use. Alcohol can impair judgment, leading to riskier behavior, decreased balance and coordination, and blunted ability to self-rescue. Furthermore, an intoxicated adult may provide less effective supervision of children around water.

Sports and Recreation

Most U.S. drowning deaths occur during recreational activities. Drowning is the leading cause of *noncardiac sports-related deaths* . Surveys confirm that alcohol use is common during water recreation, as is not using a personal flotation device (PFD) during boating activities. In 2015 the U.S. Coast Guard reported that 85% of those who drowned in boating accidents were not wearing a PFD.

Global Impact of Drowning

Drowning injury is the 3rd leading cause of unintentional death worldwide, with the majority (90%) of fatalities occurring in low- and middle-income countries. More than half of the global drowning occurs in the World Health Organization (WHO) Western Pacific and Southeast Asia regions. Global drowning rates are vastly underestimated, since many drowning deaths in this region go unreported, and many immediate fatalities are unrecognized. In addition, these data exclude any cases of drowning as the result of intentional harm or assault, accidents of watercraft or water transport, and drowning related to forces of nature or cataclysmic storms, which usually claim large numbers of lives per incident; thus, true numbers of fatal drowning are likely much higher.

Some patterns of pediatric drowning are similar in all countries. By most accounts, the highest rates are seen in males and in children 1-4 yr old.

Whereas bathtubs and places of recreation (i.e., pools, spas) are significant locations for drowning in U.S. children, these are virtually unreported locations for drownings in developing countries. Instead, the predominant locations are near or around the home, involving bodies of water used for activities of daily living. These include water-collecting systems, ponds, ditches, creeks, and watering holes. In tropical areas, death rates increase during monsoon season, when ditches and holes rapidly fill with rain, and are highest during daylight hours, when caregivers are busy with daily chores.

Drowning during natural disasters such as **storms** and **floods** is important in all areas of the world. The largest numbers of reported flood-related deaths occur in developing nations; most are drownings that occur during the storm surge. In the United States and much of Europe, advances in weather monitoring and warning systems have reduced such deaths. U.S. flooding incidents, including hurricanes Katrina and Sandy, showed that drowning caused the most deaths, particularly when people became trapped in their vehicles, were unable or refused to evacuate homes, or attempted to rescue others.

Pathophysiology

Drowning victims drown silently and do not signal distress or call for help. Vocalization is precluded by efforts to achieve maximal lung volume to keep the head above the water or by aspiration leading to **laryngospasm** . Young children can struggle for only 10-20 sec and adolescents for 30-60 sec before final submersion. A swimmer in distress is vertical in the water, pumping the arms up and down. This splashing or efforts to breathe are often misconstrued by nearby persons as merely playing in the water, until the victim sinks.

Anoxic-Ischemic Injury

After experimental submersion, a conscious animal initially panics, trying to surface. During this stage, small amounts of water enter the hypopharynx, triggering laryngospasm. There is a progressive decrease in arterial blood oxyhemoglobin saturation (SaO_2), and the animal soon loses consciousness from hypoxia. Profound hypoxia and medullary depression lead to terminal apnea. At the same time, the cardiovascular response leads to progressively decreasing cardiac output and oxygen delivery to other organs. By 3-4 min, myocardial hypoxia leads to abrupt circulatory failure. Ineffective cardiac contractions with electrical activity may occur briefly, without effective perfusion (**pulseless electrical activity**). With early initiation of CPR, spontaneous circulation may initially be successfully restored. The extent of the global **hypoxic-ischemic injury** determines the final outcome and becomes more evident over subsequent hours.

With modern intensive care, the cardiorespiratory effects of resuscitated drowning victims are usually manageable and are less often the cause of death than irreversible hypoxic-ischemic central nervous system (CNS) injury (see Chapter 85). CNS injury is the most common cause of mortality and long-term morbidity. Although the duration of anoxia before irreversible CNS injury begins is uncertain, it is probably on the order of 3-5 min. Submersions <5 min are associated with a favorable prognosis, whereas those >25 min are generally fatal.

Several hours after cardiopulmonary arrest, **cerebral edema** may occur, although the mechanism is not entirely clear. Severe cerebral edema can elevate intracranial pressure (ICP), contributing to further ischemia; intracranial hypertension is an ominous sign of profound CNS damage.

All other organs and tissues may exhibit signs of hypoxic-ischemic injury. In the lung, damage to the pulmonary vascular endothelium can lead to **acute respiratory distress syndrome** (see Chapter 89). Aspiration may also compound pulmonary injury. Myocardial dysfunction (so-called stunning), arterial hypotension, decreased cardiac output, arrhythmias, and cardiac infarction may also occur. Acute kidney injury, cortical necrosis, and renal failure are common complications of major hypoxic-ischemic events (see Chapter 550.1). Vascular endothelial injury may initiate disseminated intravascular coagulation, hemolysis, and thrombocytopenia. Many factors contribute to gastrointestinal damage; bloody diarrhea with mucosal sloughing may be seen and often portends a fatal injury. Serum levels of hepatic transaminases and pancreatic enzymes are often acutely increased. Violation of normal mucosal protective barriers predisposes the victim to bacteremia and sepsis.

Pulmonary Injury

Pulmonary aspiration occurs in many drowning victims, but the amount of aspirated fluid is usually small (see Chapter 425). Aspirated water does not obstruct airways and is readily moved into the pulmonary circulation with positive pressure ventilation. More importantly, it can wash out surfactant and cause alveolar instability, ventilation-perfusion mismatch, and intrapulmonary shunting. In humans, aspiration of small amounts (1-3 mL/kg) can lead to marked hypoxemia and a 10–40% reduction in lung compliance. The composition of aspirated material can also affect the patient's clinical course: Gastric contents, pathogenic organisms, toxic chemicals, and other foreign matter can injure the lung or cause airway obstruction. Clinical management is not significantly different in saltwater and freshwater aspirations, because most victims do not aspirate enough fluid volume to make a clinical difference.

Cold Water Injury

Drowning should be differentiated from cold water **immersion** injuries, in which the victim remains afloat, keeping the head above water without respiratory impairment in cold waters. The definition of cold water varies from <15 to 20°C (<59 to 68°F).

Heat loss through conduction and convection is more efficient in water than in air. Children are at increased risk for **hypothermia** because of their relatively high ratio of body surface area (BSA) to mass, decreased subcutaneous fat, and limited thermogenic capacity. Hypothermia can develop because of prolonged surface contact with cold water during immersion, while the airway is above water, or with submersion. Body temperature may also continue to fall because of cold air, wet clothes, hypoxia, and hospital transport. Hypothermia in pediatric drowning victims may be observed even after drowning in relatively warm water and in warm climates.

Immersion in cold water has immediate respiratory and cardiovascular effects. Victims experience **cold water shock** , a dynamic series of cardiorespiratory physiologic responses that can cause drowning. In adults, immersion in icy water results in intense involuntary reflex hyperventilation and to a decrease in breath-holding ability to <10 sec, which leads to fluid aspiration. Severe bradycardia, the *diving reflex* , occurs in adults but is transient and rapidly followed by supraventricular and ectopic tachycardia and hypertension. There is *no evidence* that the diving reflex has any protective effect.

Even after surviving the chaotic minutes of cold water shock, after an additional 5-10 min of cold water immersion, the victim can become incapacitated. Cooling of large and small muscles disables the victim's ability to grab hold, swim, or perform other self-rescue maneuvers. Depending on water and air temperature, insulation, BSA, thermogenic capacity, physical condition, swimming efforts, or high-water flow rates, heat loss with continued immersion can significantly decrease core temperature to hypothermic levels within 30-60 min.

The symptoms and severity of hypothermia are categorized based on body temperature. The victim with mild hypothermia has a temperature of 34-36°C (93.2-96.8°F) with intact thermogenic mechanisms (shivering and nonshivering thermogenesis, vasoconstriction) and active movements. Compensatory mechanisms usually attempt to restore normothermia at body temperatures >32°C (89.6°F). Lower core temperatures lead to impaired cognition, coordination, and muscle strength and with it, less ability to self-rescue. Thermoregulation may fail and spontaneous rewarming will not occur. With moderate hypothermia (30 to <34°C [86 to <93.2°F]), loss of consciousness leads to water aspiration. Progressive bradycardia, impaired myocardial contractility, and loss of vasomotor tone contribute to inadequate perfusion, hypotension, and possible shock. At body temperatures <28°C (82.4°F), extreme bradycardia is usually present with decreases in cardiac output, and the propensity for spontaneous ventricular fibrillation or asystole is high. Central respiratory center depression with moderate to severe hypothermia results in hypoventilation and eventual apnea. A deep coma, with fixed and dilated pupils and absence of reflexes at very low body temperatures (<25-29°C [77-84.2°F]), may give the false appearance of death.

If the cooling process is quick—and cardiac output lasts long enough for sufficient heat loss to occur before the onset of severe hypoxia—the brain can cool to a level that may be considered in the *neuroprotective* range, approximately 33°C (91.4°F) in controlled, experimental conditions. However, if submersion leading to drowning occurs before development of a neuroprotective level of hypothermia, severe anoxia devastates tissue organs. The theoretical benefits, implications, and consequences of hypothermia in drowning victims are areas of controversy. Known adverse effects are associated with hypothermia, and these must be balanced against the potential benefits observed in experimental data. One should clearly differentiate among **controlled hypothermia** , such as that used in the operating room before the onset of hypoxia or ischemia; **accidental hypothermia** , such as occurs in drowning, which is uncontrolled and variable, with onset during or shortly after hypoxia-ischemia; and **therapeutic hypothermia** , involving the purposeful and controlled lowering and maintenance of body (or brain) temperature after a hypoxic-ischemic event.

In drowning victims with uncontrolled accidental hypothermia associated with icy water submersion, there are a few case reports of good neurologic recovery after prolonged (10-150 min) cardiopulmonary arrest. Almost all these rare survivors have been in freezing water (<5°C [41°F]) and had core body temperatures <30°C (86°F), often much lower. Presumably, very rapid and sufficiently deep hypothermia developed in these fortunate survivors before irreversible hypoxic-ischemic injury occurred.

Most often, hypothermia is a poor prognostic sign, and a neuroprotective effect has not been demonstrated A 2014 study from Washington State found that submersion duration <6 min is most strongly related to good outcome, not water temperature. In another study of comatose drowning patients admitted to pediatric intensive care unit (PICU), 65% of hypothermic patients (body temperature <35°C [95°F]) died, compared with a 27% observed mortality rate in nonhypothermic victims. Similarly, in Finland (where the median water temperature was 16°C [60.9°F]) and in the United States, a beneficial effect of drowning-associated hypothermia was not seen in pediatric submersion victims; submersion duration <10 min was most strongly related to good outcome, not water temperature.

Management

Duration of submersion, speed of the rescue, effectiveness of resuscitative efforts, and clinical course determine the outcome in submersion victims. Two groups may be identified on the basis of responsiveness at the scene. The **first group** consists of children who require minimal resuscitation at the scene and quickly regain spontaneous respiration and consciousness. They have good outcomes and minimal complications. These victims should be transported from the scene to the ED for further evaluation and observation. The **second group** comprises children in cardiac arrest who require aggressive or prolonged resuscitation and have a high risk of multiple–organ system complications, major neurologic morbidity, or death. Compared with cardiac arrest from other causes, cardiac arrest from drowning has a higher survival rate.

Initial management of drowning victims requires coordinated and experienced prehospital care following the ABCs (airway, breathing, circulation) of emergency resuscitation. CPR of drowning victims must include providing ventilation. Children with severe hypoxic injury and symptoms often remain comatose and lack brainstem reflexes despite the restoration of oxygenation and circulation. Subsequent ED and PICU care often involve advanced life support (ALS) strategies and management of multiorgan dysfunction with discussions about end-of-life care.

Initial Evaluation and Resuscitation

See Chapter 81 .

Once a submersion has occurred, immediate institution of CPR efforts at the scene is imperative. The goal is to reverse the anoxia from submersion and limit secondary hypoxic injury after submersion. Every minute that passes without the reestablishment of adequate breathing and circulation dramatically decreases the possibility of a good outcome. When safe for the victim and the rescuer, institution of in-water resuscitation for nonbreathing victims by trained personnel may improve the likelihood of survival. Victims usually need to be extricated from the water as quickly as possible so that effective CPR can be provided. Common themes in children who have good recovery are a short duration of event and initiation of CPR as soon as possible, before arrival of emergency medical services.

Initial resuscitation must focus on rapidly restoring oxygenation, ventilation, and adequate circulation. The airway should be clear of vomitus and foreign material, which may cause obstruction or aspiration. Abdominal thrusts should not be used for fluid removal, because many victims have a distended abdomen from swallowed water; abdominal thrusts may increase the risk of regurgitation and aspiration. In cases of suspected airway foreign body, chest compressions or back blows are preferable maneuvers.

The cervical spine should be protected in anyone with potential traumatic neck injury (see Chapters 82 and 85). Cervical spine injury is a rare concomitant injury in drowning; only approximately 0.5% of submersion victims have C-spine injuries, and history of the event and victim's age should guide suspicion of C-spine injury. Drowning victims with C-spine injury are usually preteens or teenagers whose drowning event involved diving, a motor vehicle crash, a fall from a height, a water sport accident, child abuse, or other clinical signs of serious traumatic injury. In such cases, the neck should be maintained in a neutral position and protected with a well-fitting cervical collar. Patients rescued from unknown circumstances may also warrant C-spine precautions. In low-impact submersions, spinal injuries are exceedingly rare, and routine spinal immobilization is not warranted.

If the victim has ineffective respiration or apnea, ventilatory support must be initiated immediately. Mouth-to-mouth or mouth-to-nose breathing by trained bystanders often restores spontaneous ventilation. As soon as it is available, supplemental oxygen should be administered to all victims. Positive pressure bag-mask ventilation with 100% inspired oxygen should be instituted in patients with respiratory insufficiency. If apnea, cyanosis, hypoventilation, or labored respiration persists, trained personnel should perform endotracheal intubation as soon as possible. Intubation is also indicated to protect the airway in patients with depressed mental status or hemodynamic instability. Hypoxia must be corrected rapidly to optimize the chance of recovery.

Concurrent with securing of airway control, oxygenation, and ventilation, the child's cardiovascular status must be evaluated and treated according to the usual resuscitation guidelines and protocols. Heart rate and rhythm, blood pressure, temperature, and end-organ perfusion require urgent assessment. CPR should be instituted immediately in pulseless, bradycardic, or severely hypotensive victims. Continuous monitoring of the electrocardiogram (ECG) allows appropriate diagnosis and treatment of arrhythmias. Slow capillary refill, cool extremities, and altered mental status are potential indicators of shock (see Chapter 88).

Recognition and treatment of hypothermia are the unique aspects of cardiac resuscitation in the drowning victim. Core temperature must be evaluated, especially in children, because moderate to severe hypothermia can depress myocardial function and cause arrhythmias. Wet clothing should be removed to prevent ongoing heat losses, although in the hemodynamically stable patient, rewarming should be initiated in the controlled environment of the receiving ED or PICU. Unstable patients (i.e., arrhythmias) should be warmed to 34°C (93.2°F), taking care not to overheat. Trials are investigating if therapeutic hypothermia might be helpful, or if avoiding hyperthermia is the key element to long-term neurologic survival.

Often, intravenous (IV) fluids and vasoactive medications are required to improve circulation and perfusion. Vascular access should be established as quickly as possible for the administration of fluids or pressors. Intraosseous catheter placement is a potentially lifesaving vascular access technique that avoids the delay usually associated with multiple attempts to establish IV access in critically ill children. Epinephrine is usually the initial drug of choice in victims with bradyasystolic cardiopulmonary arrest (IV dose is 0.01 mg/kg using the 1 : 10,000 [0.1 mg/mL] solution given every 3-5 min, as needed). Epinephrine can be given intratracheally (endotracheal tube dose is 0.1-0.2 mg/kg of 1 : 1,000 [1 mg/mL] solution) if no IV access is available. An intravascular bolus of lactated Ringer solution or 0.9% normal saline (10-20 mL/kg) is often used to augment preload; repeated doses may be necessary. Hypotonic or glucose-containing solutions should not be used for intravascular volume administration of drowning victims.

Hospital-Based Evaluation and Treatment

Most pediatric drowning victims should be observed for at least 6-8 hr, even if they are asymptomatic on presentation to the ED. At a minimum, serial monitoring of vital signs (respiratory rate, heart rate, blood pressure, and temperature) and oxygenation by pulse oximetry, repeated pulmonary examination, and neurologic assessment should be performed in all drowning victims. Other studies may also be warranted, depending on the specific circumstances (possible abuse or neglect, traumatic injuries, or suspected intoxication). Almost half of asymptomatic or minimally symptomatic alert children (those who do not require ALS in the prehospital setting or who have an initial ED **Glasgow Coma Scale [GCS]** score of ≥13) experience some level of respiratory distress or hypoxemia progressing to pulmonary edema, usually during the 1st 4-8 hr after submersion. Most alert children with early respiratory symptoms respond to oxygen and, despite abnormal initial radiographs, become asymptomatic with a return of normal room-air pulse oximetry oxyhemoglobin saturation ($\mathrm{Sp}_{\mathrm{O}_2}$) and pulmonary examination by 4-6 hr. Subsequent delayed respiratory deterioration is extremely unlikely in such children. Selected low-risk patients who are alert and asymptomatic with normal physical findings and oxygenation levels may be considered for discharge after 6-8 hr of observation if appropriate follow-up can be ensured.

Cardiorespiratory Management

For children who are not in cardiac arrest, the level of respiratory support should be appropriate to the patient's condition and is a continuation of prehospital management. Frequent assessments are required to ensure that adequate oxygenation, ventilation, and airway control are maintained (see Chapter 89). Hypercapnia should generally be avoided in potentially brain-injured children. Patients with actual or potential hypoventilation or markedly elevated work of breathing should receive mechanical ventilation to avoid hypercapnia and decrease the energy expenditures of labored respiration.

Measures to stabilize cardiovascular status should also continue. Conditions contributing to myocardial insufficiency include hypoxic-ischemic injury, ongoing hypoxia, hypothermia, acidosis, high airway pressures during mechanical ventilation, alterations of intravascular volume, and electrolyte disorders. Heart failure, shock, arrhythmias, or cardiac arrest may occur. Continuous ECG monitoring is mandatory for recognition and treatment of arrhythmias (see Chapter 462).

The provision of adequate oxygenation and ventilation is a prerequisite to improving myocardial function. Fluid resuscitation and inotropic agents are often necessary to improve heart function and restore tissue perfusion (see Chapter 81). Increasing preload with IV fluids may be beneficial through improvements in stroke volume and cardiac output. Overzealous fluid administration, however, especially in the presence of poor myocardial function, can worsen pulmonary edema.

For patients with persistent cardiopulmonary arrest on arrival in the ED after *non–icy water* drowning, the decision to withhold or stop resuscitative efforts can be addressed by review of the history and the response to treatment. Because there are reports of good outcome following ongoing CPR in the ED, most drowning victims should be treated aggressively on presentation. However, for children who do not show ready response to aggressive resuscitative efforts, the need for prolonged ongoing CPR after non–icy water submersion almost invariably predicts death or persistent vegetative state. Consequently, in most cases, discontinuation of CPR in the ED is probably warranted for victims of non–icy water submersion who do not respond to resuscitation within 25-30 min. Final decisions regarding whether and when to discontinue resuscitative efforts must be individualized, with the understanding that the possibility of good outcome is generally very low with protracted resuscitation efforts.

Neurologic Management

Drowning victims who present to the hospital awake and alert usually have normal neurologic outcomes. In comatose victims, irreversible CNS injury is highly likely. The most critical and effective neurologic intensive care measures after drowning are rapid restoration and maintenance of adequate oxygenation, ventilation, and perfusion. Core body temperature and glucose management may also be important modulators of neurologic injury after hypoxia-ischemia.

Comatose drowning patients are at risk for intracranial hypertension. There is little evidence that ICP monitoring and therapy to reduce intracranial hypertension improve outcomes for drowning victims. Patients with elevated

ICP usually have poor outcomes—either death or persistent vegetative state. Children with normal ICP can also have poor outcomes, although less frequently. Conventional neurologic intensive care therapies, such as fluid restriction, hyperventilation, and administration of muscle relaxants, osmotic agents, diuretics, barbiturates, and corticosteroids, have not been shown to benefit the drowning victim, either individually or in combination. There is some evidence that these therapies may reduce overall mortality but increase the number of survivors with severe neurologic morbidity.

Seizures after hypoxic brain injury are common, although detection is often difficult in the ICU because these patients are frequently sedated, thus masking clinical signs. Continuous electroencephalographic (EEG) monitoring in critically ill patients revealed a 13% incidence of seizures, 92% of which were exclusively nonconvulsive. However, EEG monitoring has only limited value in the management of drowning victims, except to detect seizures or as an adjunct in the clinical evaluation of brain death (see Chapter 86). Seizures should be treated if possible to stabilize cerebral oxygen use, although benefits are inconclusive. Fosphenytoin or phenytoin (loading dose of 10-20 mg of phenytoin equivalents/kg, followed by maintenance dosing with 5-8 mg of phenytoin equivalents/kg/day in 2-3 divided doses; levels should be monitored) may be considered as an anticonvulsant; it may have some neuroprotective effects and may mitigate neurogenic pulmonary edema. Benzodiazepines, barbiturates, and other anticonvulsants may also have some role in seizure therapy, although no conclusive studies have shown improved neurologic outcome.

With optimal management, many initially comatose children can have impressive neurologic improvement, but usually do so within the 1st 24-72 hr. Unfortunately, half of deeply comatose drowning victims admitted to the PICU die of their hypoxic brain injury or survive with severe neurologic damage. Many children become brain dead. Deeply comatose drowning victims who do not show substantial improvement on neurologic examination after 24-72 hr and whose coma cannot be otherwise explained should be seriously considered for limitation or withdrawal of support.

Other Management Issues

A few drowning victims may have traumatic injury (see Chapter 82), especially if their drowning event involved participation in high-energy water sports such as personal watercraft, boating, diving, or surfing. A high index of suspicion for such injury is required. *Spinal precautions should be maintained in victims with altered mental status and suspected traumatic injury.* Significant anemia suggests trauma and internal hemorrhage.

Hypoxic-ischemic injury can have multiple systemic effects, although protracted organ dysfunction is uncommon in the absence of severe CNS injury. Hyperglycemia is associated with a poor outcome in critically ill pediatric drowning victims. Its etiology is unclear, but hyperglycemia is possibly a stress response. Glucose control in patients after drowning should be focused on avoiding hypoglycemia, hyperglycemia, and wide or rapid fluctuations in serum glucose, to prevent further harm.

Manifestations of acute kidney injury may be seen after hypoxic-ischemic injury (see Chapter 550). Diuretics, fluid restriction, and dialysis are occasionally needed to treat fluid overload or electrolyte disturbances; renal function usually normalizes in survivors. **Rhabdomyolysis** after drowning has been reported.

Profuse bloody diarrhea and mucosal sloughing usually portend a grim prognosis; conservative management includes bowel rest, nasogastric suction, and gastric pH neutralization. Nutritional support for most drowning victims is usually not difficult, because the majority of children either die or recover quickly and resume a normal diet within a few days. Enteral tube feeding or parenteral nutrition is occasionally indicated in children who do not recover quickly.

Hyperthermia after drowning or other types of brain injury may increase the risk of mortality and exacerbate hypoxic-ischemic CNS damage. Almost half of drowning victims have a fever during the 1st 48 hr after submersion. Hyperthermia is usually not caused by infection and resolves without antibiotics in approximately 80% of patients. Generally, prophylactic antibiotics are not recommended. However, there is general consensus that fever or hyperthermia (core body temperature >37.5°C [99.5°F]) in comatose drowning victims resuscitated from cardiac arrest should be prevented at all times in the acute recovery period (at least the 1st 24-48 hr).

Psychiatric and psychosocial sequelae in the family of a pediatric drowning victim are common. Grief, guilt, and anger are typical among family members, including siblings. Divorce rates increase within a few years of the injury, and parents often report difficulties with employment or substance abuse. Friends and family may blame the parents for the event. Professional counseling, pastoral care, or social work referral should be initiated for drowning victims and their families.

Hypothermia Management

Attention to core body temperature starts in the field and continues during transport and in the hospital. The goal is to prevent or treat moderate or severe hypothermia. Damp clothing should be removed from all drowning victims. Rewarming measures are generally categorized as passive, active external, or active internal (see Chapter 93). **Passive rewarming measures** can be applied in the prehospital or hospital setting and include the provision of dry blankets, a warm environment, and protection from further heat loss. These should be instituted as soon as possible for hypothermic drowning victims who have not had a cardiac arrest.

Full CPR with chest compressions is indicated for hypothermic victims if no pulse can be found or if narrow complex QRS activity is absent on ECG (see Chapters 81 and 93). When core body temperature is <30°C (86°F), resuscitative efforts should proceed according to the American Heart Association guidelines for CPR, but IV medications may be given at a lower frequency in moderate hypothermia because of decreased drug clearance. When ventricular fibrillation is present in severely hypothermic victims (core temperature <30°C [86°F]), defibrillation should be initiated but may not be effective until the core temperature is ≥30°C (86°F), at which time successful defibrillation may be more likely.

Significant controversy surrounds the discontinuation of prolonged resuscitative efforts in hypothermic drowning victims. Body temperature should be taken into account before resuscitative efforts are terminated. Other considerations include whether the victim may have been immersed before submerged, whether water was icy, or the cooling was very rapid with fast-flowing cold water. Victims with profound hypothermia may appear clinically dead, but full neurologic recovery is possible, although rare. Attempts at lifesaving resuscitation should not be withheld based on initial clinical presentation unless the victim is obviously dead (dependent lividity or rigor mortis). Rewarming efforts should usually be continued until the temperature is 32-34°C (89.6-93.2°F); if the victim continues to have no effective cardiac rhythm and remains unresponsive to aggressive CPR, resuscitative efforts can be discontinued.

Complete rewarming is not indicated for all arrest victims before resuscitative efforts are abandoned. Discontinuing resuscitation in victims of non–icy water submersion who remain asystolic despite 30 min of CPR is probably warranted. Physicians must use their individual clinical judgment about deciding to stop resuscitative efforts, taking into account the unique circumstances of each incident.

Once a drowning victim has undergone successful CPR after a cardiac arrest, temperature management should be carefully considered and body temperature continuously monitored. In victims in whom resuscitation duration was brief and who are awake soon after resuscitation, attempts to restore and maintain normothermia are warranted. Careful monitoring is necessary to prevent unrecognized worsening hypothermia, which can have untoward consequences.

For drowning victims who remain comatose after successful CPR, more contentious issues include rewarming of hypothermic patients and controlled application of therapeutic hypothermia. Although there is no evidence basis or opinion consensus, many investigators cautiously recommend that hypothermic drowning victims who remain unresponsive because of hypoxic-ischemic encephalopathy after restoration of adequate spontaneous circulation should not be actively rewarmed to normal body temperatures. Active rewarming should be limited to victims with core body temperatures <32°C (89.6°F), but temperatures 32-37.5°C (89.6-99.5°F) should be allowed without further rewarming efforts.

More controversial is the **induction of therapeutic hypothermia** in drowning victims who remain comatose because of hypoxic-ischemic encephalopathy after CPR for cardiac arrest. *A specific recommendation for therapeutic hypothermia, especially in children, is not yet generally accepted.* The Advanced Life Support Task Force of the International Liaison Committee on Resuscitation (2002) did not recommend therapeutic hypothermia in drowned children resuscitated after cardiopulmonary arrest, citing insufficient evidence and older studies demonstrating a potential deleterious effect in pediatric drowning victims. Several subsequent studies evaluating extracorporeal membrane circulation, rewarming, and therapeutic hypothermia in pediatric and adult drowning patients have shown no significant improvement in neurologic outcome or mortality.

The Therapeutic Hypothermia After Out-of-Hospital Pediatric Cardiac Arrest (THAPCA) randomized controlled trial (RCT) investigators analyzed post hoc the findings of *targeted temperature management* (TTM) in pediatric comatose survivors of out-of-hospital cardiac arrest due to drowning. Drowning comprised 28% of the landmark pediatric TTM (33°C vs 36.8°C) RCT, and the authors’ principal observation is that targeting hypothermia, compared with targeting normothermia, did not result in better survival.

Prognosis

The outcomes for drowning victims are remarkably bimodal: The great majority of victims either have a good outcome (intact or mild neurologic sequelae) or a poor outcome (severe neurologic sequelae, persistent vegetative state, or death), with very few exhibiting intermediate neurologic injury at hospital discharge. Subsequent evaluation of good outcome survivors may identify significant persistent cognitive deficits. Of hospitalized pediatric drowning victims, 15% die and as many as 20% survive with severe permanent neurologic damage.

Strong predictors of outcome are based on the incident and response to treatment at the scene. Intact survival or mild neurologic impairment has been seen in 91% of children with submersion duration <5 min and in 87% with resuscitation duration <10 min. Children with normal sinus rhythm, reactive pupils, or neurologic responsiveness at the scene virtually always had good outcomes (99%). Poor outcome is highly likely in patients with deep coma, apnea, absence of papillary responses, and hyperglycemia in the ED, with submersion durations >10 min, and with failure of response to CPR given for 25 min. In one comprehensive case series, all children with *resuscitation durations* >25 min either died or had severe neurologic morbidity, and all victims with *submersion durations* >25 min died. Long-term health-related quality of life and school performance in those who had received either bystander- or emergency medical service personnel–initiated CPR was high if their submersion duration was <5 min. Higher morbidity, mortality, and lower quality of life were reported in patients with >10 min submersion duration. In several studies of pediatric drowning, submersion duration was the best predictor of outcome, and water temperature was not. However, there are rare case reports of intact recovery following non–icy water drowning with longer submersion or resuscitation duration.

The GCS score has some limited utility in predicting recovery. Children with a score ≥6 on hospital admission generally have a good outcome, whereas those with a score ≤5 have a much higher probability of poor neurologic outcome. Occasionally, children with a GCS score of 3 or 4 in the ED have complete recovery. Improvement in the GCS score during the 1st several hr of hospitalization may indicate a better prognosis. Overall, early GCS assessments fail to adequately distinguish children who will survive intact from those with major neurologic injury.

Neurologic examination and progression during the 1st 24-72 hr are the best prognosticators of long-term CNS outcome. Children who regain consciousness within 48-72 hr, even after prolonged resuscitation, are unlikely to have serious neurologic sequelae. On the contrary, several studies have shown that patients with minimal improvement during this initial period rarely show significant subsequent neurologic recovery despite aggressive resuscitation efforts and remain in a persistent vegetative state or die. Laboratory and technologic methods to improve prognostication have not yet proved superior to neurologic examination. Serial neurologic evaluations after CPR should be performed over the ensuing 48-72 hr, with consideration given to limitation or withdrawal of support in patients who do not have significant neurologic recovery, even though this may occur before absolute prognostic certainty is achieved.

Prevention

The most effective way to decrease the injury burden of drowning is prevention. Drowning is a multifaceted problem, but several evidence-based preventive strategies are effective. The pediatrician has a prime opportunity to identify and inform families at risk of these strategies through anticipatory guidance. Advocacy should focus on anticipatory guidance regarding the appropriate supervision of children, access to swim lessons, presence of lifeguards, barriers to swimming pools, and use of personal floatation devices (PFDs). A family-centered approach to anticipatory guidance for water safety helps explore and identify the water hazards that each family is exposed to in their environment. The practitioner can then discuss the best tools and strategies for prevention that are relevant for the family. It is important to identify the risk both in and around the home and in other locations they may frequent, often when vacationing, such as vacation or relatives' homes. For some families the focus may be on bathtubs and bucket safety; for others, home pools or hot tubs may be the major hazards. If the family recreates near or on open water, they also need to learn about safety around boats and open water. In a rural environment, water collection systems and natural bodies of water may pose great risk.

Parents must build layers of water protection around their children. Table 91.1 provides an approach to the hazards and preventive strategies relevant to the most common sources of water involved in childhood drowning. A common preventive strategy for exposure to all water types and all ages is ensuring **appropriate supervision** . Pediatricians should define for parents what constitutes appropriate supervision at the various developmental levels of childhood. Many parents either underestimate the importance of adequate supervision or are simply unaware of the risks associated with water. Even parents who say that constant supervision is necessary will often admit to brief lapses while their child is alone near water. Parents also overestimate the supervisory abilities of older siblings; many bathtub drownings occur when an infant or toddler is left with a child <5 yr old.

Table 91.1

Approach to Prevention Strategies for Drowning

	HOME	RECREATION	NEIGHBORHOOD
Water hazards	Swimming pools Ponds Bathtubs Large buckets	Playing in water-swimming, wading Playing near water Being on water—boating	Irrigation ditches Watering holes Water drainage
Common risks	Lapse in supervision Unexpected toddler exposure Delayed discovery of child Reliance on water wings or pool toys Reliance on sibling or bath seat for bathing supervision	Lapse in supervision Change in weather Unfamiliarity with or change(s) in water conditions: Steep drop-off Current/tide Low temperature Alcohol use Peer pressure	Lapse in supervision, particularly when caregiver is socializing Risky behavior when with peers
Prevention strategies	Recognize hazards and risks. Provide constant adult supervision around water. Install 4-sided, isolation fencing of pools. Install rescue equipment and phone at poolside. Learn swimming and water survival skills. Avoid bath; instead shower, if a child/teen with seizure disorder. Learn first aid and CPR.	Provide constant adult supervision. Swim in lifeguarded areas. Know when and how to wear U.S. Coast Guard–approved PFDs. Avoid alcohol and other drugs. Learn swimming and water survival skills. Teach children about water safety. Be aware of current weather and water conditions. Learn first aid and CPR.	Identify hazardous bodies of water. Prevent access to water with barriers. Provide fenced-in “safe area” for water recreation. Provide lifeguarded swim sites. Provide access to low-cost swim/water survival lessons.

CPR, Cardiopulmonary resuscitation; PFDs, personal floatation devices.

Supervision of infants and young children means that a responsible adult should be with the child every moment. The caregiver must be alert, must not be consuming alcohol or other drugs or socializing, and must be attentive and focused entirely on watching the child. Even a brief moment of inattention, such as to answer a phone, get a drink, or hold a conversation, can have tragic consequences. If the child does not swim, *touch supervision* is required, meaning that the caregiver should be within arm's reach at all times. Adolescents require active adult supervision and avoidance of alcohol or drug use during water activities.

Learning to swim offers another layer of protection. Children may start swim lessons at an early age that are developmentally appropriate and aimed at the individual child's readiness and skill level. Swim lessons are beneficial and provide some level of protection to young children. A study from Bangladesh, where drowning accounts for 20% of all deaths in children ages 1-4 yr, showed that swim lessons and water safety curricula are cost-effective and led to a decrease in mortality from drowning. As with any other water safety intervention, parents need to know that swimming lessons and acquisition of swim skills cannot be solely relied on to prevent drowning. *No child can be drown-proof.* A supervising caretaker should be aware of where and how to get help and know how to safely rescue a child in trouble. Because only those trained in water rescue can safely attempt it, families should be encouraged to swim in designated areas only when and where a lifeguard is on duty.

Children and adolescents should never swim alone regardless of their swimming abilities. Even as they become more independent and participate in recreational activities without their parents, they should be encouraged to seek areas that are watched by **lifeguards** . In 2015, lifeguards rescued 940,000 Americans from drowning, and they probably prevent millions more drownings through verbal warnings and prompt interventions when needed. It is important to emphasize that even if the child is considered a strong swimmer, the ability to swim in a pool does not translate to being safe in open water, where water temperature, currents, and underwater obstacles can present additional and unfamiliar challenges. For swimmers, supervision by lifeguards reduces drowning risk, because lifeguards monitor risk behaviors and are trained in the difficult and potentially dangerous task of rescuing drowning victims.

Two of the preventive strategies listed in Table 91.1 deserve special mention. The most vigorously evaluated and effective drowning intervention applies to swimming pools. **Isolation fencing** that surrounds a pool with a secure, self-locking gate could prevent up to 75% of swimming pool–related drowning. Guidelines for appropriate fencing, provided by the U.S. Consumer Product

Safety Commission, are very specific; they were developed through testing of active toddlers in a gymnastics program on their ability to climb barriers of different materials and heights, and recent studies show them to be effective in preventing drowning in young children. In families who have a pool on their property, caregivers often erroneously believe that if a child falls into the water, there will be a loud noise or splash to alert them. Unfortunately, these events are usually silent, delaying timely rescue. This finding highlights the need for a fence that separates the pool from the house, not just surrounds the entire property.

The use of U.S. Coast Guard–approved **lifejackets or PFDs** should be advised with all families spending time around open water, not just those who consider themselves boaters. This issue is also particularly important for families who will participate in aquatic activities on a vacation. A PFD should be chosen with respect to the weight of the child and the proposed activity. Young children should wear PFDs that will float their head up. Parents should be urged to wear PFDs as well, since their use of PFDs is associated with greater use by their children. Toys such as water wings and "floaties" should not be relied on as drowning prevention measures.

Effective preventive efforts must also consider **cultural practices** . Different ethnic groups may have certain attitudes, beliefs, dress, or other customs that may affect their water safety. The higher drowning risk of minority children needs to be addressed by community-based prevention programs.

In addition to anticipatory guidance, pediatricians can play an active role in drowning prevention by participating in advocacy efforts to improve legislation for pool fencing, PFD use, and alcohol consumption in various water activities. Several counties in the United States, Australia, and New Zealand have laws requiring isolation fencing for pools. Their effectiveness has been limited by a lack of enforcement. Similarly, all states have boating-under-the-influence laws but, similarly, rarely enforce them. Furthermore, efforts at the community level may be needed to ensure the availability of swimming lessons for underserved populations and lifeguarded swim areas.

CHAPTER 92

Burn Injuries

Alia Y. Antoon

Burns are a leading cause of *unintentional injury* in children, second only to motor vehicle crashes. There has been a decline in the incidence of burn injury requiring medical care that has coincided with a stronger focus on burn treatment and prevention, increased fire and burn prevention education, greater availability of regional treatment centers, widespread use of smoke detectors, greater regulation of consumer products and occupational safety, and societal changes such as reductions in smoking and alcohol abuse.

Epidemiology

Approximately 2 million people in the United States require medical care for burn injuries each year. Approximately 50% of these patients are younger than 5 yr, with an average age of 32 mo. The principal cause of the burn is scald; one of the causes of **scald burn** is heating liquids in the microwave. The leading cause of burn in children 5-14 yr old is **flame injury** . In children 5-10 yr old, burns are usually a result of match play, whereas for older children, it is usually a result of gasoline ignition. **Fires** are a major cause of mortality in children, accounting for up to 34% of fatal injuries in those <16 yr old.

Scald burns account for 85% of total injuries and are most prevalent in children <4 yr old. Although the incidence of hot water scalding has been reduced by legislation requiring new water heaters to be preset at 48.9°C (120°F), scald injury remains the leading cause of hospitalization for burns. *Steam inhalation* used as a home remedy to treat respiratory infections is another potential cause of burns. Flame burns account for 13%; the remaining are electrical and chemical burns. **Clothing ignition** events have declined since passage of the Federal Flammable Fabric Act requiring sleepwear to be flame-retardant; however, the U.S. Consumer Product Safety Commission has voted to relax the existing children's sleepwear flammability standard. *Polyester* is the fabric most resistant to ignition by small flame source. Polyester does burn deeply as it melts, but it self-extinguishes when the flame source is removed. *Cotton,* on the other hand, continues to burn after the flame source has been removed, resulting in large, deep burns. Polyester melts downward, sparing the face and respiratory tract; cotton burns upward toward the face. Pellet stove, glass front stoves, and flat top stoves are becoming frequent sources of hand burns in children. Approximately 18% of burns are the result of **child abuse** (usually scalds), making it important to assess the pattern and site of injury and their consistency with the patient history (see Chapter 16). **Friction burns** from treadmills are also a problem. Hands are the most commonly injured sites, with deep 2nd-degree friction injury sometimes associated with fractures of the fingers. *Anoxia,* not the actual burn, is a major cause of morbidity and mortality in house fires.

Review of the history usually shows a common pattern: scald burns to the side of the face, neck, and arm if liquid is pulled from a table or stove; burns in the pant leg area if clothing ignites; burns in a splash pattern from cooking; and burns on the palm of the hand from contact with a hot stove. However, **glove or stocking burns** of the hands and feet; single-area deep burns on the trunk, buttocks, or back; and small, full-thickness burns (e.g., cigarette burns) in young children should raise the suspicion of child abuse.

Burn care involves a range of activities: prevention, acute care and resuscitation, wound management, pain relief, reconstruction, rehabilitation, and psychosocial adjustment. Children with massive burns require early and appropriate psychological and social support as well as resuscitation. Surgical debridement, wound closure, and rehabilitative efforts should be instituted concurrently to promote optimal rehabilitation. In order to maximize survival, the clinical approach includes aggressive surgical removal of devitalized tissue, infection control, and judicious use of antibiotics; life support with endotracheal intubation and mechanical ventilation; and use of early nutrition. Children who have sustained burn injuries differ in appearance from their peers, necessitating supportive efforts for reentry to school and social and sporting activities.

Prevention

The aim of burn prevention is a continuing reduction in the number of serious burn injuries (Table 92.1). Effective first aid and triage can decrease both the extent (area) and the severity (depth) of injuries. The use of flame-retardant clothing and smoke detectors, control of hot water temperature (thermostat settings) to 48.9°C (120°F) within buildings, and prohibition of cigarette smoking have been partially successful in reducing the incidence of burn injuries. Treatment of children with significant burn injuries in dedicated burn centers facilitates medically effective care, improves survival, and leads to greater cost efficiency. Survival of at least 80% of patients with burns of 90% of the body surface area (BSA) is possible; the overall survival rate of children with burns of all sizes is 99%. Death is more likely in children with irreversible anoxic brain injury sustained at the time of the burn. It is well known that burns occur in predictable patterns. Sources of burns include, by season:

Table 92.1

Burn Prophylaxis

Prevent Fires

Install and use smoke detectors.
Control the hot water thermostat; in public buildings, maximum water temperature should be 48.9°C (120°F).
Keep fire, matches, and lighters out of the reach of children.
Avoid cigarette smoking, especially in bed.
Do not leave lit candles unattended.
Use flame retardant–treated clothing.
Use caution when cooking, especially with oil.
Keep cloth items off heaters.

Prevent Injury

Roll, but do not run, if clothing catches fire; wrap in a blanket.
Practice escape procedures.
Crawl beneath smoke if a fire occurs indoors.
Use educational materials.*

[*] National Fire Protection Association pamphlets and videos.

Winter :

- Glass front fireplaces/pellet stoves and radiators increase hand burns.
- Treadmill injuries as more people exercise inside—child imitates adults or young child touches belt.

Summer :

- Fireworks, sparkler—temperatures reach 537.8°C (1,000°F).
- Burn contact with hot grill; hand/feet burn from hot embers.
- Lawnmowers

Spring/Fall :

- Burning leaves
- Gasoline burns
- Tap water scalds are essentially preventable through a combination of behavioral and environmental changes.

Pediatricians can play a major role in preventing the most common burns by educating parents and healthcare providers. Simple, effective, efficient, and cost-effective preventive measures include the use of appropriate clothing and smoke detectors and the planning of routes for emergency exit from the home. The National Fire Protection Association (NFPA) recommends replacing smoke detector batteries annually and the smoke detector alarm every 10 yr (or earlier, if indicated on the device). Child neglect and abuse must be seriously considered when the history of the injury and the distribution of the burn do not match.

Acute Care, Resuscitation, and Assessment

Indications for Admission

Burns covering >10% of total body surface area (BSA), burns associated with smoke inhalation, burns resulting from high-tension (voltage) electrical injuries, and burns associated with suspected child abuse or neglect should be treated as emergencies and the child hospitalized (Table 92.2). Small 1st- and 2nd-degree burns of the hands, feet, face, perineum, and joint surfaces also require admission if close follow-up care is difficult to provide. Children who have been in enclosed-space fires and those who have face and neck burns should be hospitalized for at least 24 hr for observation for signs of central nervous system (CNS) effects of anoxia from carbon monoxide (CO) poisoning and pulmonary effects from smoke inhalation.

Table 92.2

Indications for Hospitalization for Burns

Burns affecting >10% of BSA
Burns >10–20% of BSA in adolescent/adult
3rd-degree burns
Electrical burns caused by high-tension wires or lightning
Chemical burns
Inhalation injury, regardless of the amount of BSA burned
Inadequate home or social environment
Suspected child abuse or neglect
Burns to the face, hands, feet, perineum, genitals, or major joints
Burns in patients with preexisting medical conditions that may complicate the acute recovery phase
Associated injuries (fractures)
Pregnancy

BSA, Body surface area.

First Aid Measures

Acute care should include the following measures:

1. Extinguish flames by rolling the child on the ground; cover the child with a blanket, coat, or carpet.
2. After determining that the airway is patent, remove smoldering clothing or clothing saturated with hot liquid. Jewelry, particularly rings and bracelets, should be removed or cut away to prevent constriction and vascular compromise during the edema phase in the first 24-72 hr after burn injury.
3. In cases of **chemical injury** , brush off any remaining chemical, if

powdered or solid; then use copious irrigation or wash the affected area with water. Call the local poison control center for the neutralizing agent to treat a chemical ingestion.

4. Cover the burned area with clean, dry sheeting and apply cold (not iced) wet compresses to small injuries. Significant large-burn injury (>15% of BSA) decreases body temperature control and contraindicates the use of cold compresses.
5. If the burn is caused by **hot tar** , use mineral oil to remove the tar.
6. Administer analgesic medications.

Emergency Care

Supportive measures are as follows (Table 92.3 and Table 92.4)

Table 92.3

Acute Treatment of Burns

First aid, including washing of wounds and removal of devitalized tissue
Fluid resuscitation
Provision of energy requirements
Control of pain
Prevention of infection—early excision and grafting
Prevention of excessive metabolic expenditures
Control of bacterial wound flora
Use of biologic and synthetic dressings to close the wound

Table 92.4

Four Phases of Burn Care, With Physiologic Changes and Objectives

PHASE AND TIMING	PHYSIOLOGIC CHANGES	OBJECTIVES
1 : Initial evaluation and resuscitation, 0 to 72 hr	Massive capillary leak and burn shock	Accurate fluid resuscitation and thorough evaluation
2 : Initial wound excision and biologic closure, days 1-7	Hyperdynamic and catabolic state with high risk of infection	Accurately identify and remove all full-thickness wounds and achieve biologic closure
3 : Definitive wound closure, day 7 to week 6	Continued catabolic state and risk of nonwound septic events	Replace temporary with definitive covers, and close small complex wounds
4 : Rehabilitation,	Waning catabolic state	Initially to maintain range of motion and reduce

reconstruction, and reintegration, day 1 through discharge	and recovering strength	edema; subsequently to strengthen and facilitate return to home, work, and school

From Sheridan RL: Burns, including inflammation injury. In Vincent JL, Abraham E, Moore FA, et al, editors: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier (Table 168-1, p. 1173).

1. Rapidly review the cardiovascular and pulmonary status and document preexisting or physiologic lesions (asthma, congenital heart disease, renal or hepatic disease).
2. Ensure and maintain an adequate airway, and provide humidified oxygen by mask or endotracheal intubation (Fig. 92.1). The latter may be needed in children who have facial burns or a burn sustained in an enclosed space, before facial or laryngeal edema becomes evident. If hypoxia or CO poisoning is suspected, 100% oxygen should be used (see Chapters 81 and 89).

FIG. 92.1 **Algorithm for primary survey of a major burn injury.** (From Hettiaratchy S, Papini R: Initial management of a major burn. I. Overview, *BMJ* 328:1555–1557, 2004.)

3. Children with burns >15% of BSA require intravenous (IV) fluid resuscitation to maintain adequate perfusion. In an emergency situation if IV access is unattainable, an intraosseous line should be placed. When inserting central lines to provide high-volume fluid, special attention should be paid to use a very-small-caliber catheter in small children to avoid injury to the vascular lining, which may predispose to formation of clots. All inhalation injuries, regardless of the extent of BSA burn, require venous access to control fluid intake. All high-tension and

electrical injuries require venous access to ensure forced alkaline diuresis in case of muscle injury to avoid myoglobinuric renal damage. Lactated Ringer solution, 10-20 mL/kg/hr (normal saline may be used if lactated Ringer solution is not available), is initially infused until proper fluid replacement can be calculated. Consultation with a specialized burn unit should be made to coordinate fluid therapy, the type of fluid, the preferred formula for calculation, and preferences for the use of colloid agents, particularly if transfer to a burn center is anticipated.

4. Evaluate the child for associated injuries, which are common in patients with a history of high-tension electrical burn, especially if there has also been a fall from a height. Injuries to the spine, bones, and thoracic or intraabdominal organs may occur (see Chapter 82). Cervical spine precautions should be observed until this injury is ruled out. There is a very high risk of cardiac abnormalities, including ventricular tachycardia and ventricular fibrillation, resulting from conductivity of the high electric voltage. Cardiopulmonary resuscitation (CPR) should be instituted promptly at the scene and cardiac monitoring started on the patient's arrival at the emergency department (ED) (see Chapter 81).
5. Children with burns of >15% of BSA should not receive oral fluids (initially) because gastric distention may develop. These children require insertion of a nasogastric tube in the ED to prevent aspiration.
6. A Foley catheter should be inserted into the bladder to monitor urine output in all children who require IV fluid resuscitation.
7. All wounds should be wrapped with sterile dressings until it is decided whether to treat the patient on an outpatient basis or refer to an appropriate facility.
8. A CO measurement (carboxyhemoglobin [HbCO]) should be obtained for fire victims and 100% oxygen administered until the result is known.
9. Review child immunization. Burns <10% BSA do not require tetanus prevention, whereas burns >10% need tetanus immunization. Use diphtheria, tetanus toxoids, and acellular pertussis (DTaP) for tetanus prophylaxis for children <11 yr old, and use tetanus, diphtheria, and pertussis (TdaP) for children >11 yr old (see Chapter 238).

Classification of Burns

Proper triage and treatment of burn injury require assessment of the extent and depth of the injury (Table 92.5 and Fig. 92.2). **1st-degree burns** involve only the epidermis and are characterized by swelling, erythema, and pain (similar to mild sunburn). Tissue damage is usually minimal, and there is no blistering. Pain resolves in 48-72 hr; in a small percentage of patients, the damaged epithelium peels off, leaving no residual scars.

Table 92.5

Categories of Burn Depth

	1ST-DEGREE BURN	2ND-DEGREE, OR PARTIAL-THICKNESS, BURN	3RD-DEGREE, OR FULL-THICKNESS, BURN
Surface appearance	Dry, no blisters Minimal or no edema Erythematous Blanches, bleeds	Moist blebs, blisters Underlying tissue is mottled pink and white, with fair capillary refill Bleeds	Dry, leathery eschar Mixed white, waxy, khaki, mahogany, soot-stained No blanching or bleeding
Pain	Very painful	Very painful	Insensate
Histologic depth	Epidermal layers only	Epidermis, papillary, and reticular layers of dermis May include domes of subcutaneous layers	Down to and may include fat, subcutaneous tissue, fascia, muscle, and bone
Healing time	2-5 days with no scarring	Superficial: 5-21 days with no grafting Deep partial: 21-35 days with no infection; if infected, converts to full-thickness burn	Large areas require grafting, but small areas may heal from the edges after weeks

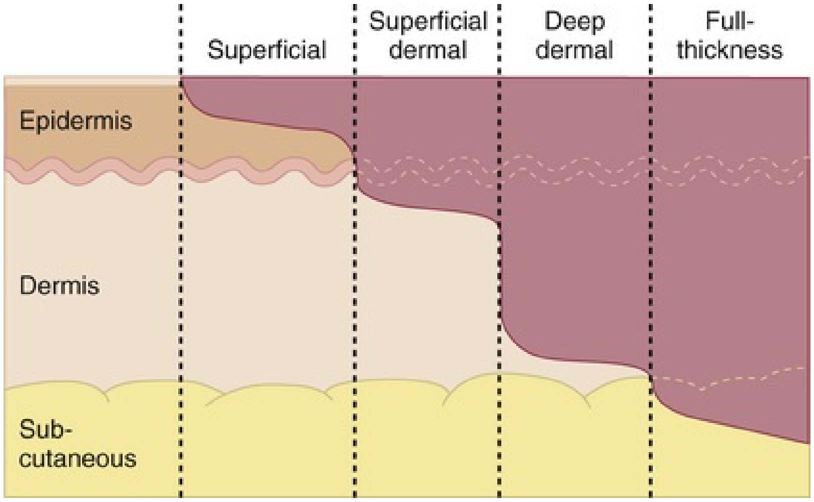

FIG. 92.2 Diagram of different burn depths. (From Hettiaratchy S, Papini R: Initial

management of a major burn. II. Assessment and resuscitation, *BMJ* 329:101–103, 2004.)

A **2nd-degree burn** involves injury to the entire epidermis and a variable portion of the dermal layer (vesicle and blister formation are characteristic). A *superficial* 2nd-degree burn is extremely painful because many remaining viable nerve endings are exposed. Superficial 2nd-degree burns heal in 7-14 days as the epithelium regenerates in the absence of infection. *Mid-level to deep* 2nd-degree burns also heal spontaneously if wounds are kept clean and infection free. Pain is less with these burns than in more superficial burns because fewer nerve endings remain viable. Fluid losses and metabolic effects of deep dermal (2nd-degree) burns are essentially the same as those of 3rd-degree burns.

Full-thickness, or **3rd-degree, burns** involve destruction of the entire epidermis and dermis, leaving no residual epidermal cells to repopulate the damaged area. The wound cannot epithelialize and can heal only by wound contraction or skin grafting. The absence of painful sensation and capillary filling demonstrates the loss of nerve and capillary elements.

Technologies are being used to help accurately determine the depth of burns. Laser *Doppler imaging* can be used from 48 hr to 5 days after the burn. It produces a color map of the affected tissue; *yellow* indicates second-degree burns, reflecting the presence of capillaries, arterioles, and venules, and *blue* reflects very low or absence of blood flow, which indicates third-degree burns. Its accuracy is up to 95%, and with accurate assessment, the proper treatment can be applied without delay. Doppler imaging can be used in both outpatients and inpatients.

Another technology called *reflectance confocal microscopy* (RCM), can be combined with *optical coherence tomography* (OCT) to visualize tissue morphology at the subcellular level. It determines if the cells are damaged and enables detection of skin morphologic changes up to 1 mm in depth. It provides accurate determination of the depth of the burn, allowing for the appropriate treatment.

Estimation of Body Surface Area for a Burn

Appropriate burn charts for different childhood age-groups should be used to accurately estimate the extent of BSA burned. The volume of fluid needed in resuscitation is calculated from the estimation of the extent and depth of burn surface. Mortality and morbidity also depend on the extent and depth of the burn. The variable growth rate of the head and extremities throughout childhood makes it necessary to use BSA charts, such as that modified by Lund and Brower or the chart used at the Shriners Hospital for Children in Boston (Fig. 92.3). The **rule of nines** used in adults may be used only in children >14 yr old or as a rough estimate to institute therapy before transfer to a burn center. In small burns, <10% of BSA, the **rule of palm** may be used, especially in outpatient settings; the area from the wrist crease to the finger crease (the palm) in the child equals 1% of the child's BSA.

Treatment

Outpatient Management of Minor Burns

A patient with 1st- and 2nd-degree burns of <10% BSA may be treated on an outpatient basis unless family support is judged inadequate or there are issues of child neglect or abuse. These outpatients do not require a tetanus booster (unless not fully immunized) or prophylactic penicillin therapy. Blisters should be left intact and dressed with *bacitracin* or *silver sulfadiazine* cream (Silvadene). Dressings should be changed once daily, after the wound is washed with lukewarm water to remove any cream left from the previous application. Very small wounds, especially those on the face, may be treated with bacitracin ointment and left open. **Debridement** of the devitalized skin is indicated when the blisters rupture. A variety of wound dressings and wound membranes (e.g., AQUACEL Ag dressing [ConvaTec USA, Skillman, NJ] in soft felt-like material impregnated with silver ion) may be applied to 2nd-degree burns and wrapped with a dry sterile dressing. Similar wound membranes provide pain control, prevent wound desiccation, and reduce wound colonization (Table 92.6). These dressings are usually kept on for 7-10 days but are checked twice a week.

Table 92.6

Select Common Wound Membranes for Burns

MEMBRANE	CHARACTERISTIC(S)
Porcine xenograft	Adheres to coagulum Excellent pain control
Biobrane	Bilaminate Fibrovascular in growth into inner layer
Acticoat	Nonadherent dressing that delivers silver
AQUACEL Ag	Absorptive hydrofiber that delivers silver
Various semipermeable membranes	Provide vapor and bacterial barrier
Various hydrocolloid dressings	Provide vapor and bacterial barrier Absorb exudates
Various impregnated gauzes	Provide barrier while allowing drainage

Burns to the palm with large blisters usually heal beneath the blisters; they should receive close follow-up on an outpatient basis. The great majority of superficial burns heal in 10-20 days. Deep 2nd-degree burns take longer to heal and may benefit from enzymatic debridement ointment (collagenase) applied daily on the wound, which aids in the removal of the dead tissue. These ointments should not be applied to the face, to avoid the risk of getting into the eyes.

The depth of scald injuries is difficult to assess early; conservative treatment is appropriate initially, with the depth of the area involved determined before grafting is attempted (Fig. 92.4). This approach obviates the risk of anesthesia and unnecessary grafting.

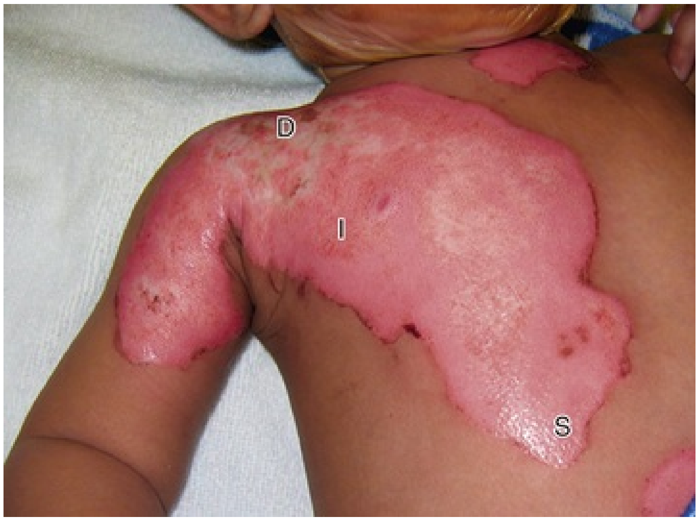

FIG. 92.4 Tea scald over the chest and shoulder of a child showing heterogeneity of burn depth. D, Deep; I, intermediate; S, superficial. (From Enoch S, Roshan A, Shah M: Emergency and early management of burns and scalds, *BMJ* 338:937–941, 2009.)

Fluid Resuscitation

Fluid resuscitation should begin soon after the injury has occurred, in the ED before transferring to a burn center. For most children, the *Parkland formula* is an appropriate starting guideline for fluid resuscitation (4 mL lactated Ringer solution/kg/% BSA burned). Half the fluid is given over the 1st 8 hr, calculated from the time of onset of injury; the remaining fluid is given at an even rate over the next 16 hr. The rate of infusion is adjusted according to the patient's response to therapy. Pulse and blood pressure should return to normal, and an adequate urine output (>1 mL/kg/hr in children; 0.5-1.0 mL/kg/hr in adolescents) should be accomplished by varying the IV infusion rate. Vital signs, acid-base balance, and mental status reflect the adequacy of resuscitation. Because of interstitial edema and sequestration of fluid in muscle cells, patients may gain up to 20% over baseline (preburn) body weight. Patients with burns of 30% BSA require a large venous access (central venous line) to deliver the fluid required over the critical 1st 24 hr. Patients with burns of >60% BSA may require a multilumen central venous catheter; these patients are best cared for in a specialized burn unit. In addition to fluid resuscitation, children should receive standard maintenance fluids (see Chapter 69).

During the 2nd 24 hr after the burn, patients begin to reabsorb edema fluid and to experience diuresis. Half the 1st day's fluid requirement is infused as lactated Ringer solution in 5% dextrose. Children <5 yr old may require the addition of 5% dextrose in the 1st 24 hr of resuscitation. Controversy surrounds whether *colloid* should be provided in the early period of burn resuscitation. One preference is to use colloid replacement concurrently if the burn is >85% of total BSA. Colloid is usually instituted 8-24 hr after the burn injury. In children <12 mo old, sodium tolerance is limited; the volume and sodium concentration of the resuscitation solution should be decreased if the urinary sodium level is rising. The adequacy of resuscitation should be constantly assessed by means of vital signs as well as urine output, blood gas, hematocrit, and serum protein measurements. Some patients require arterial and central venous lines, particularly those undergoing multiple excision and grafting procedures, as needed, for monitoring and replacement purposes. Central venous pressure monitoring may be indicated to assess circulation in patients with hemodynamic or cardiopulmonary instability. Femoral vein cannulation is a safe access for fluid resuscitation, especially in infants and children. Burn patients who require frequent blood gas monitoring benefit from radial or femoral arterial catheterization.

Oral supplementation may start as early as 48 hr after the burn. Milk formula, artificial feedings, homogenized milk, or soy-based products can be given by bolus or constant infusion through a nasogastric or small bowel feeding tube. As oral fluids are tolerated, IV fluids are decreased proportionately in an effort to keep the total fluid intake constant, particularly if pulmonary dysfunction is present.

A **5% albumin infusion** may be used to maintain the serum albumin levels at a desired 2 g/dL. The following rates are effective: for burns of 30–50% of total BSA, 0.3 mL of 5% albumin/kg/% BSA burn is infused over 24 hr; for burns of 50–70% of total BSA, 0.4 mL/kg/% BSA burn is infused over 24 hr; and for burns of 70–100% of total BSA, 0.5 mL/kg/% BSA burn is infused over 24 hr. **Infusion of packed red blood cells** is recommended if the hematocrit falls to <24% (hemoglobin = 8 g/dL). Some authorities recommend treatment for hematocrit <30% or hemoglobin <10 g/dL in patients with systemic infection, hemoglobinopathy, cardiopulmonary disease, anticipated (or ongoing) blood loss, and if repeated excision and grafting of full-thickness burns are needed.

Fresh-frozen plasma (FFP) is indicated if clinical and laboratory assessment shows a deficiency of clotting factors, a prothrombin level >1.5 times control, or a partial thromboplastin time >1.2 times control in children who are bleeding or are scheduled for an invasive procedure or a grafting procedure that could result in an estimated blood loss of more than half of blood volume. FFP may be used for volume resuscitation within 72 hr of injury in patients <2 yr old with burns >20% BSA and associated inhalation injury.

Sodium supplementation may be required for children with burns of >20% BSA if 0.5% silver nitrate solution is used as the topical antibacterial burn dressing. Sodium losses with silver nitrate therapy are regularly as high as 350 mEq/m^2 burn surface area. Oral sodium chloride supplement of 4 g/m^2 burn area/24 hr is usually well tolerated, divided into 4-6 equal doses to avoid osmotic diarrhea. The aim is to maintain serum sodium levels >130 mEq/L and urinary sodium concentration >30 mEq/L. Young children <5 yr are especially susceptible to hyponatremic and cerebral edema. IV **potassium supplementation** is supplied to maintain a serum potassium level >3 mEq/dL. Potassium losses may be significantly increased when 0.5% silver nitrate solution is used as the topical antibacterial agent or when aminoglycoside, diuretic, or amphotericin therapy is required.

Prevention of Infection and Surgical Management of the Burn Wound

Controversy surrounds the use of **prophylactic penicillin** for all patients hospitalized with acute burn injury and the periodic **replacement of central venous catheters** to prevent infection. In some units, a 5-day course of penicillin therapy is used for all patients with acute burns; standard-dose crystalline penicillin is given orally or intravenously in 4 divided doses. *Erythromycin* may be used as an alternative in penicillin-allergic children. Other units have discontinued prophylactic use of penicillin therapy without an increase in the infection rate. Similarly, there is conflicting evidence as to whether relocation of the IV catheter every 48-72 hr decreases or increases the incidence of catheter-related sepsis. Some recommend that the central venous catheter be replaced and relocated every 5-7 days, even if the site is not inflamed and there is no suspicion of catheter-related sepsis.

Mortality related to burn injury is associated not with the toxic effect of thermally injured skin, but with the metabolic and bacterial consequences of a large open wound, reduction of the patient's host resistance, and malnutrition. These abnormalities set the stage for life-threatening bacterial infection originating from the burn wound. Wound treatment and prevention of wound infection also promote early healing and improve aesthetic and functional outcomes. Topical treatment of the burn wound with 0.5% silver nitrate solution, silver sulfadiazine cream, or mafenide acetate (Sulfamylon) cream or topical solution at a concentration of 2.5–5% to be used for wounds with multidrug–resistant bacteria aims at prevention of infection (Table 92.7). These 3 agents have tissue-penetrating capacity. Regardless of the choice of topical antimicrobial agent, it is essential that all 3rd-degree burn tissue be fully excised before bacterial colonization occurs, and that the area is grafted as early as possible to prevent deep wound sepsis. Children with a burn of >30% BSA should be housed in a bacteria-controlled nursing unit to prevent cross-contamination and to provide a temperature- and humidity-controlled environment to minimize hypermetabolism.

Table 92.7

Topical Agents Used for Burns

AGENT	EFFECTIVENESS	EASE OF USE
Silver sulfadiazine cream (Silvadene)	Good penetration	Changed once daily
		Residue *must* be washed off with each dressing change
Mafenide acetate cream* (Sulfamylon)	Broad spectrum, including *Pseudomonas*	Closed dressings Changed twice daily
	Rapid and deep wound penetration	Residue *must* be washed off with each dressing changed
0.5% Silver nitrate solution	Bacteriostatic	Closed bulky dressing soaked every 2 hr and changed once daily
	Broad spectrum, including some fungi	
	Superficial penetration	
AQUACEL Ag	Dressing impregnated with silver	Applied directly to 2nd-degree burn; occlusive dressing kept for 10 days

* Mafenide acetate solution at concentrations of 2.5% or 5% for use on heavily colonized, multidrug-resistant organisms to be used for 5 days only.

Deep 3rd-degree burns of >10% BSA benefit from early excision and grafting. To improve outcome, sequential excision and grafting of 3rd-degree and deep 2nd-degree burns is required in children with large burns. Prompt excision with immediate wound closure is achieved with **autografts** , which are often meshed to increase the efficiency of coverings. Alternatives for wound closure, such as allografts, xenografts, and Integra (Integra LifeSciences, York, PA) and other synthetic skin coverings (bilaminate membrane composed of a porous lattice of crosslinked chondroitin-6-sulfate engineered to induce neovascularization as it is biodegraded), may be important for wound coverage in patients with extensive injury to limit fluid, electrolyte, and protein losses and to reduce pain and minimize temperature loss. Epidermal cultured cells (autologous keratinocytes) are a costly alternative and are not always successful. An experienced burn team can safely perform early-stage or total excision while burn fluid resuscitation continues. Important keys to success are: (1) accurate preoperative and intraoperative determination of burn depth; (2) the choice of excision area and appropriate timing; (3) control of intraoperative blood loss; (4) specific instrumentation; (5) the choice and use of perioperative antibiotics; and (6) the type of wound coverage chosen. This process can accomplish early wound coverage without the use of recombinant human growth hormone.

Nutritional Support

Supporting the increased energy requirements of a patient with a burn is a high priority. The burn injury produces a hypermetabolic response characterized by both protein and fat catabolism. Depending on the time lapse since the burn, children with a burn of 40% of total BSA require basal energy expenditure (oxygen consumption) approximately 50–100% higher than predicted for their age. Early excision and grafting can decrease the energy requirement. Pain, anxiety, and immobilization increase the physiologic demands. Additional energy expenditure is caused by cold stress if environmental humidity and temperature are not controlled; this is especially true in young infants, in whom the large BSA:mass ratio allows proportionately greater heat loss than in adolescents and adults. Providing environmental temperatures of 28-33°C (82.4-91.4°F), adequate covering during transport, and liberal use of analgesics and anxiolytics can decrease caloric demands. Special units to control ambient temperature and humidity may be necessary for children with large surface area burns. Appropriate sleep intervals are necessary and should be part of the regimen. Sepsis increases metabolic rates, and early enteral nutrition, initially with high-carbohydrate, high-protein caloric support (1,800 kcal/m^2 /24 hr maintenance plus 2,200 kcal/m^2 of burn/24 hr) reduces metabolic stress.

The objective of **caloric supplementation** programs is to maintain body weight and minimize weight loss by meeting metabolic demands. This reduces the loss of lean body mass. Calories are provided at approximately 1.5 times the basal metabolic rate, with 3-4 g/kg of protein/day. The focus of nutritional therapy is to support and compensate for the metabolic needs. Multivitamins, particularly the B vitamin group, vitamin C, vitamin A, and zinc, are also necessary.

Alimentation should be started as soon as is practical, both enterally and parenterally, to meet all the caloric needs and keep the gastrointestinal (GI) tract active and intact after the resuscitative phase. Patients with burns of >40% of total BSA need a flexible nasogastric or small bowel feeding tube to facilitate continuous delivery of calories without the risk of aspiration. To decrease the risk of infectious complications, parenteral nutrition is discontinued as soon as is practical, after delivery of sufficient enteral calories are established. Continuous GI feeding is essential, even if feeding is interrupted, causing frequent visits to the operating room, until full grafting takes place. The use of anabolic agents (growth hormone, oxandrolone, low-dose insulin) or anticatabolic agents (propranolol) remains controversial, although β-blocking agents may reduce metabolic stress. Burn centers caring for large burns (>50% BSA, 3rd-degree) in patients who might be malnourished have used the anabolic steroid *oxandrolone,* at a dose of 0.1-0.2 mg/kg/day orally, to promote better protein synthesis while the nutritional support by nasogastric feeding and IV hyperalimentation continues.

Topical Therapy

Topical therapy is widely used and is effective against most burn wound pathogens (see Table 92.7). A number of topical agents are used: 0.5% silver nitrate solution, sulfacetamide acetate cream or solution, silver sulfadiazine cream, and Accuzyme ointment or AQUACEL Ag^+ . Accuzyme is an enzymatic debridement agent and may cause a stinging feeling for 15 min after application. Preferences vary among burn units. Each topical agent has advantages and disadvantages in application, comfort, and bacteriostatic spectrum. *Mafenide acetate* is a very effective broad-spectrum agent with the ability to diffuse through the burn eschar; it is the treatment of choice for injury to cartilaginous surface, such as the ear. Mafenide acetate solution at a concentration of 5% is useful for the treatment of burn wounds that are heavily colonized with multidrug-resistant bacteria (use should be limited to 5 days). The carbonic anhydrase inhibition activity of mafenide acetate may cause acid-base imbalance if large surface areas are treated, and adverse reactions to the sulfur-containing agents may produce transient **leukopenia** . This latter reaction is mostly noted with the use of silver sulfadiazine cream when applied over large surface areas in children <5 yr old. This phenomenon is transient, self-limiting, and reversible. No sulfa-containing agent should be used if the child has a history of sulfa allergies.

Inhalational Injury

Inhalational injury is serious in the infant and child, particularly if preexisting pulmonary conditions are present (see Chapter 89). Inhalation injury should be suspected in a patient confined to a closed space (building), with a history of an explosion or a decreased level of consciousness, or with evidence of carbon deposits in the oropharynx or nose, singed facial hair, and carbonaceous sputum. Mortality estimates vary, depending on the criteria for diagnosis, but are 45–60% in adults; exact figures are not available in children. Evaluation aims at early identification of inhalation airway injuries, which may result from (1) direct heat (greater problems with steam burns); (2) acute asphyxia; (3) CO poisoning; and (4) toxic fumes, including cyanides from combustible plastics. Sulfur and nitrogen oxides and alkalis formed during the combustion of synthetic fabrics produce corrosive chemicals that may erode mucosa and cause significant tissue sloughing. Exposure to smoke may cause degradation of surfactant and decrease its production, resulting in atelectasis. Inhalation injury and burn injury are synergistic, and the combined effect can increase morbidity and mortality.

The pulmonary complications of burns and inhalation can be divided into 3 syndromes that have distinct clinical manifestations and temporal patterns:

1. Early complications include CO and/or cyanide poisoning, airway obstruction, and pulmonary edema.
2. Acute respiratory distress syndrome (ARDS) usually becomes clinically evident later, at 24-48 hr, although it can occur even later (see Chapter 89).
3. Late complications (days to weeks) include pneumonia and pulmonary emboli.

Inhalation injury should be assessed from the evidence of obvious injury (swelling or carbonaceous material in the nasal passages), wheezing, crackles or poor air entry, and laboratory determinations of HbCO and arterial blood gases.

Treatment is initially focused on establishing and maintaining a patent airway through prompt and early nasotracheal or orotracheal intubation and adequate ventilation and oxygenation. **Wheezing** is common, and β-agonist aerosols or inhaled corticosteroids are useful. Aggressive pulmonary toilet and chest physiotherapy are necessary in patients with prolonged nasotracheal intubation or in the rare patient with a tracheotomy. An endotracheal tube can be maintained for months without the need for tracheostomy. If tracheotomy must be performed, it should be delayed until burns at and near the site have healed, and then it should be performed electively, with the child under anesthesia with optimal tracheal positioning and hemostasis. In children with inhalation injury or burns of the face and neck, upper airway obstruction can develop rapidly; endotracheal intubation becomes a lifesaving intervention. Extubation should be delayed until the patient meets the accepted criteria for maintaining the airway.

Signs of CNS injury from hypoxemia caused by asphyxia or **carbon monoxide poisoning** vary from irritability to depression. CO poisoning may be *mild* (<20% HbCO), with slight dyspnea, headache, nausea, and decreased visual acuity and higher cerebral functions; *moderate* (20–40% HbCO), with irritability, agitation, nausea, dimness of vision, impaired judgment, and rapid fatigue; or *severe* (40–60% HbCO), producing confusion, hallucination, ataxia, collapse, acidosis, and coma. Measurement of HbCO is important for diagnosis and treatment. The PaO_2 value may be normal and the HbCO saturation values misleading because HbCO is not detected by the usual tests of oxygen saturation. CO poisoning is assumed until the tests are performed, and it is treated with 100% oxygen. Significant CO poisoning requires hyperbaric oxygen therapy (see Chapter 77). **Cyanide poisoning** should be suspected if a metabolic acidosis persists despite adequate fluid resuscitation, and in environments containing synthetic polymers. Unless specifically suspected, most burn centers do not routinely screen for cyanide poisoning.

Patients with severe inhalation injury or with other causes of respiratory deterioration that lead to ARDS who do not improve with conventional pressure-controlled ventilation (progressive oxygenation failure, as manifested by oxygen saturation <90% while receiving FIO_2 of 0.9-1.0 and positive end-expiratory pressure of at least 12.5 cm H_2O) may benefit from high-frequency ventilation or nitric oxide inhalation treatment. Nitric oxide usually is administered through the ventilator at 5 parts per million (ppm) and increased to 30 ppm. This method of therapy reduces the need for extracorporeal membrane oxygenation (see

Chapter 89).

Pain Relief and Psychologic Adjustment

See Chapter 76 .

It is important to provide adequate analgesia, anxiolytics, and psychologic support to reduce early metabolic stress, decrease the potential for posttraumatic stress disorder (PTSD), and allow future stabilization as well as physical and psychologic rehabilitation. Patients and family members require team support to work through the grieving process and accept long-term changes in appearance.

Children with burn injury show frequent and wide fluctuations in pain intensity. Appreciation of pain depends on the depth of the burn; the stage of healing; the patient's age, stage of emotional development, and cognition; the experience and efficiency of the treating team; the use of analgesics and other drugs; the patient's pain threshold; and interpersonal and cultural factors. From the onset of treatment, **preemptive pain control** during dressing changes is crucial. The use of a variety of nonpharmacologic interventions as well as pharmacologic agents must be reviewed throughout the treatment period. Opiate analgesia, prescribed in an adequate dose and timed to cover dressing changes, is essential to comfort management. A supportive person who is consistently present and knows the patient profile can integrate and encourage patient participation in burn care. The problem of *undermedication* is most prevalent in adolescents, in whom fear of drug dependence may inappropriately influence treatment. A related problem is that the child's specific pain experience may be misinterpreted; for anxious patients, those who are confused and alone, or those with preexisting emotional disorders, even small wounds may illicit intense pain. Anxiolytic medication added to the analgesic is usually helpful and has more than a synergistic effect. Equal attention is necessary to decrease stress in the intubated patient. Other modalities of pain and anxiety relief (**relaxation techniques**) can decrease the physiologic stress response.

Oral *morphine sulfate* (immediate release) is recommended at a consistent schedule at a dose of 0.3-0.6 mg/kg every 4-6 hr initially and until wound cover is accomplished. Morphine sulfate IV bolus is administered at a dose of 0.05-0.1 mg/kg (maximum, 2-5 mg) every 2 hr. Morphine sulfate rectal suppositories may be useful at a dose of 0.3-0.6 mg/kg every 4 hr when oral administration is not possible. The use of *codeine* preparation should be limited to children >6 yr old because of the ultrarapid metabolizers of codeine into morphine. For anxiety, *lorazepam* is given on a consistent schedule, 0.05-0.1 mg/kg/dose every 6-8 hr. To control pain during a procedure (dressing change or debridement), oral morphine, (0.3-0.6 mg/kg) is given 1-2 hr before the procedure, supplemented by a morphine IV bolus (0.05-0.1 mg/kg) given immediately before the procedure. Lorazepam, 0.04 mg/kg, is given orally or intravenously, if necessary, for anxiety before the procedure. *Midazolam* is also very useful for conscious sedation at a dose of 0.01-0.02 mg/kg for nonintubated patients and 0.05-0.1 mg/kg for intubated patients, as an IV infusion or bolus, and may be repeated in 10 min. During the process of weaning from analgesics, the dose of oral opiates is reduced by 25% over 1-3 days, sometimes with the addition of acetaminophen as opiates are tapered. When weaning off antianxiety medications, the approach involves reducing the dose of benzodiazepines, at 25–50% per dose, daily over 1-3 days. *Risperidone*, up to 2.5 mg/day, is being used in children with severe burns.

For ventilated patients, pain control is accomplished by using morphine sulfate intermittently as an IV bolus at 0.05-0.1 mg/kg every 2 hr. Doses may need to be increased gradually, and some children may need continuous infusion; a starting dose of 0.05 mg/kg/hr as an infusion is increased gradually as the need of the child changes. Naloxone is rarely needed but should be immediately available to reverse the effect of morphine, if necessary; if needed for an airway crisis, it should be given in a dose of 0.1 mg/kg up to a total of 2 mg, either intramuscularly or intravenously. For patients undergoing assisted respiration who require treatment of anxiety, midazolam is used as an intermittent IV bolus (0.04 mg/kg by slow push every 4-6 hr) or as a continuous infusion. For intubated patients, opiates do not need to be discontinued during the process of weaning from the ventilator. Benzodiazepine should be reduced to approximately half the dose over 24-72 hr before extubation; too-rapid weaning from a benzodiazepine can lead to seizures.

There is a growing use of *psychotropic medication* in the care of children with burns, including prescription of selective serotonin reuptake inhibitors as antidepressants, the use of haloperidol as a neuroleptic in the critical care setting, and the treatment of PTSD with benzodiazepines. Conscious sedation using ketamine or propofol may be used for major dressing changes.

Reconstruction and Rehabilitation

To ensure maximum cosmetic and functional outcome, occupational and physical therapy must begin on the day of admission, continue throughout hospitalization, and for some patients, continue after discharge. Physical rehabilitation involves body and limb positioning, splinting, exercises (active and passive movement), assistance with activities of daily living, and gradual ambulation. These measures maintain adequate joint and muscle activity with as normal a range of movement as possible after healing or reconstruction. **Pressure therapy** is necessary to reduce hypertrophic scar formation; a variety of prefabricated and custom-made garments are available for use in different body areas. These custom-made garments deliver consistent pressure on scarred areas, shorten the time of scar maturation, and decrease scar thickness, redness, and associated itching. Continued adjustments to scarred areas (scar release, grafting, rearrangement) and multiple minor cosmetic surgical procedures are necessary to optimize long-term function and improve appearance. Replacement of areas of alopecia and scarring has been achieved with the use of tissue-expander techniques. The use of ultrapulse laser for reduction of scarring is an adjunct in scar management.

School Reentry and Long-Term Outcome

It is best for the child to return to school immediately after discharge. Occasionally, a child may need to attend a few half-days (because of rehabilitation needs). It is important for the child to return to the normal routine of attending school and being with peers. Planning for a return to home and school often requires a **school reentry program** that is individualized to each child's needs. For a school-age child, planning for the return to school occurs simultaneously with planning for discharge. The hospital schoolteacher contacts the local school and plans the program with the school faculty, nurses, social workers, recreational/child-life therapists, and rehabilitation therapists. This team should work with students and staff to ease anxiety, answer questions, and provide information. Burns and scars evoke fears in those who are not familiar with this type of injury and can result in a tendency to withdraw from or reject the burned child. A school reentry program should be appropriate to a child's development and changing educational needs.

Major advances have made it possible to save the lives of children with massive burns. Although some children have had lingering physical difficulties, most have a satisfactory quality of life. The comprehensive burn care that includes experienced multidisciplinary aftercare plays an important role in recovery. Table 92.8 lists the long-term disabilities and complications of burns.

Table 92.8

Common Long-Term Complications and Disabilities in Patients With Burn Injuries

Complications Affecting the Skin and Soft Tissue

- Hypertrophic scars
- Susceptibility to minor trauma
- Dry skin
- Contractures
- Itching and neuropathic pain
- Alopecia
- Chronic open wounds
- Skin cancers

Orthopedic Disabilities

- Amputations
- Contractures
- Heterotopic ossification
- Temporary reduction in bone density

Metabolic Disabilities

- Heat sensitivity
- Obesity

Psychiatric and Neurologic Disabilities

- Sleep disorders
- Adjustment disorders
- Posttraumatic stress disorder
- Depression

Body image issues
Neuropathy and neuropathic pain
Long-term neurologic effects of carbon monoxide poisoning
Anoxic brain injury

Long-Term Complications of Critical Care

Deep vein thrombosis, venous insufficiency, or varicose veins
Tracheal stenosis, vocal cord disorders, or swallowing disorders
Renal or adrenal dysfunction
Hepatobiliary or pancreatic disease
Cardiovascular disease
Reactive airway disease or bronchial polyposis

Preexisting Disabilities That Contributed to the Injuries

Risk-taking behavior
Untreated or poorly treated psychiatric disorder

Modified from Sheridan RL, Schultz JT, Ryan CM, et al: Case records of the Massachusetts General Hospital. Weekly clinicopathological exercises. Case 6-2004: a 35-year-old woman with extensive, deep burns from a nightclub fire, *N Engl J Med* 350:810–821, 2004.

Electrical Burns

There are 3 types of electrical burns: extension cord (minor), high-tension wire, and lightning. **Minor electrical burns** usually occur as a result of biting on an extension cord. These injuries produce localized burns to the mouth, which usually involve the portions of the upper and lower lips that come in contact with the extension cord. The injury may involve or spare the corners of the mouth. Because these are *nonconductive* injuries (do not extend beyond the site of injury), hospital admission is not necessary, and care is focused on the area of the injury visible in the mouth, ensuring it is low voltage and does not cause entry or exit wounds or cardiac issues. Treatment with topical antibiotic creams is sufficient until the patient is seen in a burn unit outpatient department or by a plastic surgeon.

A more serious category of electrical burn is the **high-tension electrical wire burn** , for which children must be admitted for observation, regardless of the extent of the surface area burn. Deep muscle injury is typical and cannot be readily assessed initially. These injuries result from high voltage (>1,000 V) and occur particularly at high-voltage installations, such as electric power stations or railroads; children climb an electric pole and touch an electric box out of curiosity or accidentally touch a high-tension electrical wire. Such injuries have a mortality rate of 3–15% for children who arrive at the hospital for treatment. Survivors have a high rate of morbidity, including major limb amputations. Points of entry of current through the skin and the exit site show characteristic features consistent with current density and heat. The majority of entrance wounds involve the upper extremity, with small exit wounds in the lower extremity. The electrical path, from entrance to exit, takes the shortest distance between the 2 points and may produce injury in any organ or tissue in the path of the current. Multiple exit wounds in some patients attest to the possibility of several electrical pathways in the body, placing virtually any structure in the body at risk (Table 92.9). Damage to the abdominal viscera, thoracic structures, and the nervous system (confusion, coma, paralysis) in areas remote from obvious extremity injury occurs and must be sought, particularly in injuries with multiple current pathways or those in which the victim falls from a high pole. Sometimes an *ignition* occurs and results in concurrent flame burn and clothing fire. **Cardiac abnormalities** , manifested as ventricular fibrillation or cardiac arrest, are common; patients with high-tension electrical injury need an initial electrocardiogram and cardiac monitoring until they are stable and have been fully assessed. Higher-risk patients have abnormal electrocardiographic findings and a history of loss of consciousness. Renal damage from **deep muscle necrosis** and subsequent myoglobinuria is another complication; such patients need forced alkaline diuresis to minimize renal damage. Soft tissue (muscle) injury of an extremity may produce a **compartment syndrome** . Aggressive removal of all dead and devitalized tissue, even with the risk of functional loss, remains the key to effective management of the electrically damaged extremity. Early debridement facilitates early closure of the wound. Damaged major vessels must be isolated and buried in a viable muscle to prevent exposure. Survival depends on immediate intensive care; functional result depends on long-term care and delayed reconstructive surgery.

Table 92.9

Electrical Injury: Clinical Considerations

SYSTEM	CLINICAL MANIFESTATIONS	MANAGEMENT
General	—	Extricate the patient. Perform ABCs of resuscitation; immobilize the spine.
		Obtain history: voltage, type of current.
		Obtain complete blood count with platelets, electrolytes, BUN, creatinine, and glucose.
Cardiac	Dysrhythmias: asystole, ventricular fibrillation, sinus tachycardia, sinus bradycardia, premature atrial contractions, premature ventricular contractions, conduction defects, atrial fibrillation, ST-T wave changes	Treat dysrhythmias. Provide cardiac monitor, electrocardiogram, and radiographs with suspected thoracic injury.
		Perform creatinine phosphokinase with isoenzyme measurements if indicated.
Pulmonary	Respiratory arrest, acute respiratory distress, aspiration syndrome	Protect and maintain the airway.
		Provide mechanical ventilation if indicated, chest radiograph, and arterial blood gas levels.
Renal	Acute kidney injury, myoglobinuria	Provide aggressive fluid management unless central nervous system injury is present.
		Maintain adequate urine output, >1 mL/kg/hr.
		Consider central venous or pulmonary artery pressure monitoring.
		Measure urine myoglobin; perform urinalysis; measure BUN, creatinine.
Neurologic	Immediate: loss of consciousness, motor paralysis, visual disturbances, amnesia, agitation; intracranial hematoma	Treat seizures. Provide fluid restriction if indicated.
	Secondary: pain, paraplegia, brachial plexus injury, syndrome of inappropriate antidiuretic hormone secretion, autonomic disturbances, cerebral edema	Consider spine radiographs and MRI, especially cervical.
	Delayed: paralysis, seizures, headache, peripheral neuropathy	Perform CT or MRI scan of the brain if indicated.
Cutaneous/oral	Oral commissure burns, tongue and dental injuries; skin burns resulting from ignition of clothes, entrance and exit burns, and arc burns	Search for the entrance and exit wounds. Treat cutaneous burns; determine patient's

		tetanus status.
		Obtain consultation for plastic surgery of ear, nose, and throat, if indicated.
	Electrical burns to mouth could include oral commissures and lips; low-voltage electrical burns secondary to high conductivity of saliva	Ensure no entry or exit wounds and no cardiac involvement. Confirm all injuries are localized. Management is observation until eschar sloughs off and granulation tissue fills in. Obtain plastic surgeon evaluation after first healing, usually with scar formation.
Abdominal	Viscus perforation and solid-organ damage; ileus; abdominal injury rare without visible abdominal burns	Place nasogastric tube if patient has airway compromise or ileus.
		Obtain serum ALT, AST, amylase, BUN, and creatinine measurements and CT scans as indicated.
Musculoskeletal	Compartment syndrome from subcutaneous necrosis limb edema and deep burns	Monitor patient for possible compartment syndrome.
	Long-bone fractures, spine injuries	Obtain radiographs and orthopedic/general surgery consultations as indicated.
Ocular	Visual changes, optic neuritis, cataracts, extraocular muscle paresis	Obtain an ophthalmology consultation as indicated.

AST, Aspartate transaminase; ALT, alanine transaminase; BUN, blood urea nitrogen.

Adapted from Hall ML, Sills RM: Electrical and lightning injuries. In Barkin RM, editor: *Pediatric emergency medicine,* St Louis, 1997, Mosby, p 484.

Lightning burns occur when a high-voltage current directly strikes a person (most dangerous) or when the current strikes the ground or an adjacent (in-contact) object. A *step voltage burn* is observed when lightning strikes the ground and travels up one leg and down the other (the path of least resistance). Lightning burns depend on the current path, the type of clothing worn, the presence of metal, and cutaneous moisture. Entry, exit, and path lesions are possible; the prognosis is poorest for lesions of the head or legs. Internal organ injury along the path is common and does not relate to the severity of the cutaneous burn. Linear burns, usually 1st or 2nd degree, are in the locations where sweat is present. *Feathering,* or an arborescent pattern, is characteristic of lightning injury. Lightning may ignite clothing or produce serious cutaneous burns from heated metal in the clothing. Internal complications of lightning burns include cardiac arrest caused by asystole, transient hypertension, premature ventricular contractions, ventricular fibrillation, and myocardial ischemia. Most severe cardiac complications resolve if the patient is supported with CPR (see Chapter 81). CNS complications include cerebral edema, hemorrhage, seizures, mood changes, depression, and paralysis of the lower extremities. Rhabdomyolysis and myoglobinuria (with possible renal failure) also occur. Ocular manifestations include vitreous hemorrhage, iridocyclitis, retinal tearing, or retinal detachment.

CHAPTER 93

Cold Injuries

Alia Y. Antoon

The involvement of children and youth in snowmobiling, mountain climbing, winter hiking, and skiing places them at risk for cold injury. Cold injury may produce either local tissue damage, with the injury pattern depending on exposure to *damp cold* (frostnip, immersion foot, or trench foot), *dry cold* (which leads to local frostbite), or generalized systemic effects (hypothermia).

Pathophysiology

Ice crystals may form between or within cells, interfering with the sodium pump, and may lead to rupture of cell membranes. Further damage may result from clumping of red blood cells or platelets, causing microembolism or thrombosis. Blood may be shunted away from an affected area by secondary neurovascular responses to the cold injury; this shunting often further damages an injured part while improving perfusion of other tissues. The spectrum of injury ranges from mild to severe and reflects the result of structural and functional disturbance in small blood vessels, nerves, and skin.

Etiology

Body heat may be lost by *conduction* from wet clothing or contact with metal or other solid conducting objects, *convection* from wind chill, *evaporation*, or *radiation* . Susceptibility to cold injury may be increased by dehydration, alcohol or drug use, impaired consciousness, exhaustion, hunger, anemia, impaired circulation from cardiovascular disease, and sepsis; very young or older persons also are more susceptible. Certain medications may contribute to hypothermia, whereas others may cause reduced metabolism or clearance during hypothermia (Table 93.1).

Table 93.1

Drugs Displaying Reduced Metabolism or Clearance in Hypothermia

Atropine
Digoxin
Fentanyl
Gentamicin
Lidocaine
Phenobarbital
Procaine
Propranolol
Sulfanilamide (AVC cream)
Succinylcholine
D -Tubocurarine

Adapted from Bope ET, Kellerman RD, editors: *Conn's current therapy 2014* , Philadelphia, 2014, Elsevier/Saunders (Box 3, p 1135).

Hypothermia occurs when the body can no longer sustain normal core temperature by physiologic mechanisms, such as vasoconstriction, shivering, muscle contraction, and nonshivering thermogenesis. When shivering ceases, the body is unable to maintain its core temperature; when the body core temperature falls to <35°C (95°F), the syndrome of hypothermia occurs. Wind chill, wet or inadequate clothing, and other factors increase local injury and may cause dangerous hypothermia, even in the presence of an ambient temperature that is not <17-20°C (50-60°F).

Clinical Manifestations

Frostnip

Frostnip results in the presence of firm, cold, white areas on the face, ears, or extremities. Blistering and peeling may occur over the next 24-72 hr, occasionally leaving mildly increased hypersensitivity to cold for days or weeks. Treatment consists of warming the area with an unaffected hand or a warm object before the lesion reaches a stage of stinging or aching and before numbness supervenes. Rewarming in a water bath (40-42.2°C [104-108°F]) is effective.

Immersion Foot (Trench Foot)

Immersion foot occurs in cold weather when the feet remain in damp or wet, poorly ventilated boots. The feet become cold, numb, pale, edematous, and clammy. Tissue maceration and infection are likely, and prolonged autonomic disturbance is common. This autonomic disturbance leads to increased sweating, pain, and hypersensitivity to temperature changes, which may persist for years. Treatment includes drying the foot, gentle rewarming and nonsteroidal antiinflammatory drugs (NSAIDs) for pain. Prevention consists of using well-fitting, insulated, waterproof, nonconstricting footwear. Once damage has occurred, patients must choose clothing and footwear that are more appropriate, dry, and well fitting. The disturbance in skin integrity is managed by keeping the affected area dry and well ventilated and by preventing or treating infection. Only supportive measures are possible for control of autonomic symptoms.

Frostbite

With frostbite, initial stinging or aching of the skin progresses to cold, hard, white anesthetic and numb areas. Clear or hemorrhagic vesicles may develop over the exposed areas. On rewarming, the area becomes blotchy, itchy, and often red, swollen, and painful. The injury spectrum ranges from complete normality to extensive tissue damage, even gangrene, if early relief is not obtained.

Treatment consists of warming the damaged area. It is important not to cause further damage by attempting to rub the area with ice or snow. The area may be warmed against an unaffected hand, the abdomen, or an axilla during transfer of the patient to a facility where more rapid warming with a warm (and not hot) water bath is possible. If the skin becomes painful and swelling occurs, NSAIDs are helpful, and an analgesic agent is necessary. Freeze and rethawing cycles are most likely to cause permanent tissue injury, and it may be necessary to delay definitive warming and apply only mild measures if the patient is required to walk on the damaged feet en route to definitive treatment. In the hospital the affected area should be immersed in warm water (approximately 42°C [107.6°F]), with care taken not to burn the anesthetized skin. Broken vesicles may be debrided, but intact vesicles should be left alone. Vasodilating agents, such as prazosin and phenoxybenzamine, may be helpful. Use of anticoagulants (e.g., heparin, dextran) has had equivocal results; results of chemical and surgical sympathectomy have also been equivocal. Oxygen is of help only at high altitudes. Meticulous local care, prevention of infection, and keeping the rewarmed area dry, open, and sterile provide optimal results.

Recovery can be complete, and prolonged observation with conservative therapy is justified before any excision or amputation of tissue is considered. Analgesia and maintenance of good nutrition are necessary throughout the prolonged waiting period.

Hypothermia

Hypothermia may occur in winter sports when injury, equipment failure, or exhaustion decreases the level of exertion, particularly if sufficient attention is not paid to wind chill. Immersion in frozen bodies of water and wet wind chill rapidly produce hypothermia. As the core temperature of the body falls, insidious onset of extreme lethargy, fatigue, incoordination, and apathy occurs, followed by mental confusion, clumsiness, irritability, hallucinations, and finally, bradycardia. A number of medical conditions, such as cardiac disease, diabetes mellitus, hypoglycemia, sepsis, β-blocking agent overdose, and substance abuse, may need to be considered in a differential diagnosis. The decrease in rectal temperature to <34°C (93°F) is the most helpful diagnostic feature. Hypothermia associated with drowning is discussed in Chapter 91 .

Prevention is a high priority. Of extreme importance for those who participate in winter sports is wearing layers of warm clothing, gloves, socks within insulated boots that do not impede circulation, and a warm head covering, as well as application of adequate waterproofing and protection against the wind. Thirty percent of heat loss for infants occurs from the head. Ample food and fluid must be provided during exercise. Those who participate in sports should be alert to the presence of cold or numbing of body parts, particularly the nose, ears, and extremities, and they should review methods to produce local warming and know to seek shelter if they detect symptoms of local cold injury.

Application of petrolatum (Vaseline) to the nose and ears helps protect against frostbite.

Treatment at the scene aims at prevention of further heat loss and early transport to adequate shelter (Table 93.2). Dry clothing should be provided as soon as practical, and transport should be undertaken if the victim has a pulse. If no pulse is detected at the initial review, cardiopulmonary resuscitation is indicated (Fig. 93.1) (see Chapter 81). During transfer, jarring and sudden motion should be avoided because of the risk of ventricular arrhythmia. It is often difficult to attain a normal sinus rhythm during hypothermia.

Table 93.2

Management of Hypothermia

History and Physical Examination

Gentle handling of the patient to prevent arrhythmias
ABCDE: cardiopulmonary resuscitation for ventricular fibrillation and asystole
Underlying disease diagnosis and treatment
Vital signs, pulse oximetry, electrocardiogram
Wet or cold clothing removed and patient placed in warm environment

Laboratory Tests

Arterial blood gas analysis corrected for temperature
Electrolytes, BUN, creatinine, Ca, Mg, P
CBC with differential, PT/PTT, fibrinogen
Glucose, amylase/lipase
Liver function tests
Additional lab tests, if appropriate, such as toxicology screen

Passive Rewarming

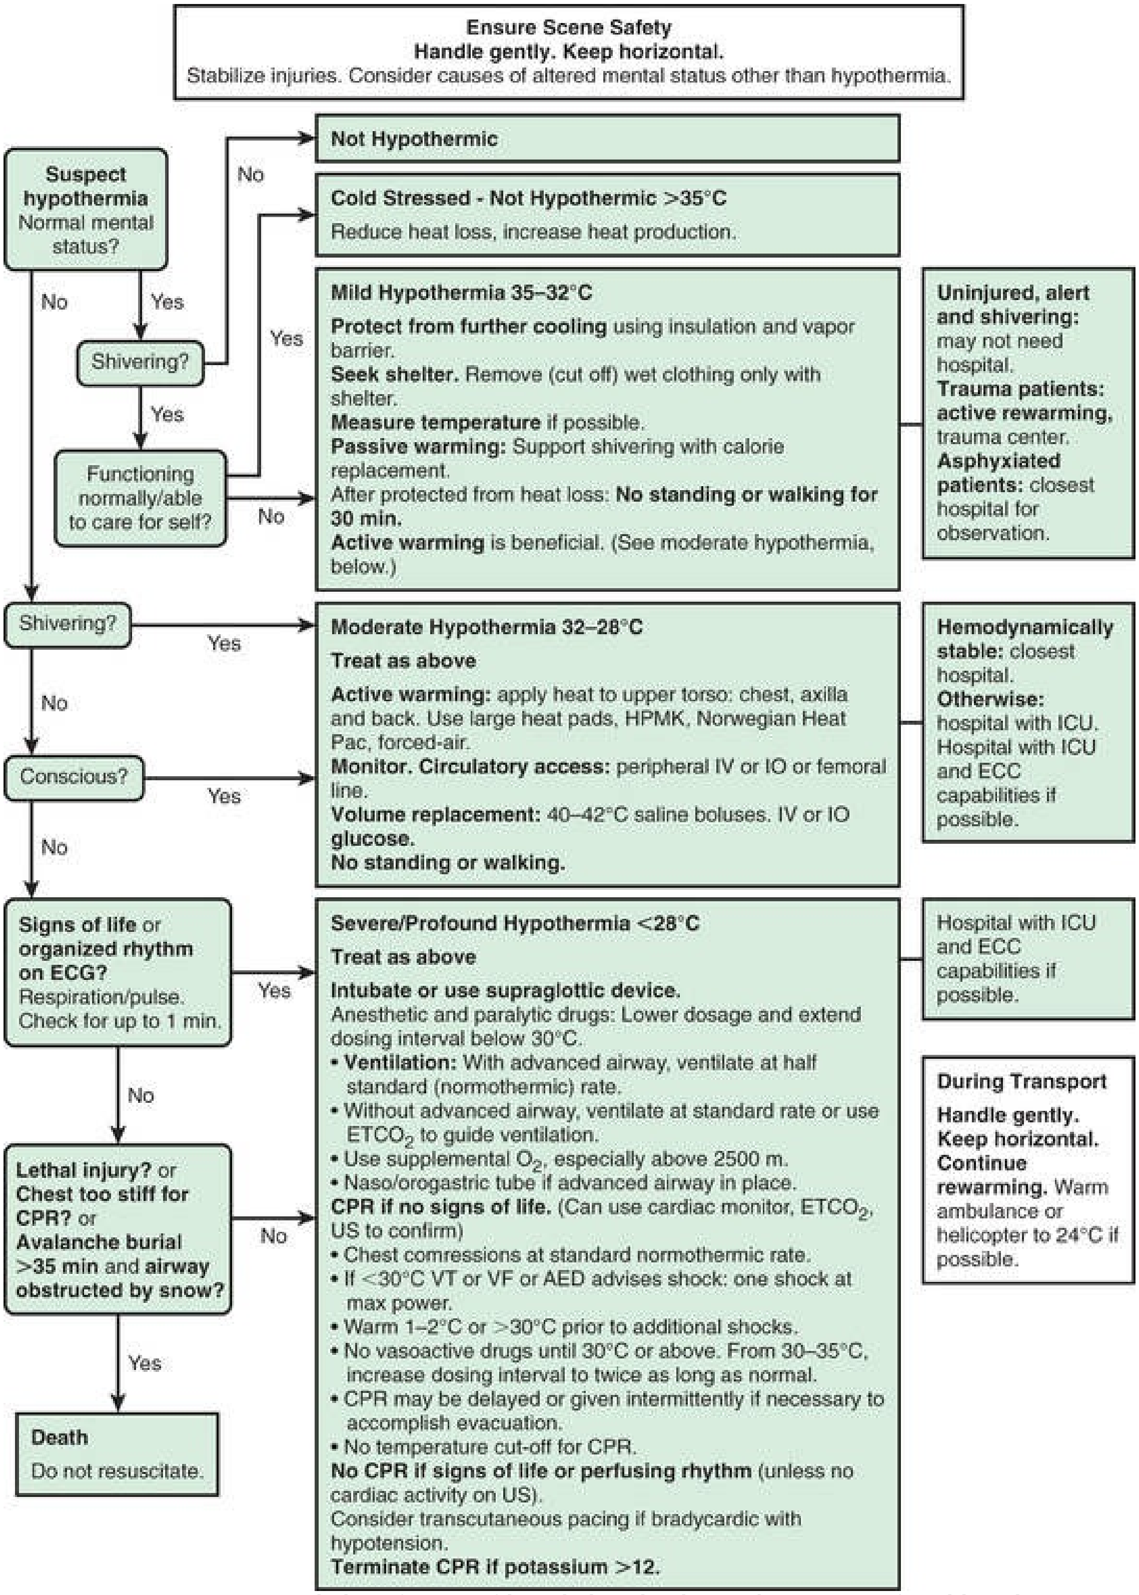
≥32°C (89.6°F) in patients who are capable of spontaneous thermogenesis

Active Rewarming

<32°C (89.6°F), cardiovascular instability, patients at risk for developing hypothermia
Close monitoring for core-temperature afterdrop
Acute: external and/or core rewarming
Chronic (<32°C [89.6°F] for >24 hr): core rewarming
Extracorporeal membrane oxygenation
Availability of rapid deployment

ABCDE, *A* irway and possibly *a* ntibiotics, *b* reathing, *c* irculation, *d* isability or neurologic and possible *d* extrose, *e* xtracorporeal support if all else fails; BUN, blood urea nitrogen; Ca, calcium; CBC, complete blood count; Mg, magnesium; P, phosphorus; PT, prothrombin time; PTT, partial thromboplastin time.

Adapted from Burg FD, Ingelfinger JR, Polin RA, Gershon AA, editors: *Current pediatric therapy*, ed 18, Philadelphia, 2006, Saunders/Elsevier (Table 4, p 174).



Suspect hypothermia
Normal mental status?
No
Yes
Shivering?
No
Yes
Functioning normally/able to care for self?
Yes
No
Shivering?
Yes
No
Conscious?
Yes
No
Signs of life or organized rhythm on ECG?
Respiration/pulse. Check for up to 1 min.
Yes
No
Lethal injury? or Chest too stiff for CPR? or Avalanche burial >35 min and airway obstructed by snow?
No
Yes
Death
Do not resuscitate.

Ensure Scene Safety
Handle gently. Keep horizontal.
Stabilize injuries. Consider causes of altered mental status other than hypothermia.

Not Hypothermic

Cold Stressed - Not Hypothermic >35°C
Reduce heat loss, increase heat production.

Mild Hypothermia 35–32°C
Protect from further cooling using insulation and vapor barrier.
Seek shelter. Remove (cut off) wet clothing only with shelter.
Measure temperature if possible.
Passive warming: Support shivering with calorie replacement.
After protected from heat loss: **No standing or walking for 30 min.**
Active warming is beneficial. (See moderate hypothermia, below.)

Uninjured, alert and shivering: may not need hospital.
Trauma patients: active rewarming, trauma center.
Asphyxiated patients: closest hospital for observation.

Moderate Hypothermia 32–28°C
Treat as above
Active warming: apply heat to upper torso: chest, axilla and back. Use large heat pads, HPMK, Norwegian Heat Pac, forced-air.
Monitor. Circulatory access: peripheral IV or IO or femoral line.
Volume replacement: 40–42°C saline boluses. IV or IO **glucose.**
No standing or walking.

Hemodynamically stable: closest hospital.
Otherwise: hospital with ICU. Hospital with ICU and ECC capabilities if possible.

Severe/Profound Hypothermia <28°C
Treat as above
Intubate or use supraglottic device.
Anesthetic and paralytic drugs: Lower dosage and extend dosing interval below 30°C.
- **Ventilation:** With advanced airway, ventilate at half standard (normothermic) rate.
- Without advanced airway, ventilate at standard rate or use $ETCO_2$ to guide ventilation.
- Use supplemental O_2, especially above 2500 m.
- Naso/orogastric tube if advanced airway in place.

CPR if no signs of life. (Can use cardiac monitor, $ETCO_2$, US to confirm)
- Chest comressions at standard normothermic rate.
- If <30°C VT or VF or AED advises shock: one shock at max power.
- Warm 1–2°C or >30°C prior to additional shocks.
- No vasoactive drugs until 30°C or above. From 30–35°C, increase dosing interval to twice as long as normal.
- CPR may be delayed or given intermittently if necessary to accomplish evacuation.
- No temperature cut-off for CPR.

No CPR if signs of life or perfusing rhythm (unless no cardiac activity on US).
Consider transcutaneous pacing if bradycardic with hypotension.
Terminate CPR if potassium >12.

Hospital with ICU and ECC capabilities if possible.

During Transport
Handle gently. Keep horizontal. Continue rewarming. Warm ambulance or helicopter to 24°C if possible.

FIG. 93.1 **Recommendations for out-of-hospital evaluation and treatment of accidental hypothermia. AED, Automatic external defibrillator; CPR, cardiopulmonary resuscitation; ECC, extracorporeal circulation; ECG, electrocardiogram; $ETCO_2$, end-tidal carbon dioxide; HPMK, Hypothermia Prevention Management Kit; ICU, intensive**

care unit; IO, intraosseous; IV, intravenous; US, ultrasound; VF, ventricular fibrillation; VT, ventricular tachycardia. (From Zafren K, Giesbrecht GG, Danzl DF, et al: Wilderness Medical Society practice guidelines for the out-of-hospital evaluation and treatment of accidental hypothermia: 2014 update, *Wilderness Environ Med* 25:S66–S85, 2014, Fig 2.)

If the patient is conscious, mild muscle activity should be encouraged and a warm drink offered. If the patient is unconscious, external warming should be undertaken initially with use of blankets and a sleeping bag; wrapping the patient in blankets or sleeping bag with a warm companion may increase the efficiency of warming. On arrival at a treatment center, while a warming bath of 45-48°C (113-118°F) water is prepared, the patient should be warmed through inhalation of warm, moist air or oxygen or with heating pads or thermal blankets. Monitoring of serum chemistry values and an electrocardiogram are necessary until the core temperature rises to >35°C (95°F) and can be stabilized. Control of fluid balance, pH, blood pressure, and arterial partial pressure of oxygen ($Pa{O_2}$) is necessary in the early phases of the warming period and resuscitation. In severe hypothermia, there may be a combined respiratory and metabolic acidosis. Hypothermia may falsely elevate pH; nonetheless, most authorities recommend warming the arterial blood gas specimen to 37°C (98.6°F) before analysis and regarding the result as one from a normothermic patient. In patients with marked abnormalities, warming measures, such as gastric or colonic irrigation with warm saline or peritoneal dialysis, may be considered, but the effectiveness of these measures in treating hypothermia is unknown. In accidental *deep hypothermia* (core temperature 28°C [82.4°F]) with circulatory arrest, rewarming with cardiopulmonary bypass may be lifesaving for previously healthy young individuals. If rewarming is not successful despite appropriate measures, one should suspect infection, drug overdose, endocrine disorders, or a futile resuscitation.

Chilblain (Pernio)

Chilblain (pernio) is a form of cold injury in which erythematous, vesicular, or ulcerative lesions occur. The lesions are presumed to be of vascular or vasoconstrictive origin. They are often itchy, may be painful, and result in swelling and scabbing. The lesions are most often found on the ears, the tips of the fingers and toes, and exposed areas of the legs. The lesions last for 1-2 wk but may persist for longer. Treatment consists of prophylaxis: avoiding prolonged chilling and protecting potentially susceptible areas with a cap, gloves, and stockings. Prazosin and phenoxybenzamine may be helpful in improving circulation if this is a recurrent problem. For significant itching, local corticosteroid preparations may be helpful.

Familial chilblain lupus , an autosomal dominant variant of lupus, is caused by mutations in the *TREX1*, *SAMHD1*, and *STING* genes. Patients develop cold-induced erythematous peripheral skin lesions and also manifest systemic disease typical of lupus (Chapter 183). In addition, fever and arthralgias may be present. Those with the *STING* mutation may develop a necrotizing acral vasculitis.

Cold-Induced Fat Necrosis (Panniculitis)

A common, usually benign injury, cold-induced fat necrosis occurs on exposure to cold air, snow, or ice and manifests in exposed (or less often covered) surfaces as red (or less often purple to blue) macular, papular, or nodular lesions. Treatment is with NSAIDs. The lesions may last 10 days to 3 wk but may persist for longer. Severe coagulopathy may be associated with poor outcome in some severe cold injuries, thus meriting anticoagulation therapy (see Chapter 680.1).

CHAPTER 94

Integration of Genetics Into Pediatric Practice

Brendan Lee

Genetic testing involves analyzing genetic material to obtain information related to a person's health status using chromosomal (cytogenetic) analysis (see Chapter 98) or DNA-based testing.

Diagnostic Testing

Diagnostic genetic testing helps explain a set of signs and symptoms of a disease. The list of disorders for which specific genetic tests are available is extensive. The website http://www.ncbi.nlm.nih.gov/gtr/ provides a database of available tests that is provider driven, so claims are not validated by the site's host, the National Institutes of Health (NIH).

Single-gene disorders can be tested by at least 3 different approaches: linkage analysis (though this is now rarely used), array comparative genomic hybridization (**aCGH**), and direct mutation analysis, usually by DNA sequencing (Table 94.1). Linkage analysis is used if the responsible gene is mapped but not yet identified, or if it is impractical to find specific mutations, usually because of the large size and larger number of different mutations in some genes. Array CGH can be used to detect large, multigene deletions or duplications (**copy number variations**). In addition, with increasing resolution, single-gene or smaller intragenic deletions or duplications can be detected by aCGH, although it is important to note that coverage of each gene may vary from different providers. *Direct DNA mutation analysis is preferred and is possible with the availability of the complete human genome sequence.* An emerging feature is the increasing recognition of oligogenic disease where more than one disease gene contributes to a complex, or “blended,” phenotype. The ability to sequence hundreds to thousands of genes at once has provided insight into this added layer of complexity in disease pathogenesis.

Table 94.1

Approaches for Genetic Testing

TYPE OF MUTATION TESTING	RESOLUTION	ADVANTAGES	DISADVANTAGES	SAMPLE REQUIREMENTS
Linkage analysis	Depends on location of polymorphic markers near putative disease gene	Possible when specific disease-causing genetic mutation is not identifiable or found	Can give only diagnostic probability based on likelihood of genetic recombination between presumed DNA mutation and polymorphic markers	Requires multiple family members with documented mendelian pattern of inheritance within family
Array comparative genomic hybridization (aCGH)	Several hundred base pairs to several hundreds of kilobases	Able to detect small deletion or duplications within 1 or more genes	Can miss small deletions or insertions depending on resolution of the array used	Single patient sample sufficient, but having sample from biological parents can help with interpretation
Direct DNA-based testing (e.g., DNA sequencing)	Single–base-pair changes	High specificity if previously described deleterious mutation is found	Can miss deletion or duplication of a segment of gene	Single patient sample sufficient, but having sample from biological parents can help with interpretation

Linkage testing involves tracking a genetic trait through a family using closely linked polymorphic markers as a surrogate for the trait (Fig. 94.1). It requires testing an extended family and is vulnerable to several pitfalls, such as genetic recombination, genetic heterogeneity, and incorrect diagnosis in the proband. **Genetic recombination** occurs between any pair of loci, the frequency being proportional to the distance between them. This problem can be ameliorated by using very closely linked markers and, if possible, using markers that flank the specific gene. **Genetic heterogeneity** can be problematic for a linkage-based test if there are multiple distinct genomic loci that can cause the same phenotype, resulting in the risk that the locus tested for is not the one responsible for disease in the family. **Incorrect diagnosis** in the proband also leads to tracking the wrong gene. Linkage testing remains useful for several genetic conditions, but it is increasingly being superseded by the availability of direct DNA sequencing of either single genes or of the whole collection of genes that encode all proteins. It is critically important that genetic counseling be provided to the family to explain the complexities of interpretation of test results.

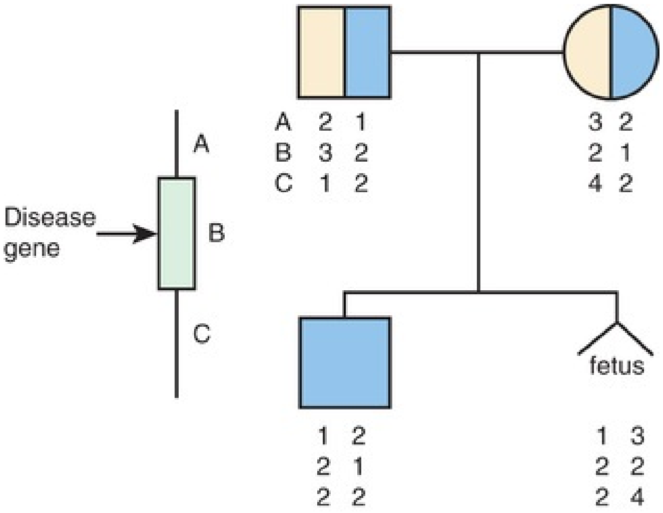

FIG. 94.1 **Use of linkage analysis in prenatal diagnosis of an autosomal recessive disorder. Both parents are carriers, and they have 1 affected son. The numbers below the symbols indicate alleles at 3 polymorphic loci: A, B, and C. Locus B resides within the disease gene. The affected son inherited the 1-2-2 chromosome from his father and the 2-1-2 chromosome from his mother. The fetus has inherited the same chromosome from the father, but the 3-2-4 chromosome from the mother and therefore is most likely to be a carrier.**

Array comparative genomic hybridization can detect copy number variation in a patient's DNA by comparing it to a standard control DNA (see Chapter 98). In so doing, aCGH provides a level of genetic resolution between that available with DNA sequencing and that available with chromosome analysis. Whereas earlier technologies could only identify large deletions or duplications that might encompass multiple genes, aCGH can resolve deletions or duplications of several kilobases within 1 gene. In theory, this approach can detect deletion and duplication mutations that would be missed by either chromosome analysis or direct mutation testing by DNA sequencing. However, because the specific resolution and coverage of different aCGH platforms can vary tremendously for different gene regions, the sensitivity for detecting deletions and duplications can vary for different diseases and laboratories. The highest resolution is what would be detection of on average deletion or duplication at the single exon level.

Direct DNA-based mutation testing avoids the pitfalls of linkage testing by detecting the specific gene mutation (i.e., sequence change). The specific approach used is customized to the biology of the gene being tested. In some disorders, 1 or a few distinct mutations occur in all affected individuals. This is the case in sickle cell anemia, in which the same single-base substitution occurs in everyone with the disorder. In other conditions, many possible mutations may account for the disorder in different individuals. In cystic fibrosis, for example, >1,000 distinct mutations have been found in the *CFTR* gene. Mutation analysis is challenging because no single technique can detect all possible mutations. However, with the completion of the human genome sequence and high-throughput DNA sequencing technology, the approach of choice is to directly sequence DNA that is generated by **polymerase chain reaction (PCR)** amplification of DNA isolated from peripheral blood white blood cells. The limitation of this approach is that only DNA that is amplified is sequenced, and usually this is restricted to the *coding* or *exonic* regions of a gene. Because mutations sometimes occur in the *noncoding intronic* regions, failure to detect a mutation does not exclude the diagnosis. Whole *genome* sequencing should identify mutations in the noncoding regions. In addition, genes in a deleted region will not be detected. Although DNA sequencing can be highly specific, it is not completely sensitive because of practical limitations of what is commercially available. Gene sequencing techniques may not be able to identify diseases caused by triplet repeat sequences; specific tests are needed.

The most useful development in clinical DNA diagnosis is application of **next-generation sequencing** technology to testing panels of genes that target disease symptoms (e.g., seizures, ataxia syndromes) or the whole exome (**whole exome sequencing [WES])** . Soon, whole genome sequencing (WGS), where both coding and noncoding sequences are identified, will provide even more information, although initial clinical interpretation will still be limited to the coding sequences of the approximately 20,000 human genes, the so-called digital exome, as it is extracted electronically from the whole genome data. The challenge is not so much the generation of DNA sequence, but the interpretation of enormous genetic variation within a single sample. Direct sequencing of tens to hundreds of genes in next-generation sequencing panels offer a potentially higher sensitivity because the “depth” of read is higher without complicating high discovery rate of **variants of unknown sequences (VUS)** . WES and WGS also offer the potential for identifying new disease-gene associations as well as phenotypes caused by more than one disease gene (i.e., oligogenic phenotypes).

An important ethical consideration is the reporting of *incidental findings,* whether medically actionable or not medically actionable in a patient. WES and WGS may identify mutations that cause aminoglycoside-sensitive hearing loss, which would be medically actionable. At the same time, the discovery of apolipoprotein E variants in a child that increase Alzheimer disease risk susceptibility may not be medically actionable. Therefore, counseling for patients undergoing these tests is important so that only wanted results are reported back to the patient. Guidelines are currently evolving for reporting of incidental findings for WES by the American College of Medical Genetics (www.acmg.net). Practice varies among institutions and recommendations vary among international genetic organizations about the approach for revealing incidental findings from WES/WGS to patients; many leave the choice up to the patient and family. Most require revealing to the patient and/or family significant diseases (actionable) with a specific and successful treatment or prevention strategy (Table 94.2).

Table 94.2

Variants That Are Incidental Findings Are Assigned to 1 of 4 Categories

Childhood onset	Medically actionable*
Childhood onset	Not medically actionable †
Adult onset	Medically actionable*
Adult onset	Not medically actionable †

* “Medically actionable” refers to a variant in a gene in which knowledge of the particular variant will affect medical decision-making, such as initiation of a treatment or family planning.

† “Not medically actionable” refers to variants that increase the individual's risk for a disease in which no treatment is proven to significantly change medical decision-making.

From Bick D, Dimmock D: Whole exome and whole genome sequencing. *Curr Opin Pediatr* 23:594–600, 2011.

Genetic testing is interpreted by 3 factors: analytic validity, clinical validity, and clinical utility. **Analytical validity** is test accuracy: Does the test correctly detect the presence or absence of mutation? Most genetic tests have a very high analytical validity, assuming that human error, such as sample mix-up, has not occurred. Human errors are possible, and unlike most medical tests, a genetic test is unlikely to be repeated, because it is assumed that the result will not change over time. Therefore, human errors can go undetected for long periods of time. However, it may be reinterpreted over time as our knowledge base of what are disease-causing mutations and genes increases over time.

Clinical validity is the degree to which the test correctly predicts presence or absence of disease. False-positive and false-negative test results can occur.

False-positive results are more likely for predictive tests than for diagnostic tests. An important contributing factor is **nonpenetrance** : an individual with an at-risk genotype might not clinically express the condition. Another factor is the finding of a **genetic variant of unknown significance** (VUS). Detection of a base sequence variation in an affected patient does not prove that it is the cause of the patient's disorder. In WES there may be more than 30,000 VUS; in WGS there may be more than 3,000,000 VUS. Various lines of evidence are used to establish pathogenicity. These include finding the variant only in affected individuals, inferring that the variant alters the function of the gene product, determining whether the amino acid altered by the mutation is conserved in evolution, and determining whether the mutation segregates with disease in the family. In some cases, it is possible to be certain whether the variant is pathogenic or incidental, but in other cases it might be impossible to definitively assign causality with 100% confidence.

False-negative results reflect an inability to detect a mutation in an affected patient. This occurs principally in disorders where genetic heterogeneity—**allelic** (different mutations occur in 1 causative gene) or **locus** (>1 gene can cause a disease) heterogeneity—is the rule. It is difficult to detect all possible mutations within a gene, because mutations can be varied in location within the gene and in the type of mutation. Direct sequencing may miss gene deletions or rearrangements (i.e. structural variants), and mutations may be found within noncoding sequences such as introns or the promoter; a negative DNA test does not necessarily exclude a diagnosis.

Clinical utility is the degree to which the results of a test guide clinical management. For genetic testing, clinical utility includes establishing a diagnosis that obviates the need for additional workup or guiding surveillance or treatment. Test results may also be used as a basis for genetic counseling. For some disorders, genetic testing is possible, but the test results do not add to the clinical assessment. If the diagnosis and genetic implications are already clear, it might not be necessary to pursue genetic testing.

Predictive Testing

Predictive genetic testing involves performing a test in a person who is at risk for developing a genetic disorder (**presymptomatic**), usually on the basis of family history, yet who does not manifest signs or symptoms. This is usually done for disorders that display age-dependent penetrance; the likelihood of manifesting signs and symptoms increases with age, as in cancer or Huntington disease.

A major caution with predictive testing is that the presence of a gene mutation does not necessarily mean that the disease will develop. Many of the disorders with age-dependent penetrance display *incomplete penetrance* . A person who inherits a mutation might never develop signs of the disorder. There is concern that a positive DNA test could result in stigmatization of the person and might not provide information that will guide medical management. Stigmatization might include psychological stress, but it could also include discrimination, including denial of health, life, or disability insurance, or employment (see Chapter 95).

It is generally agreed that predictive genetic tests should be performed for children only if the results of the test will benefit the medical management of the child. Otherwise, the test should be deferred until the child has an understanding of the risks and benefits of testing and can provide informed consent. Individual states offer varying degrees of protection from discrimination on the basis of genetic testing. A major milestone in the prevention of genetic discrimination was the passage of the **Genetic Information Nondiscrimination Act** (GINA) in 2008, which is a U.S. federal law that prohibits discrimination in health coverage or employment based on genetic information; *it does not* protect against refusal of life insurance.

Predispositional Testing

It is expected that genetic tests will become available that will predict risk of disease. Common disorders are multifactorial in etiology; many different genes may contribute to risk of any specific condition (see Chapter 99). Most of the genetic variants that have been found to correlate with risk of a common disease add small increments of relative risk, probably in most cases too little to guide management. It is possible that further discovery of genes that contribute to common disorders will reveal examples of variants that convey more significant levels of risk. It is also possible that testing several genes together will provide more information about risk than any individual gene variant would confer.

The rationale for predispositional testing is that the results would lead to strategies aimed at risk reduction as part of a *personalized approach* to healthcare maintenance. This might include avoidance of environmental exposures that would increase risk of disease (cigarette smoking and α_1 -

antitrypsin deficiency), medical surveillance (familial breast cancer and mammography), or in some cases, pharmacologic treatment (statins and hypercholesterolemia). The value of predispositional testing will need to be critically appraised through outcomes studies as these tests are developed.

Pharmacogenetic Testing

Polymorphisms in drug metabolism genes can result in distinctive patterns of drug absorption, metabolism, excretion, or effectiveness (see Chapters 72 and 99). Knowledge of individual genotypes will guide pharmacologic therapy, allowing customization of choice of drug and dosage to avoid toxicity and provide a therapeutic response. An example is testing for polymorphisms within the methylenetetrahydrofolate reductase (*MTHFR*) gene for susceptibility of potentially increased toxicity to methotrexate antimetabolite therapy for acute lymphoblastic leukemia.

94.1

Genetic Counseling

Brendan Lee, Pilar L. Magoulas

Genetic counseling is a communication process in which the genetic contribution to health, specific risks of transmission of a trait, and options to manage the condition are explained to individuals and their family members (Table 94.3). Genetic counselors are specialized healthcare providers trained in the psychosocial aspects of counseling and the science of medical genetics who may serve as members of medical teams in many different specialties. The genetic counselor is expected to present information in a neutral, nondirective manner while providing resources and psychosocial support to the individual and family to cope with decisions that are made.

Table 94.3

Indications for Genetic Counseling

- Advanced parental age
    - Maternal age ≥35 yr
    - Paternal age ≥40 yr
- Previous child with or family history of:
    - Congenital abnormality
    - Dysmorphology
    - Intellectual disability
    - Isolated birth defect
    - Metabolic disorder
    - Chromosome abnormality
    - Single-gene disorder
- Adult-onset genetic disease (presymptomatic testing)
    - Cancer
    - Huntington disease
- Pharmacogenomics
- Consanguinity
- Teratogen exposure (occupational, abuse)
- Repeated pregnancy loss or infertility
- Pregnancy screening abnormality
    - Maternal serum α-fetoprotein
- Maternal 1st-trimester screen
    - Maternal triple or quad screen or variant of this test
    - Fetal ultrasonography
- Noninvasive prenatal testing (NIPT)
    - Fetal karyotype
- Heterozygote screening based on ethnic risk
    - Sickle cell anemia
    - Tay-Sachs, Canavan, and Gaucher diseases
    - Thalassemias
- Universal carrier screening panels
- Follow-up to abnormal neonatal genetic testing
- Prior to whole genome or exome sequencing
- Prior to preimplantation genetic testing

Genetic counseling has evolved from a model of care that was developed in the context of prenatal diagnosis and pediatrics into a multidisciplinary approach to medicine that factors into all aspects of healthcare (Table 94.3). In the prenatal setting, a common indication for genetic counseling is to assess risk of occurrence or recurrence of having a child with a genetic condition and to discuss management or treatment options that might be available before, during, or after the pregnancy, such as preimplantation genetic diagnosis, prenatal diagnosis or fetal intervention, and perinatal management. In pediatrics and adult genetics practices, the goals of genetic counseling are to help establish a diagnosis in an individual, provide longitudinal care and psychosocial support to the family, and discuss the genetic basis and inheritance of the condition as it relates to immediate and distant family members.

The genetic counseling role has expanded, particularly with advances in understanding the genetics of adult-onset or common and rare disease therapeutics. In the former context, genetic counseling has a major role in risk assessment for cancer, especially breast, ovarian, or colon cancer, for which well-defined risk models and genetic tests are available to assess risk to an individual. In the latter, the genetic counselor may discuss developments in rare disease therapeutics and make appropriate referral for medical therapies.

Talking to Families

The type of information provided to a family depends on the urgency of the situation, the need to make decisions, and the need to collect additional information. There are 4 situations in which genetic counseling plays a particularly important role in this process.

The 1st situation is the **prenatal diagnosis** of a congenital anomaly or genetic disease. The need for information is urgent because a family must often make time-sensitive decisions about treatment and management options, such as fetal intervention or continuation of a pregnancy in the context of fetal anomalies. Risks to the mother must also be considered. The 2nd type of situation occurs when a child is born with a life-threatening **congenital anomaly** or suspected **genetic disease** . Decisions must be made immediately with regard to how much support should be provided for the child and whether certain types of therapy should be attempted. The 3rd situation arises when there are concerns about a **genetic condition** affecting one later in life. For example, this may occur in an adolescent or young adult with a family history of an adult-onset genetic disorder (e.g., Huntington disease, hereditary breast/ovarian cancer), in an individual with a suspected yet undiagnosed genetic condition, or if a couple with a personal or family history of a genetic condition (or a carrier) is planning a family. In these situations it is often necessary to have several meetings with a family to discuss possible testing, screening, and management options. Urgency is not as much of an issue as being sure that they have as much information and as many options as are available. The 4th situation is **genetic counseling** before genome sequencing, where the family is given options of what they want reported back to them (actionable/nonactionable incidental findings vs a specific diagnosis).

Genetic Counseling

Providing accurate information to families requires the following:

- Taking a careful family history and constructing a pedigree that lists the patient's relatives (including miscarriages, abortions, stillbirths, deceased persons) with their sex, age, ethnicity, and state of health, up to and including third-degree relatives.
- Gathering information from hospital records about the affected individual and, in some cases, about other family members.
- Documenting prenatal, pregnancy, and delivery histories.
- Reviewing the latest available medical, laboratory, and genetic information concerning the disorder.
- Performing a careful physical examination of the affected individual (photographs, measurements) and of apparently unaffected individuals in the family

(this is usually performed by a physician rather than a genetic counselor).

◆ Establishing or confirming the diagnosis by the diagnostic tests available.

◆ Giving the family information about support groups and local and national resources.

◆ Providing new information to the family as it becomes available (a mechanism for updating needs to be established).

Counseling sessions must include the specific condition, knowledge of the diagnosis of the particular condition, natural history of the condition, genetic aspects of the condition and risk of recurrence, prenatal diagnosis and reproductive options, therapies and referrals, support groups, and nondirective counseling.

Specific Condition or Conditions

If a specific diagnosis is made and confirmed, this should be discussed with the family and information provided in writing. Often, however, the disorder fits into a spectrum (e.g., one of many types of arthrogryposis) or the diagnosis is clinical rather than laboratory based. In these situations the family needs to understand the limits of present knowledge, and that additional research will probably lead to better information in the future.

Knowledge of the Diagnosis of the Particular Condition

Although it is not always possible to make an exact diagnosis, having a diagnosis *as accurate as possible* is important. Estimates of recurrence risk for various family members depend on an accurate diagnosis, that considers the likelihood that a particular finding is isolated, associated with a syndrome, or nonsyndromic (e.g., isolated cleft lip and palate). When a specific diagnosis cannot be made (as in many cases of multiple congenital anomalies), the various possibilities in the differential diagnosis should be discussed with the family and empirical information provided. If available, specific diagnostic tests should be discussed. Often, empirical recurrence risks can be given even without a specific laboratory-based diagnosis. At the same time, even negative laboratory testing can further modify this risk.

Natural History of the Condition

It is important to discuss the natural history of the specific genetic disorder in the family. Affected persons and their families have questions regarding the prognosis and potential management or therapy that can be answered only with knowledge of the natural history. If there are other possible diagnoses, their natural history may also be discussed. If the disorder is associated with a spectrum of clinical outcomes or complications, the range of possible outcomes and variability of the condition, as well as treatment and referral to the appropriate specialist, should be addressed.

Genetic Aspects of the Condition and Recurrence Risk

The genetic aspects and risk of recurrence are important because all family members should be informed of their reproductive choices. The genetic basis of the disorder can be explained with visual aids (e.g., diagrams of chromosomes and inheritance patterns). It is important to provide accurate occurrence and recurrence risks for various members of the family, including unaffected individuals. If a definite diagnosis cannot be made, it is necessary to use empirical recurrence risks. Genetic counseling gives patients the necessary information to understand the various options and to make their own informed decisions regarding pregnancy, adoption, artificial insemination, prenatal diagnosis, screening, carrier detection, or termination of pregnancy. It may be necessary to have more than one counseling session.

Prenatal Diagnosis and Prevention

Many different methods of prenatal diagnosis are available, depending on the specific genetic disorder (see Chapter 115). The use of ultrasonography allows prenatal screening of anatomic abnormalities such as congenital heart defects. Amniocentesis and chorionic villus sampling are used to obtain fetal tissue for analysis of chromosomal abnormalities, biochemical disorders, and DNA studies. Maternal blood or serum sampling is used for some types of screening, including noninvasive prenatal screening by direct analysis of fetal DNA fragments found in maternal blood. This has gained widespread use for screening of conditions such as trisomy 21. In addition, this source of cell free fetal DNA has also been used clinically for DNA sequencing for dominant de novo conditions in the fetus that may occur with increased frequency with increasing paternal age. In the research arena, intact fetal cells can also be retrieved from maternal blood (though this is not yet readily available compared to free fetal DNA) for testing, and this may potentially offer higher resolution testing including whole exome or whole genome testing. Importantly, current tests of fetal DNA from maternal blood should be considered screening tests, and invasive testing like amniocentesis or chorionic villus sampling should be considered for confirmatory diagnostic testing.

Therapies and Referral

A number of genetic disorders require the care of multiple specialists. Many genetic conditions now have diagnosis and management guidelines to aid in the treatment and management of these complex patients. Prevention of known complications is a priority, so close follow-up with the necessary specialists involved in the child's care is essential to identify any potentially concerning issues early. The psychological adjustment of the family might also require specific intervention. Some challenges may involve when to discuss the diagnosis of a chronic disease with the patient, siblings, and other family members or friends. The decision to do so should always involve the parents and an assessment of the maturity and capacity of the child or adolescent.

Alternative medicines or nontraditional therapies are often brought to attention by parents after exhaustive internet searches. Such treatments should not necessarily be dismissed out of hand because the physician and genetic counselor should serve as an important resource for helping parents navigate the maze of nonstandard treatments. Instead, the relative merits of treatments should be framed in the context of cost and benefit, scientific rationale, evidence from controlled and observational studies, the placebo effect, safety of the treatment, and the gaps in our own scientific knowledge base.

Support Groups

A large number of community and online lay support groups have been formed to provide information and to fund research on specific genetic and nongenetic conditions. An important part of genetic counseling is to give information about these groups to patients and to suggest a contact person for the families. Many groups have established websites with very helpful information. With the rise of social media and its ability to connect families with rare syndromes from around the world, it is important to stress to families that their individual disease course will be unique.

Follow-up

Families should be encouraged to continue to ask questions and keep up with new information about the specific disorder. New developments often influence the diagnosis and therapy of specific genetic disorders. Lay support groups are a good source of new information.

Nondirective Counseling

Genetic counseling is usually nondirective; choices about reproduction are left to the family to decide what is right for them. The role of the counselor (physician, genetic counselor, nurse, medical geneticist) is to provide information in understandable terms and outline the range of options available.

94.2

Management and Treatment of Genetic Disorders

Brendan Lee, Nicola Brunetti-Pierri

Genetic conditions are often chronic disorders; few are amenable to curative therapies, although there has been a rapid increase in the number available in recent years. All patients and families should be provided information about the disorder, genetic counseling, anticipatory guidance, and appropriate medical surveillance. Surgical management is available for many conditions that are associated with congenital anomalies or predisposition to tumors.

Resources for patients include the National Organization of Rare Disorders (www.rarediseases.org), the Genetic Alliance (www.geneticalliance.org), the National Library of Medicine (www.nlm.nih.gov/medlineplus/geneticdisorders.html), and a large number of disease-specific websites. A current listing of federally and privately funded clinical trials, including many for genetic diseases, is available at www.ClinicalTrials.gov .

Specific medical therapies for genetic disorders can be classified into physiologic and replacement therapies. Another approach corrects protein misfolding induced by missense mutations through use of small molecules that specifically bind to mutant proteins stabilizing their conformation, thereby preventing early degradation and allowing proper cellular trafficking and localization. This strategy has found successful applications for therapy of cystic fibrosis caused by specific *CFTR* mutations, including the F508del (see Chapter 432).

Physiologic Therapies

Physiologic therapies attempt to ameliorate the phenotype of a genetic disorder by modifying the physiology of the affected individual. The underlying defect itself is not altered by treatment. Physiologic therapies are used in the treatment of **inborn errors of metabolism** (see Chapter 102). These include dietary manipulation, such as avoiding phenylalanine by persons with phenylketonuria; coenzyme supplementation for some patients with methylmalonic acidemia and mitochondrial diseases; stimulation of alternative pathways to excrete ammonia for those with urea cycle disorders; phototherapy to increase excretion of neurotoxic unconjugated bilirubin in Crigler-Najjar syndrome; bisphosphonate treatment for those with osteogenesis imperfecta to reduce bone fractures; and avoiding cigarette smoking by persons with α_1 -antitrypsin deficiency or specific foods and drugs by persons with glucose-6-phosphate dehydrogenase deficiency or acute intermittent porphyria. Physiologic treatments can be highly effective, but they usually need to be maintained for a lifetime because they do not affect the underlying genetic disorder. Many of these treatments are most effective when begun early in life, before irreversible damage has occurred. This is the rationale for comprehensive newborn screening for inborn errors of metabolism.

Many physiologic therapies use small-molecule pharmaceuticals (e.g., to remove ammonia in those with urea cycle disorders). **Pharmacologic treatments** directly target a defective cellular pathway that is altered by an abnormal or a missing gene product. However, there are relatively few such therapies. One example is the inhibition of an enzyme reaction that is upstream of the deficient enzyme, to prevent accumulation of the toxic metabolites, such as the nitisinone (NTBC) for therapy of tyrosinemia type I. A similar approach focuses on partially reducing the synthesis of the substrate of the mutant enzyme or its precursors in lysosomal storage disorders (see Chapter 104.4).

Replacement Therapies

Replacement therapies include replacement of a missing metabolite, an enzyme, an organ, or even a specific gene.

Enzyme Replacement

Enzyme replacement therapy is a component of the treatment of cystic fibrosis to manage intestinal malabsorption. Pancreatic enzymes are easily administered orally, because they must be delivered to the gastrointestinal tract. Recombinant alkaline phosphatase coupled to bone targeting motif is available for intravenous therapy of hypophosphatasia, a skeletal disorder caused by alkaline-phosphatase deficiency.

Enzyme replacement strategies are effective for several lysosomal storage disorders. Enzymes are targeted for the lysosome by modification with mannose-6-phosphate, which binds to a specific receptor. This receptor is also present on the cell surface, so lysosomal enzymes with exposed mannose-6-phosphate residues can be infused into the blood and are taken into cells and transported to lysosomes. Enzyme replacement therapies are available for Gaucher disease and Fabry disease, some mucopolysaccharidoses (MPS I, II, IVA, VI), acid lipase deficiency, and Pompe disease, and are being tested for MPS IIIA, MPS VII, metachromatic leukodystrophy, α-mannosidosis, Niemann-Pick disease type B, and neuronal ceroid lipofuscinosis, late infantile (CLN2). Other examples include enzyme replacement therapy for hypophosphatasia.

One complication of enzyme replacement therapy is antibody response to the infused recombinant enzyme. The magnitude of this response is not always predictable and varies depending on the enzyme preparation and the disease. In most cases, the patient's antibody response does not affect the treatment's efficacy (e.g., Gaucher disease), but in other situations it may be a significant hurdle (e.g., Pompe disease and phenylketonuria).

Transplantation

Cell transplantation and **organ transplantation** are potentially effective approaches to replacement of a defective gene. Aside from transplantation to replace damaged tissues, transplantation of stem cells, liver, or bone marrow is also used for several diseases, mainly inborn errors of metabolism, and hematologic or immunologic disorders. A successful transplant is essentially curative, although there may be significant risks and side effects (see Chapters 161-165). Cell and tissue transplantation is effective in many clinical scenarios, but there is always short-term morbidity, often associated with either surgical (liver) or preparative (bone marrow) regimens, and long-term morbidity related to chronic immunosuppression and graft failure. Bone marrow transplantation is the best example of stem cell therapy, but much effort also is focused on identifying, characterizing, expanding, and using other tissue stem cells for regenerative therapies.

Alternatively, research has focused on replacing a defective gene (**gene therapy**). In theory, if one can target the specific tissue that has a deficiency in the gene or gene product, this can offer a less invasive means of achieving a cure for a genetic disorder. Ultimately, gene therapy depends on the unique interaction of the disease pathophysiology, which is specific to the patient, and the gene delivery vehicle.

Gene-transfer vehicles include viral and nonviral vectors administered through ex vivo or in vivo approaches. In ex vivo approaches the patient's cells are removed and after gene correction are infused into the patient. An example of this is the FDA approved CAR-T cell therapy for non-Hodgkin lymphoma. In the in vivo approaches the gene therapy vector is directly injected into the body by either systemic (e.g., intravenous) or localized (e.g., intramuscular, intracerebral, intraocular) injections. Most human clinical trials have used viral vectors because of their efficiency of tissue transduction. In some diseases, such as X-linked and adenosine deaminase–deficient severe combined immunodeficiency, chronic granulomatous disease, and Wiskott-Aldrich syndrome, clinical gene therapy is a viable and effective option (see Chapter 152.1). Ex vivo gene transfer of hematopoietic stem cells can now be considered at least as effective to allogenic hematopoietic stem cells transplantation in presymptomatic patients with X-linked adrenoleukodystrophy and metachromatic leukodystrophy. In vivo gene therapy is also promising for Leber congenital amaurosis by intraocular delivery, lipoprotein lipase deficiency by intramuscular injections, and hemophilia B by systemic intravenous injection. The first ever human in vivo gene therapy was recently approved in the United States by the FDA for treatment of a specific RPE65-deficient form of retinitis pigmentosa using adenoassociated virus (AAV)-mediated expression of the normal RPE65 gene via intraretinal injection.

Gene editing with direct correction of a pathologic mutation is a possible approach to genetic therapy. **CRISPR/Cas9** (clustered regularly interspaced short palindromic repeats/CRISPR-associated system) is a mechanism that permits permanent gene modification of genes in cells. CRISPR genes are bacterial DNA sequences used as a defense mechanism to destroy DNA from viral infections. Combined with related Cas nuclease proteins, the foreign RNA or DNA is recognized, excised, and digested. In gene editing, a complex of the nuclease enzyme and a complementary RNA sequence recognizes the base sequence in the mutated gene. Once bound to the targeted sequence, the nuclease excises both strands and inserts the corrected (nonmutated) sequence. The CRISPR system has corrected the gene defect in a mouse model of Duchenne muscular dystrophy and reduced the tumor burden in explanted human prostate cancer cells in mice. CRISPR-edited T cells can be modified to target and kill tumor cells. CRISPR/Cas9 has been employed to correct the mutation in *MYBPC3* (hypertrophic cardiomyopathy) in an experimental human embryo model. Clinical trials are now in progress applying this approach in somatic tissue. Currently, germline and/or embryonic gene editing studies in humans have not been approved.

Prevention of genetic disease has been accomplished by **preimplantation genetic diagnosis** . This procedure requires in vitro fertilization and single–embryo cell genetic testing of the known families' mutation and is performed with PCR amplification of the affected gene. To avoid recurrent disease, only the unaffected embryos are used for implantation.

In addition, mitochondrial DNA mutations may be avoided by using **mitochondrial replacement therapies** . In one technique the mutation carrier mother's nuclear DNA is removed from the unfertilized oocyte and transferred to the unaffected mitochondrial donor oocyte (minus that cell's nuclear DNA). In another approach the pronucleus from the mutation-carrier mother's fertilized oocyte is transferred to the unaffected mitochondrial donor's fertilized oocyte (minus the pronucleus).

These different and promising methodologies have many technical and ethical considerations that are being discussed by medical, ethical, legal, and policymaking organizations.

CHAPTER 95

The Genetic Approach in Pediatric Medicine

Daryl A. Scott, Brendan Lee

Since the completion of the Human Genome Project, we have seen an unprecedented expansion in our understanding of how human health is impacted by variations in genomic sequence and **epigenetic** , non-sequence-based, changes that affect gene expression. This period has also seen the development and implementation of new clinical tests that have made it easier for physicians to detect such changes. In addition, there has been a dramatic increase in the availability of information about the genetic aspects of pediatric diseases, particularly on the internet (Table 95.1).

The Burden of Genetic Disorders in Childhood

Medical problems associated with genetic disorders can appear at any age, with the most obvious and serious problems typically manifesting in childhood. It has been estimated that 53/1,000 children and young adults can be expected to have diseases with an important genetic component. If congenital anomalies are included, the rate increases to 79/1,000. In 1978 it was estimated that just over half of admissions to pediatric hospitals were for a genetically determined condition. By 1996, because of changes in healthcare delivery and a greater understanding of the genetic basis of many disorders, that percentage rose to 71%, in one large pediatric hospital in the United States, with 96% of chronic disorders leading to admission having an obvious genetic component or being influenced by genetic susceptibility.

Major categories of genetic disorders include single-gene, genomic, chromosomal, and multifactorial conditions.

Individually, each **single-gene disorder** is rare, but collectively they represent an important contribution to childhood disease. The hallmark of a single-gene disorder is that the phenotype is overwhelmingly determined by changes that affect an individual gene. The phenotypes associated with single-gene disorders can vary from one patient to another based on the severity of the change affecting the gene and additional modifications caused by genetic, environmental, and stochastic factors. This feature of genetic disease is termed **variable expressivity** . Common single-gene disorders include sickle cell anemia and cystic fibrosis. Some identifiable syndromes and diseases can be caused by more than one gene (e.g., Noonan syndrome by *RAF1*, *NF1*, *NRAS*, *PTPN11*, *SOS1*, *SOS2*, *KRAS*, *BRAF*, *SOC2*, *LZTR1*, and *RIT1*). In addition, mutations affecting a single gene may produce different phenotypes (e.g., *SCN5A* and Brugada syndrome, long QT syndrome 3, dilated cardiomyopathy, familial atrial fibrillation, and congenital sick sinus syndrome).

Single-gene disorders tend to occur when changes in a gene have a profound effect on the *quantity* of the gene product produced, either too much or too little, or the *function* of the gene product, either a loss of function or a harmful gain of function. Single-gene disorders can be caused by de novo sequence changes that are not found in the unaffected parents of the affected individual, or they may be caused by inherited changes. When a single-gene disorder is known to be caused by changes in only 1 gene, or a small number of individual genes, searching for deleterious changes is most often performed by directly sequencing that gene and, in some cases, looking for small deletions and/or duplications. When multiple genes can cause a particular disorder, it is sometimes more efficient and cost-effective to screen large numbers of disease-causing genes using a disease-specific panel that takes advantage of next-generation sequencing technology than to screen genes individually. When such panels are not available, or when the diagnosis is in question, physicians may consider screening the protein-coding regions of all genes by **whole exome sequencing (WES)** on a clinical basis. In many circumstances, WES is less expensive than sequencing multiple individual genes. In the future, **whole genome sequencing** , in which an individual's entire genome is sequenced, may become a valid clinical option as the cost of such tests fall and our ability to interpret the clinical consequences of the thousands of changes identified in such tests improves (see Chapter 94).

The risk of having a child with a particular single-gene disorder can vary from one population to another. In some cases, this is the result of a **founder effect** , in which a specific change affecting a disease-causing gene becomes relatively common in a population derived from a small number of founders. This high frequency is maintained when there is relatively little interbreeding with persons outside that population because of social, religious, or physical barriers. This is the case for Tay-Sachs disease in Ashkenazi Jews and French Canadians. Other changes may be subject to **positive selection** when found in the heterozygous carrier state. In this case, individuals who carry a single copy of a genetic change (**heterozygotes**) have a survival advantage over noncarriers. This can occur even when individuals who inherit 2 copies of the change (**homozygotes**) have severe medical problems. This type of positive selection is evident among individuals in sub-Saharan Africa who carry a single copy of a hemoglobin mutation that confers relative resistance to malaria but causes sickle cell anemia in homozygotes.

Genomic disorders are a group of diseases caused by alterations in the genome, including **deletions** (copy number loss), **duplications** (copy number gain), **inversions** (altered orientation of a genomic region), and **chromosomal**

rearrangements (altered location of a genomic region). **Contiguous gene disorders** are caused by changes that affect 2 or more genes that contribute to the clinical phenotype and are located near one other on a chromosome. DiGeorge syndrome, which is caused by deletions of genes located on chromosome 22q11, is a common example. Some genomic disorders are associated with distinctive phenotypes whose pattern can be recognized clinically. Other genomic disorders do not have a distinctive pattern of anomalies but can cause developmental delay, cognitive impairment, structural birth defects, abnormal growth patterns, and changes in physical appearance. **Fluorescent in situ hybridization (FISH)** can provide information about the copy number and location of a specific genomic region. **Array-based copy number detection assays** can be used to screen for chromosomal deletions (large and small) and duplications across the genome, but do not provide information about the orientation or location of genomic regions. A **chromosome analysis (karyotype**) can detect relatively large chromosomal deletions and duplications and can also be useful in identifying inversions and chromosomal rearrangements even when they are **copy number neutral** changes that do not result in a deletion or duplication of genomic material.

Deletions, duplications, and chromosomal rearrangements that affect whole chromosomes, or large portions of a chromosome, are typically referred to as **chromosomal disorders** . One of the most common chromosomal disorders is Down syndrome, most often associated with the presence of an extra copy, or **trisomy** , of an entire chromosome 21. When all or a part of a chromosome is missing, the disorder is referred to as **monosomy** . **Translocations** are a type of chromosomal rearrangement in which a genomic region from one chromosome is transferred to a different location on the same chromosome or on a different (nonhomologous) chromosome. Translocations can be *balanced,* meaning that no genetic material has been lost or gained, or they can be *unbalanced,* in which some genetic material has been deleted or duplicated.

In some cases, only a portion of cells that make up a person's body are affected by a single-gene defect, a genomic disorder, or a chromosomal defect. This is referred to as **mosaicism** and indicates that the individual's body is made up of 2 or more distinct cell populations.

Polygenic disorders are caused by the cumulative effects of changes or variations in more than 1 gene. **Multifactorial** disorders are caused by the cumulative effects of changes or variations in multiple genes and/or the combined effects of both genetic and environmental factors. Spina bifida and isolated cleft lip or palate are common birth defects that display multifactorial inheritance patterns. Multifactorial inheritance is seen in many common pediatric disorders, such as asthma and diabetes mellitus. These traits can cluster in families but do not have a mendelian pattern of inheritance (see Chapter 97). In these cases the genetic changes or variations that are contributing to a particular disorder are often unknown, and genetic counseling is based on empirical data.

The Changing Paradigm of Genetics in Medicine

Genetic testing is increasingly available for a wide variety of both rare and relatively common genetic disorders. Genetic testing is typically used in pediatric medicine to resolve uncertainty regarding the underlying etiology of a child's medical problems and provides a basis for improved genetic counseling and possibly a specific therapy. Even in cases where a specific treatment is not available, identifying a genetic cause can aid physicians in providing individuals and family with accurate prognostic and recurrence risk information and usually helps to relieve unfounded feelings of guilt and stem the tide of misdirected blame.

Genetic tests will ultimately come to underlie a high proportion of medical decisions and will be seamlessly incorporated into routine medical care. Although most genetic testing is presently aimed at identifying or confirming a diagnosis, in the future, genetic testing may find wider application as a means of determining if an individual is predisposed to develop a particular disease. Another area in which genetic testing could make a significant impact is on individualized drug treatment. It has long been known that genetic variation in the enzymes involved in drug metabolism underlies differences in the therapeutic effect and toxicity of some drugs. As the genetic changes that underlie these variations are identified, new genetic tests are being developed that allow physicians to tailor treatments based on individual variations in drug metabolism, responsiveness, and susceptibility to toxicity (see Chapter 72). It is likely that the expansion of such testing will depend, at least in part, on the extent to which such tests can be linked to strategies to prevent disease or improve outcome (see Chapter 94). As such links are made, we will enter into a new era of personalized medical treatment.

Long-standing and highly successful carrier screening programs have existed for disorders such as Tay-Sachs disease and many other rare, single-gene disorders that are prevalent in specific populations. Couples are usually offered screening for a variety of conditions, in part based on ancestry (Tay-Sachs disease, hemoglobinopathies, cystic fibrosis). Couples found to be at increased risk for such disorders can be offered preconception or prenatal testing aimed at detecting specific disease-causing mutations.

Prenatal screening is routinely offered for chromosomal disorders such as trisomy 13, trisomy 18, and Down syndrome. An increasing number of pregnancies affected by these and other genetic disorders are being recognized by noninvasive screening tests targeting fetal cell-free DNA in maternal blood and by fetal ultrasound. When genetic disorders are suspected, chorionic villus sampling at 10-12 wk of gestation or amniocentesis at 16-18 wk of gestation can provide material for genetic testing. When a couple are at risk for a specific genetic defect, **preimplantation genetic diagnosis** can sometimes be used to select unaffected early embryos, which are then implanted as part of an in vitro fertilization procedure.

Although prenatally obtained genetic material can be used to identify single-gene disorders, genomic disorders, and chromosomal anomalies, the information obtained on any pregnancy depends on the tests that are ordered. It is important that physicians select the most appropriate prenatal tests, and that couples understand the limitations of these tests. No amount of genetic testing can guarantee the birth of a healthy child.

Specific treatments are not available for the majority of genetic disorders, although some important exceptions exist (Chapter 94). **Inborn errors of metabolism** were the first genetic disorders to be recognized, and many are amenable to treatment by dietary manipulation (see Chapter 102). These conditions result from genetically determined deficiency of specific enzymes, leading to the buildup of toxic substrates and/or deficiency of critical end products.

Individual metabolic disorders tend to be very rare, but their combined impact on the pediatric population is significant. Tandem mass spectrometry has made it relatively inexpensive to screen for a large number of these disorders in the newborn period. Use of this technology not only dramatically increases the number of metabolic disorders identified within a population, but also allows treatment to be initiated at a much earlier stage in development.

Another area showing progress in genetic therapies is the treatment of

lysosomal storage disorders (see Chapter 104.4). These metabolic diseases are caused by defects in lysosomal function. *Lysosomes* are cellular organelles that contain specific digestive enzymes. Some of these disorders that were characterized by early lethal or intractable chronic illness can now be treated using specially modified enzymes administered by intravenous infusion. These enzymes are taken up by cells and incorporated into lysosomes. Conditions such as Gaucher disease and Fabry disease are routinely treated using **enzyme replacement** , and similar therapies are being developed for other lysosomal disorders.

Therapeutic advances are also being made in the treatment of nonmetabolic genetic disorders. Improvements in surgical techniques and intensive care medicine are extending the survival of children with life-threatening birth defects such as congenital diaphragmatic hernia and severe cardiac defects. In many cases the life expectancy of children with debilitating genetic disorders is also increasing. For example, in cystic fibrosis, improvements in nutrition and the management of chronic pulmonary disease allow an increasing percentage of affected patients to survive into adulthood, creating a need to transition care from pediatric to adult providers.

Gene replacement therapies have long been anticipated and are starting to show some benefit (see Chapter 94). Stem cell–based therapies have also been touted as a potential treatment for a number of intractable disorders, but clear evidence that such therapies are effective has yet to materialize.

Ethics Issues

As with all medical care, genetic testing, diagnosis, and treatment should be performed *confidentially* . Nothing is as personal as one's genetic information, and all efforts should be made to avoid any stigma for the patient. Many people worry that results of genetic testing will put them, or their child, at risk for genetic discrimination. **Genetic discrimination** occurs when people are treated unfairly because of a difference in their DNA that suggests they have a genetic disorder or they are at an increased risk of developing a certain disease. In the United States the Genetic Information Nondiscrimination Act of 2008 protects individuals from genetic discrimination at the hands of health insurers and employers, but does not extend protection against discrimination from providers of life, disability, or long-term care insurance.

As in all medical decision-making, the decisions about genetic testing should be based on a careful evaluation of the potential benefits and risks. In the pediatric setting, these decisions may be more difficult because physicians and parents are often called on to make decisions for a child who cannot directly participate in discussions about testing. Molecular diagnostic tests are often used to diagnose malformation syndromes, cognitive delay, or other disabilities in which there is a clear benefit to the child. In other cases, such as genetic testing for susceptibility to adult-onset diseases, it is appropriate to wait until the child or adolescent is mature enough to weigh the potential risks and benefits and make his or her own decisions about genetic testing.

Policies regarding genetic testing of children have been developed collaboratively by the American Academy of Pediatrics (AAP) and the American College of Medical Genetics and Genomics (ACMG; *Pediatrics* 131[3]:620–622, 2013). These recommendations are outlined next.

General Recommendations

1. Decisions about whether to offer genetic testing and screening should be driven by the best interest of the child.
2. Genetic testing is best offered in the context of genetic counseling. Genetic counseling can be performed by clinical geneticists, genetic counselors, or any other health care provider with appropriate training and expertise. AAP and ACMG support the expansion of educational opportunities in human genomics and genetics for medical students, residents, and practicing pediatric primary care providers.

Diagnostic Testing

3. In a child with symptoms of a genetic condition, the rationale for genetic testing is similar to that of other medical diagnostic evaluations. Parents or guardians should be informed about the risks and benefits of testing, and their permission should be obtained. Ideally, and when appropriate, the assent of the child should be obtained.
4. When performed for therapeutic purposes, pharmacogenetic testing of children is acceptable, with permission of parents or guardians and, when appropriate, the child's assent. If a pharmacogenetic test result carries implications beyond drug targeting or dose responsiveness, the broader implications should be discussed before testing.

Newborn Screening

5. AAP and ACMG support the mandatory offering of newborn screening for all children. After education and counseling about the substantial

benefits of newborn screening, its remote risks, and the next steps in the event of a positive screening result, parents should have the option of refusing the procedure, and an informed refusal should be respected.

Carrier Testing

6. AAP and ACMG do not support routine carrier testing in minors when such testing does not provide health benefits in childhood. The AAP and ACMG advise against school-based testing or screening programs, because the school environment is unlikely to be conducive to voluntary participation, thoughtful consent, privacy, confidentiality, or appropriate counseling about test results.
7. For pregnant adolescents or for adolescents considering reproduction, genetic testing and screening should be offered as clinically indicated, and the risks and benefits should be explained clearly.

Predictive Genetic Testing

8. Parents or guardians may authorize predictive genetic testing for asymptomatic children at risk of childhood-onset conditions. Ideally, the assent of the child should be obtained.
9. Predictive genetic testing for adult-onset conditions generally should be deferred unless an intervention initiated in childhood may reduce morbidity or mortality. An exception might be made for families for whom diagnostic uncertainty poses a significant psychosocial burden, particularly when an adolescent and the parents concur in their interest in predictive testing.
10. For ethical and legal reasons, healthcare providers should be cautious about providing predictive genetic testing to minors without the involvement of their parents or guardians, even if a minor is mature. Results of such tests may have significant medical, psychological, and social implications, not only for the minor but also for other family members.

Histocompatibility Testing

11. Tissue compatibility testing of minors of all ages is permissible to benefit immediate family members but should be conducted only after thorough exploration of the psychosocial, emotional, and physical implications of the minor serving as a potential stem cell donor. A donor advocate or similar mechanism should be in place from the outset to avert coercion and safeguard the interests of the child.

Adoption

12. The rationale for genetic testing of children in biological families should apply for adopted children and children awaiting placement for adoption. If a child has a known genetic risk, prospective adoptive parents must be made aware of this possibility. In rare cases, it may be in a child's best interest to undergo predictive genetic testing for a known risk before adoption, to ensure the child's placement with a family capable of and willing to accept the child's potential medical and developmental challenges. In the absence of such indications, genetic testing should not be performed as a condition of adoption.

Disclosure

13. At the time of genetic testing, parents or guardians should be encouraged to inform their child of the test results at an appropriate age. Parents or guardians should be advised that, under most circumstances, a request by a mature adolescent for test results should be honored.
14. Results from genetic testing of a child may have implications for the parents and other family members. Healthcare providers have an obligation to inform parents and the child, when appropriate, about these potential implications. Healthcare providers should encourage patients and families to share this information and offer to help explain the results to the extended family or refer them for genetic counseling.
15. Misattributed paternity, use of donor gametes, adoption, or other questions about family relationships may be uncovered “incidentally” whenever genetic testing is performed, particularly when testing multiple family members. This risk should be discussed, and a plan about disclosure or nondisclosure should be in place before testing.

Direct-to-Consumer Testing

16. AAP and ACMG strongly discourage the use of direct-to-consumer and home-kit genetic testing of children because of the lack of oversight on test content, accuracy, and interpretation.

CHAPTER 96

The Human Genome

Daryl A. Scott, Brendan Lee

The human genome has approximately 20,000 genes that encode the wide variety of proteins found in the human body. Reproductive or germline cells contain 1 copy (N) of this genetic complement and are **haploid** , whereas somatic (nongermline) cells contain 2 complete copies (2N) and are **diploid** . Genes are organized into long segments of deoxyribonucleic acid (**DNA**), which, during cell division, are compacted into intricate structures together with proteins to form chromosomes. Each somatic cell has 46 chromosomes: 22 pairs of **autosomes** , or nonsex chromosomes, and 1 pair of **sex chromosomes** (XY in a male, XX in a female). Germ cells (ova or sperm) contain 22 autosomes and 1 sex chromosome, for a total of 23. At fertilization, the full diploid chromosome complement of 46 is again realized in the embryo.

Most of the genetic material is contained in the cell's nucleus. The mitochondria (the cell's energy-producing organelles) contain their own unique genome. The **mitochondrial chromosome** consists of a double-stranded circular piece of DNA, which contains 16,568 base pairs (bp) of DNA and is present in multiple copies per cell. The proteins that occupy the mitochondria are produced either in the mitochondria, using information contained in the mitochondrial genome, or are produced outside of the mitochondria, using information contained in the nuclear genome, and then transported into the organelle. Sperm do not usually contribute mitochondria to the developing embryo, so all mitochondria are maternally derived, and a child's mitochondrial genetic makeup derives exclusively from the child's biological mother (see Chapter 106).

Fundamentals of Molecular Genetics

DNA consists of a pair of chains of a sugar-phosphate backbone linked by pyrimidine and purine bases to form a **double helix** (Fig. 96.1). The sugar in DNA is deoxyribose. The pyrimidines are cytosine (C) and thymine (T); the purines are guanine (G) and adenine (A). The bases are linked by hydrogen bonds such that A always pairs with T and G with C. Each strand of the double helix has polarity, with a free phosphate at one end (5′) and an unbonded hydroxyl on the sugar at the other end (3′). The 2 strands are oriented in opposite polarity in the double helix.

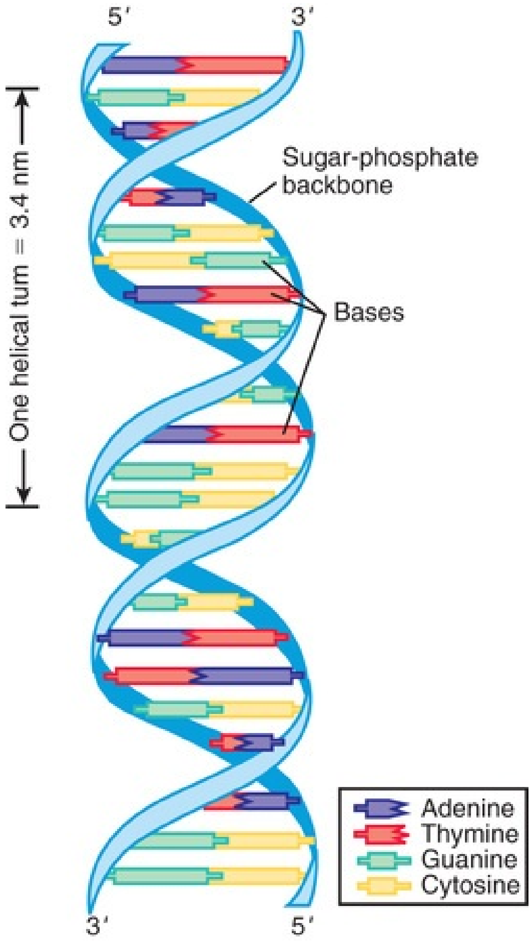

FIG. 96.1 DNA double helix, with sugar-phosphate backbone and nitrogenous bases. (From Jorde LB, Carey JC, Bamshad MJ, et al, editors: *Medical genetics* , ed 2, St Louis, 1999, Mosby, p 8.)

The replication of DNA follows the pairing of bases in the parent DNA strand. The original 2 strands unwind by breaking the hydrogen bonds between base pairs. Free nucleotides, consisting of a base attached to a sugar-phosphate chain, form new hydrogen bonds with their complementary bases on the parent strand;

new phosphodiester bonds are created by enzymes called **DNA polymerases.** Replication of chromosomes begins simultaneously at multiple sites, forming replication bubbles that expand bidirectionally until the entire DNA molecule (chromosome) is replicated. Errors in DNA replication, or mutations induced by environmental mutagens such as irradiation or chemicals, are detected and potentially corrected by DNA repair systems.

The central tenet of molecular genetics is that information encoded in DNA, predominantly located in the cell nucleus, is transcribed into **messenger** ribonucleic acid (**mRNA**), which is then transported to the cytoplasm, where it is translated into protein. A prototypical gene consists of a regulatory region, segments called **exons** that encode the amino acid sequence of a protein, and intervening segments called **introns** (Fig. 96.2).

FIG. 96.2 Flow of information from DNA to RNA to protein for a hypothetical gene with 3 exons and 2 introns. Within the exons, *colored regions* indicate coding sequences. Steps include transcription, RNA processing and splicing, RNA transport from the nucleus to the cytoplasm, translation, and protein assembly. (From Nussbaum RL, McInnis RR, Willard HF, Hamosh A, editors: *Thompson & Thompson genetics in medicine,* ed 7, Philadelphia, 2007, Saunders/Elsevier, p 31.)

Transcription is initiated by attachment of ribonucleic acid (**RNA**) polymerase to the promoter site upstream of the beginning of the coding sequence. Specific proteins bind to the region to repress or activate transcription by opening up the **chromatin** , which is a complex of DNA and histone proteins. It is the action of these regulatory proteins (**transcription factors**) that determines, in large part, when a gene is turned on or off. Some genes are also turned on and off by methylation of cytosine bases that are adjacent to guanine bases (**cytosine-phosphate-guanine bases, CpGs**). Methylation is an example of an **epigenetic** change, meaning a change that can affect gene expression, and possibly the characteristics of a cell or organism, but that *does not* involve a change in the underlying genetic sequence. Gene regulation is flexible and responsive, with genes being turned on or off during development and in response to internal and external environmental conditions and stimuli.

Transcription proceeds through the entire length of the gene in a 5′ to 3′ direction to form an mRNA transcript whose sequence is complementary to that of one of the DNA strands. RNA, like DNA, is a sugar-phosphate chain with pyrimidines and purines. In RNA the sugar is ribose, and uracil replaces the thymine found in DNA. A “cap” consisting of 7-methylguanosine is added to the 5′ end of the RNA in a 5′-5′ bond and, for most transcripts, several hundred adenine bases are enzymatically added to the 3′ end after transcription.

mRNA processing occurs in the nucleus and consists of excision of the introns and splicing together of the exons. Specific sequences at the start and end of introns mark the sites where the splicing machinery will act on the transcript. In some cases, there may be tissue-specific patterns to splicing, so that the same primary transcript can produce multiple distinct proteins.

The processed transcript is next exported to the cytoplasm, where it binds to ribosomes, which are complexes of protein and **ribosomal** RNA (**rRNA**). The genetic code is then read in triplets of bases, each triplet corresponding with a specific amino acid or providing a signal that terminates **translation** . The triplet codons are recognized by **transfer** RNAs (**tRNAs**) that include complementary anticodons and bind the corresponding amino acid, delivering it to the growing peptide. New amino acids are enzymatically attached to the peptide. Each time an amino acid is added, the ribosome moves 1 triplet codon step along the mRNA. Eventually a **stop codon** is reached, at which point translation ends and the peptide is released. In some proteins, there are **posttranslational modifications** , such as attachment of sugars (**glycosylation**); the protein is then delivered to its destination within or outside the cell by trafficking mechanisms that recognize portions of the peptide.

Another mechanism of genetic regulation is **noncoding** RNAs, which are RNAs transcribed from DNA but not translated into proteins. Noncoding RNAs function in mediating splicing, the processing of coding RNAs in the nucleus, and the translation of coding mRNAs in ribosomes. The roles of *large* noncoding RNAs (>200 bp) and *short* noncoding RNAs (<200 bp) extend beyond these processes to impact a diverse set of biologic functions, including the regulation of gene expression. For example, **micro** RNAs (**miRNAs**) are a class of small RNAs that control gene expression in the cell by directly targeting specific sets of coding RNAs by direct RNA–RNA binding. This RNA–RNA interaction can lead to degradation of the target-coding RNA or inhibition of translation of the protein specified by that coding RNA. miRNAs, in general, target and regulate several hundred mRNAs.

Genetic Variation

The process of producing protein from a gene is subject to disruption at multiple levels because of alterations in the coding sequence (Fig. 96.3). Changes in the regulatory region can lead to altered gene expression, including increased or decreased rates of transcription, failure of gene activation, or activation of the gene at inappropriate times or in inappropriate cells. Changes in the coding sequence can lead to **substitution** of one amino acid for another (**missense variant** or **nonsynonymous variant**) or creation of a stop codon in the place of an amino acid codon. Overall, missense or nonsense variants are the most common (56% of variants); small deletions or insertions represent approximately 24% of variants (Table 96.1). Some single-base changes do not affect the amino acid (**silent** , **wobble** , or **synonymous variants**), because there may be several triplet codons that correspond to a single amino acid. Amino acid substitutions can have a profound effect on protein function if the chemical properties of the substituted amino acid are markedly different from the usual one. Other substitutions can have a subtle or no effect on protein function, particularly if the substituted amino acid is chemically similar to the original one.

FIG. 96.3 Various types of intragenic sequence variants. Promoter variants alter rate of transcription or disrupt gene regulation. Base changes within exons can have various effects, as shown. Variants within introns can lead to inclusion of some intronic sequence in the final processed mRNA, or it can lead to exon skipping.

Table 96.1

Main Classes, Groups, and Types of Sequence Variants and Their Effects on Protein Products

CLASS	GROUP	TYPE	EFFECT ON PROTEIN PRODUCT
Substitution	Synonymous	Silent*	Same amino acid
	Nonsynonymous	Missense*	Altered amino acid—may affect protein function or stability
		Nonsense*	Stop codon—loss of function or expression from degradation of mRNA
		Splice site	Aberrant splicing—exon skipping or intron retention
		Promoter	Altered gene expression
Deletion	Multiple of 3 (codon)		In-frame deletion of 1 or more amino acid(s)—may affect protein function or stability
	Not multiple of 3	Frameshift	Likely to result in premature termination with loss of function or expression
	Large deletion	Partial gene deletion	May result in premature termination with loss of function or expression
		Whole gene deletion	Loss of expression
Insertion	Multiple of 3 (codon)		In-frame insertion of 1 or more amino acid(s)—may affect protein function or stability
	Not multiple of 3	Frameshift	Likely to result in premature termination with loss of

			function or expression
	Large insertion	Partial gene duplication	May result in premature termination with loss of function or expression
		Whole gene duplication	May have an effect because of increased gene dosage
	Expansion of trinucleotide repeat	Dynamic mutation	Altered gene expression or altered protein stability or function

[*] Some have been shown to cause aberrant splicing.

From Turnpenny P, Ellard S (Editors): *Emery's elements of medical genetics,* ed 14, Philadelphia, 2012, Elsevier/Churchill Livingstone, p 23.

Genetic changes can also include **insertions** or **deletions** . Insertions or deletions of a nonintegral multiple of 3 bases into the coding sequence leads to a **frameshift,** altering the grouping of bases into triplets. This leads to translation of an incorrect amino acid sequence and often a premature stop to translation. Insertion or deletion of an integral multiple of 3 bases into the coding sequence will insert or delete a corresponding number of amino acids from the protein, leading to **in-frame** alterations that maintain the amino acid sequence outside the deleted or duplicated amino acids. Larger-scale insertions or deletions can disrupt a coding sequence or result in complete deletion of an entire gene or group of genes.

Pathogenic variants usually can be classified as causing a loss of function or a gain of function. **Loss-of-function variants** cause a reduction in the level of protein function as a result of decreased expression or production of a protein that does not work as efficiently. In some cases, loss of protein function from 1 gene is sufficient to cause disease. **Haploinsufficiency** describes the situation in which maintenance of a normal phenotype requires the proteins produced by both copies of a gene, and a 50% decrease in gene function results in an abnormal phenotype. Thus, haploinsufficient phenotypes are, by definition, dominantly inherited. Loss-of-function variants can also have a dominant negative effect when the abnormal protein product actively interferes with the function of the normal protein product. Both these situations lead to diseases inherited in a dominant fashion. In other cases, loss-of-function variants must be present in both copies of a gene before an abnormal phenotype results. This situation typically results in diseases inherited in a recessive fashion (see Chapter 97).

Gain-of-function variants typically cause dominantly inherited diseases. These variants can result in production of a protein molecule with an increased ability to perform a normal function or can confer a novel property on the protein. The gain-of-function variant in **achondroplasia** , the most common of the disproportionate, short-limbed short stature disorders, exemplifies the enhanced function of a normal protein. Achondroplasia results from a mutation in the fibroblast growth factor (FGF) receptor 3 gene (*FGFR3*), which leads to activation of the receptor, even in the absence of FGF. In **sickle cell disease** an amino acid is substituted into the hemoglobin molecule and has little effect on the ability of the protein to transport oxygen. However, sickle hemoglobin chains have a novel property. Unlike normal hemoglobin, sickle hemoglobin chains aggregate under conditions of deoxygenation, forming fibers that deform the red cells.

Other gain-of-function mutations result in overexpression or inappropriate expression of a gene product. Many cancer-causing genes (**oncogenes**) are normal regulators of cellular proliferation during development. However, expression of these genes in adult life and/or in cells in which they usually are not expressed can result in neoplasia.

In some cases, changes in gene expression are caused by changes in the number of copies of a gene that are present in the genome (Fig. 96.4). Although some **copy number variations** are common and do not appear to cause or predispose to disease, others are clearly disease causing. **Charcot-Marie-Tooth disease type 1A** , the most common inherited form of chronic peripheral neuropathy of childhood, is caused by duplications of the gene for peripheral myelin protein 22, resulting in overexpression as a result of the existence of 3 active copies of this gene (see Chapter 631.1). Deletions of this same gene leaving only 1 active copy are responsible for a different disorder, hereditary neuropathy with liability to pressure palsies.

FIG. 96.4 **Array comparative genomic hybridization. Test and reference DNA samples are differentially labeled, mixed, and passed over a target array of probes (e.g., bacterial artificial chromosome clones or oligonucleotides) containing DNA fragments from across the whole human genome. The experiment is often repeated with reversal of the test and reference dyes to detect dye effects or identify spurious signals. DNA samples hybridize with their corresponding probe, and the ratio of fluorescence from each probe (test:reference) is used to detect regions that vary in copy number between the test and the reference sample (*red line,* original hybridization; *blue line,* dye-swapped hybridization). Equal copy number for both the test and the reference DNA is identified by equal binding, resulting in a ratio of 1 : 1. Duplication in a genomic region of the test sample is identified by an increased ratio, and a deletion is identified by a decreased ratio, but a deletion in the test sample is indistinguishable from a duplication in the reference sample. These ratios are usually converted to log2 scale for further analysis. (Adapted from Feuk L, Carson AR, Scherer SW: Structural variation in the human genome, *Nat Rev Genet* 7:85–97, 2006, with permission from *Nature Reviews Genetics.*)**

Deletions and duplications can vary in their extent and can involve several genes, even when they are not visible on a traditional chromosome analysis. Such changes are commonly called **microdeletions** and **microduplications** . When deletion or duplication of 2 or more genes in the same chromosomal region each play a role in the resulting clinical features, the condition can also be referred to as a **contiguous gene disorder** .

In some cases the recognition of a specific constellation of features leads the clinician to suspect a specific microdeletion or microduplication syndrome. Examples of such disorders include Smith-Magenis, DiGeorge, and Williams syndromes. In other cases the clinician may be alerted to this possibility by an unusually diverse array of clinical features in one patient or the presence of unusual features in a person with a known condition. Because of the close physical proximity of a series of genes, different deletions involving the short arm of the X chromosome can produce individuals with various combinations of ichthyosis, Kallmann syndrome, ocular albinism, intellectual disability, chondrodysplasia punctata, and short stature.

DNA rearrangements can also take place in **somatic cells** (cells that do not go on to produce ova or sperm). Rearrangements that occur in **lymphoid** cells are required for the formation of functional immunoglobulin in B cells and antigen-recognizing receptors on T cells. Large segments of DNA, which code for the variable and the constant regions of either immunoglobulin or the T-cell receptor (TCR), are physically joined at a specific stage in the development of an immunocompetent lymphocyte. These rearrangements take place during development of the lymphoid cell lineage in humans and result in the extensive diversity of immunoglobulin and TCR molecules. Because of this postgermline DNA rearrangement, no 2 individuals, not even identical twins, are really identical, because mature lymphocytes from each will have undergone random DNA rearrangements at these loci.

Studies of the human genome sequence reveal that any 2 individuals differ in about 1 base in 1,000. Some of these differences are silent; some result in changes that explain phenotypic differences (hair or eye color, physical appearance); some have medical significance, causing single-gene disorders such as sickle cell anemia or explaining susceptibility to common pediatric disorders such as asthma. Genetic variants in a single gene that occur at a frequency of >1% in a population are often referred to as **polymorphisms** . These variations may be silent or subtle or may have significant phenotypic effects.

Genotype-Phenotype Correlations in Genetic Disease

The term **genotype** is used to signify the internally coded, heritable information of an individual and can also be used to refer to which particular alternative version (**allele**) of a gene is present at a specific location (**locus**) on a chromosome. A **phenotype** is the observed structural, biochemical, and physiologic characteristics of an individual, determined by the genotype, and can also refer to the observed structural and functional effects of a variant allele at a specific locus. Many sequence variants result in predictable phenotypes. In these cases, physicians can predict clinical outcomes and plan appropriate treatment strategies based on a patient's genotype. Increasingly, there is phenotypic expansion where multiple alleles (variants) within a gene can be associated with often diverse and distinct clinical presentations.

The **long QT syndrome** exemplifies a disorder with predictable associations between a patient's genotype and his or her phenotype (see Chapter 462.5). Long QT syndrome is genetically heterogeneous, meaning that pathogenic variants in several different genes can cause the same disorder. The risk for cardiac events (syncope, aborted cardiac arrest, or sudden death) is higher in patients with long QT syndrome involving the *KCNQ1* gene (63%) or *KCNH2* (46%) than in those with pathogenic variants in *SCN5A* (18%). In addition, those with *KCNQ1* variants experience most of their episodes during exercise and rarely during rest or sleep. In contrast, individuals with pathogenic variants in *KCNH2* and *SCN5A* are more likely to have episodes during sleep or rest and rarely during exercise. Therefore, variants in specific genes (genotype) are correlated with specific manifestations (phenotype) of long QT syndrome. These types of relationships are commonly referred to as *genotype-phenotype correlations.*

Pathogenic variants in the fibrillin-1 gene associated with **Marfan syndrome** represent another example of predictable genotype-phenotype correlations (see Chapter 722). Marfan syndrome is characterized by the combination of skeletal, ocular, and aortic manifestations, with the most devastating outcome being aortic root dissection and sudden death. The fibrillin-1 gene consists of 65 exons, and mutations have been found in almost all these. The location of the mutation within the gene (genotype) might play a significant role in determining the severity of the condition (phenotype). Neonatal Marfan syndrome is caused by mutations in exons 24-27 and in exons 31 and 32, whereas milder forms are caused by mutations in exons 59-65 and in exons 37 and 41.

Genotype-phenotype correlations have also been observed in some complications of **cystic fibrosis** (CF; see Chapter 432). Although pulmonary disease is the major cause of morbidity and mortality, CF is a multisystem disorder that affects not only the epithelia of the respiratory tract but also the exocrine pancreas, intestine, male genital tract, hepatobiliary system, and exocrine sweat glands. CF is caused by pathologic variants in the CF transmembrane conductance regulator (*CFTR*) gene; >1,600 different pathogenic variants have been identified. The most common is a deletion of 3 nucleotides that removes the amino acid phenylalanine (F) at the 508th position on the protein (ΔF508 variant), which accounts for approximately 70% of all pathogenic CF variants and is associated with severe disease. The best genotype-phenotype correlations in CF are seen in the context of pancreatic function, with most common mutations being classified as either *pancreatic sufficient* or *pancreatic insufficient.* Persons with pancreatic sufficiency usually have either 1 or 2 pancreatic-sufficient alleles, indicating that pancreatic-sufficient alleles are dominant. In contrast, the genotype-phenotype correlation in pulmonary disease is much weaker, and persons with identical genotypes have wide variations in the severity of their pulmonary disease. This finding may be accounted for in part by genetic modifiers or environmental factors.

In many disorders the effects of variants on phenotype can be modified by changes in the other allele of the same gene, by changes in specific **modifier genes** , and/or by variations in a number of unspecified genes (**genetic background**). When sickle cell anemia is co-inherited with the gene for hereditary persistence of fetal hemoglobin, the sickle cell phenotypic expression is less severe. Modifier genes in CF can influence the development of congenital meconium ileus, or colonization with *Pseudomonas aeruginosa.* Modifier genes can also affect the manifestations of Hirschsprung disease, neurofibromatosis type 2, craniosynostosis, and congenital adrenal hyperplasia. The combination of genetic variants producing glucose-6-phosphate dehydrogenase deficiency and longer versions of the TATAA element in the uridine diphosphate–glucuronosyltransferase gene promoter exacerbates neonatal physiologic hyperbilirubinemia.

Human Genome Project

A rudimentary genetic map can be made using genetic linkage, which is based on the principle that alleles at 2 genetic loci that are located near each other segregate together in a family unless they are separated by genetic **recombination** . The frequency of recombination between the loci can be used to estimate the physical distance between points. Some of the first maps of the human genome were linkage maps based on a set of polymorphic genetic loci located along the entire human genome. Linkage analysis is still used to map the location of genetic changes responsible for phenotypic traits and genetic disorders that are inherited in a mendelian fashion.

In contrast to linkage maps, which are based on recombination frequencies, physical maps rely on overlapping DNA fragments to determine the location of loci with respect to one another. Several strategies can be used to create physical maps of a chromosomal region. In one strategy, segments of the region of interest with lengths from hundreds or thousands to a few million base pairs are isolated and placed in microorganisms such as bacteria or yeast. Common regions contained in different organisms can then be identified and this information used to piece together a map composed of overlapping DNA pieces, each contained in a different microorganism. The pieces contained in each organism can then be sequenced to obtain the DNA sequence of the entire region. An alternative strategy involves breaking the entire genome into random fragments, sequencing the fragments, and then using a computer to order the fragments based on overlapping segments. This whole genome approach in combination with new next-generation sequencing technologies has resulted in a dramatic reduction in the cost of sequencing an individual's entire genome.

Analysis of the human genome has produced some surprising results. The number of genes appears to be about 20,000. This is fewer than had been expected and is in the same range as many simpler organisms. *The number of protein products encoded by the genome is greater than the number of genes.* This is a result of the presence of alternative promoter regions, alternative splicing, and posttranslational modifications, which can allow a single gene to encode a number of protein products.

It is also apparent that most of the human genome does not encode protein, with <5% being transcribed and translated, although a much larger percentage may be transcribed without translation. Many transcribed sequences are not translated but represent genes that encode RNAs that serve a regulatory role. A large fraction of the genome consists of repeated sequences that are interspersed among the genes. Some of these are transposable genetic elements that can move from place to place in the genome. Others are static elements that were expanded and dispersed in the past during human evolution. Other repeated sequences might play a structural role. There are also regions of genomic duplications. Such duplications are substrate for evolution, allowing genetic motifs to be copied and modified to serve new roles in the cell. Duplications can also play a role in chromosomal rearrangement, permitting nonhomologous chromosome segments to pair during meiosis and exchange material. This is another source of evolutionary change and a potential source of chromosomal instability leading to congenital anomalies or cancer. Low copy repeats also play an important role in causing genomic disorders. When low copy repeats flank unique genomic segments, these regions can be duplicated or deleted through a process known as *nonallelic homologous recombination.*

Availability of the entire human genomic sequence permits the study of large groups of genes, looking for patterns of gene expression or genome alteration. Microarrays permit the expression of thousands of genes to be analyzed on a small glass chip. Increasingly, studies of gene expression are being performed using next generation sequencing techniques to obtain information about all of the RNA transcripts in a tissue sample. In some cases the patterns of gene expression provide signatures for particular disease states, such as cancer, or change in response to therapy (Fig. 96.5).

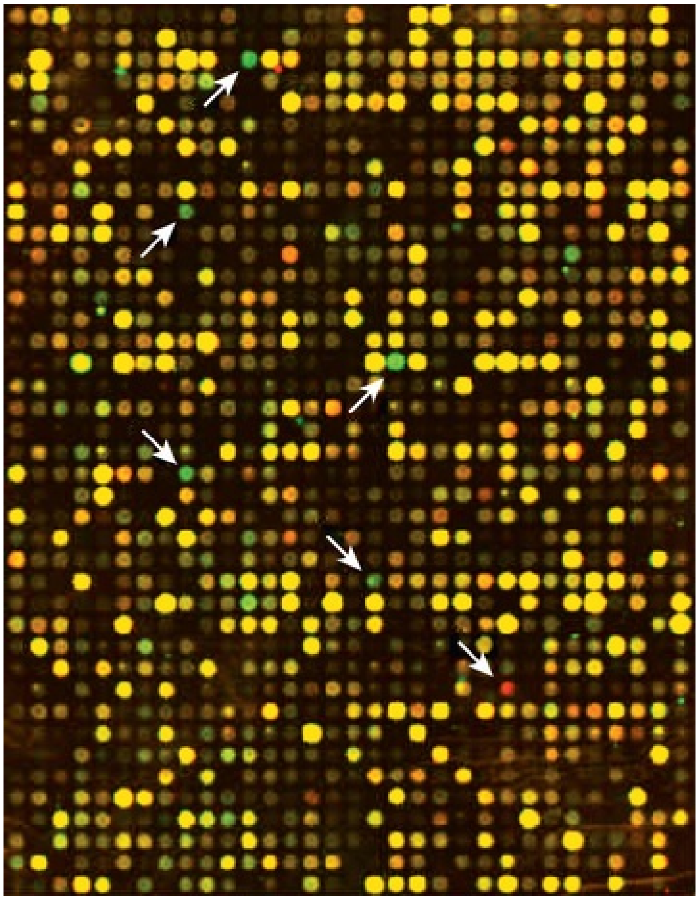

FIG. 96.5 **Microarray containing 36,000 oligonucleotides. The microarray was exposed to RNA from normal fibroblasts (labeled in *red* ; see *arrows*) and fibroblasts from a**

patient with Niemann-Pick disease, type C (labeled *green*). *Arrows* point to regions in which there was a strong hybridization signal with either normal or disease RNA. This microarray was used to search for genes that are highly expressed in the fibroblasts of patients. (From Jorde LB, Carey JC, Bamshad MJ, et al, editors: *Medical genetics* , ed 3, St Louis, 2006, Mosby, p 116.)

CHAPTER 97

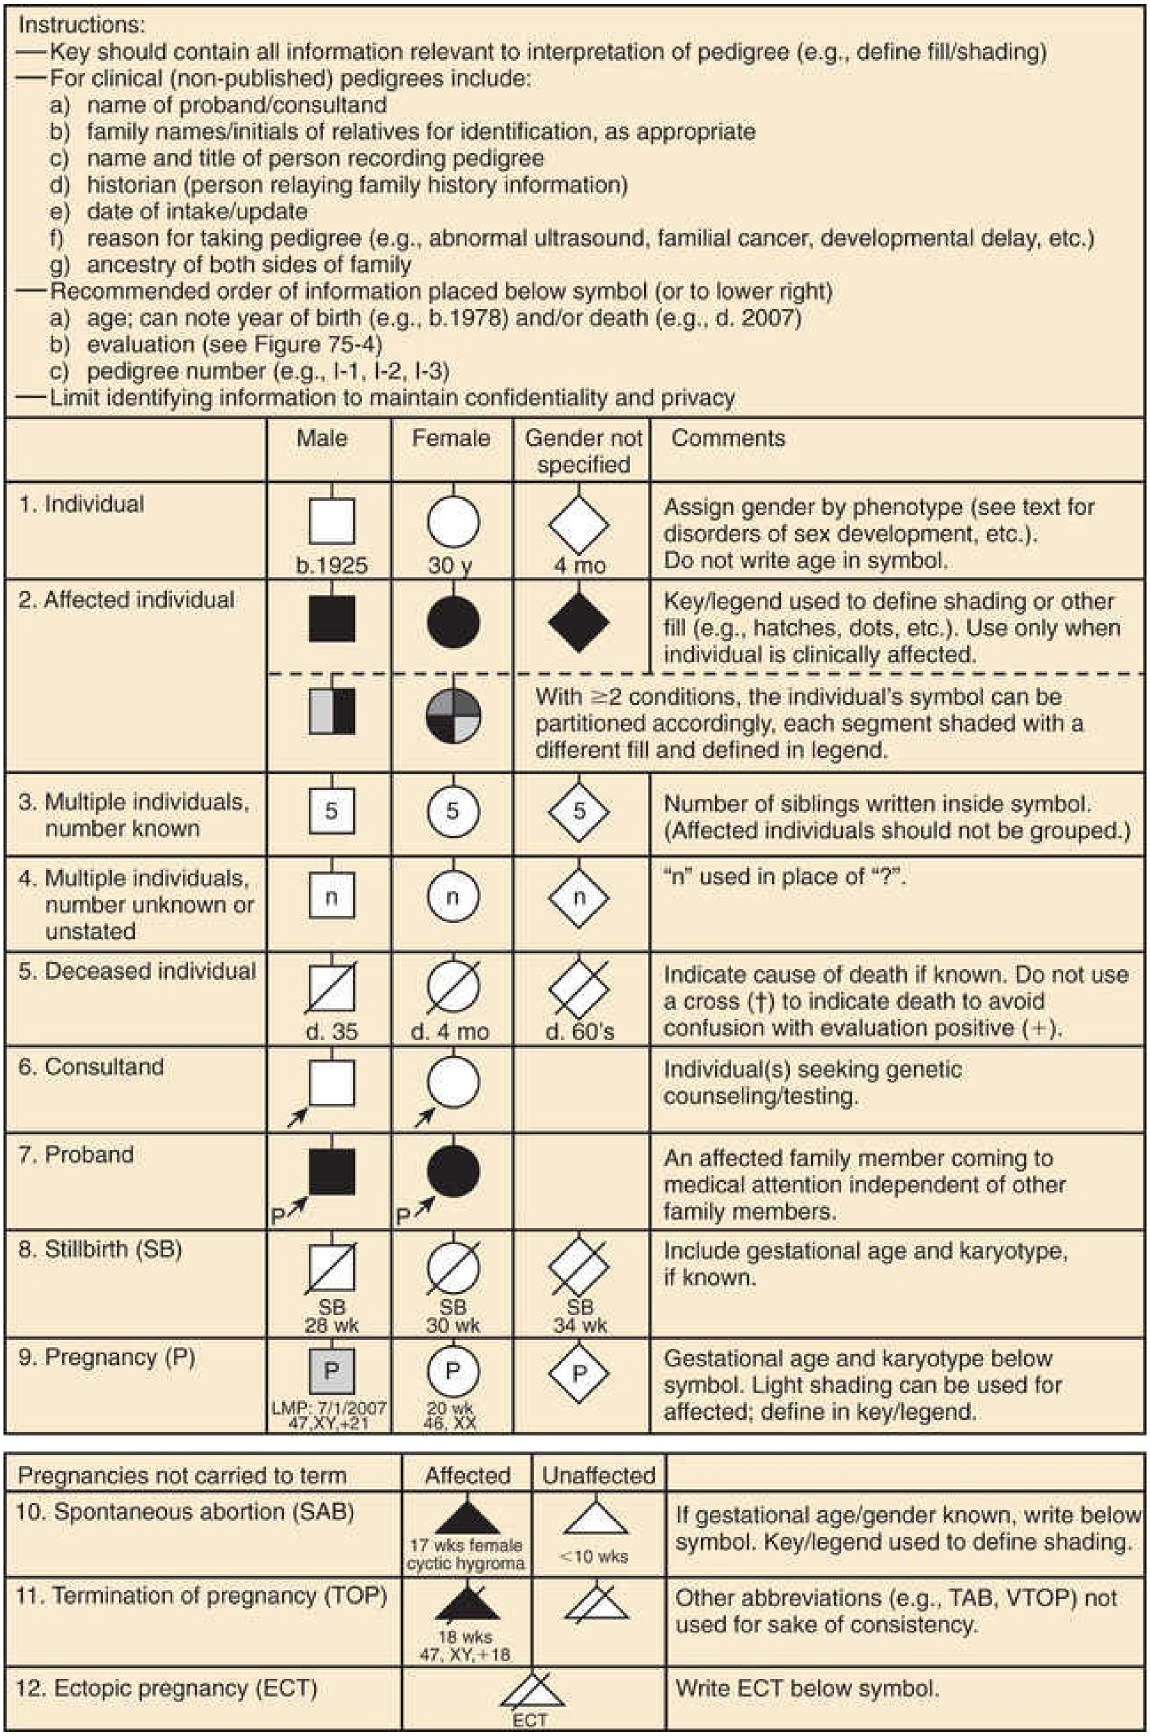
Patterns of Genetic Transmission

Daryl A. Scott, Brendan Lee

Family History and Pedigree Notation

The family history remains the most important screening tool for pediatricians in identifying a patient's risk for developing a wide range of diseases, from multifactorial conditions such as diabetes and attention-deficit/hyperactivity disorder, to single-gene disorders such as sickle cell anemia and cystic fibrosis. Through a detailed family history, the physician can often ascertain the mode of genetic transmission and the risks to family members. Because not all familial clustering of disease is caused by genetic factors, a family history can also identify common environmental and behavioral factors that influence the occurrence of disease. The main goal of the family history is to identify genetic susceptibility, and the cornerstone of the family history is a systematic and standardized pedigree.

A **pedigree** provides a graphic depiction of a family's structure and medical history. It is important when taking a pedigree to be systematic and use standard symbols and configurations so that anyone can read and understand the information (Figs. 97.1 to 97.4). In the pediatric setting, the **proband** is typically the child or adolescent who is being evaluated. The proband is designated in the pedigree by an arrow.

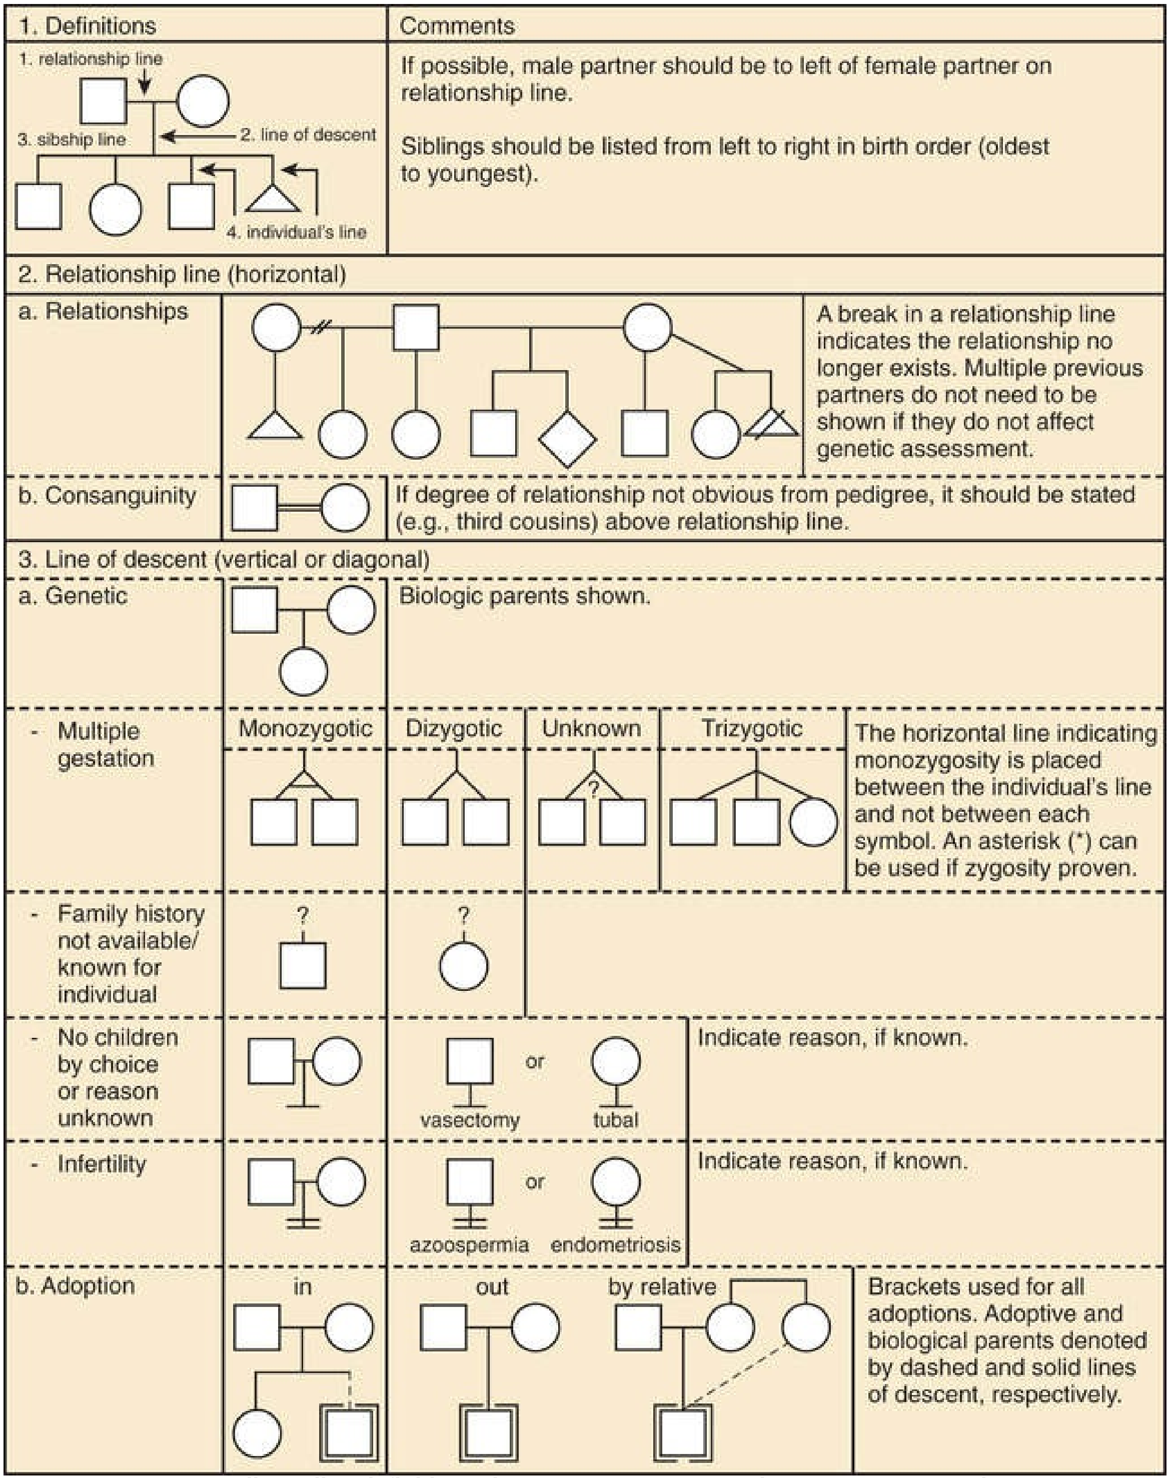


Instructions:
- Key should contain all information relevant to interpretation of pedigree (e.g., define fill/shading)
- For clinical (non-published) pedigrees include:
  - a) name of proband/consultand
  - b) family names/initials of relatives for identification, as appropriate
  - c) name and title of person recording pedigree
  - d) historian (person relaying family history information)
  - e) date of intake/update
  - f) reason for taking pedigree (e.g., abnormal ultrasound, familial cancer, developmental delay, etc.)
  - g) ancestry of both sides of family
- Recommended order of information placed below symbol (or to lower right)
  - a) age; can note year of birth (e.g., b.1978) and/or death (e.g., d. 2007)
  - b) evaluation (see Figure 75-4)
  - c) pedigree number (e.g., I-1, I-2, I-3)
- Limit identifying information to maintain confidentiality and privacy

	Male	Female	Gender not specified	Comments
1. Individual	□ b.1925	○ 30 y	◇ 4 mo	Assign gender by phenotype (see text for disorders of sex development, etc.). Do not write age in symbol.
2. Affected individual	■	●	◆	Key/legend used to define shading or other fill (e.g., hatches, dots, etc.). Use only when individual is clinically affected.
	◧	◕	With ≥2 conditions, the individual's symbol can be partitioned accordingly, each segment shaded with a different fill and defined in legend.	
3. Multiple individuals, number known	5	5	5	Number of siblings written inside symbol. (Affected individuals should not be grouped.)
4. Multiple individuals, number unknown or unstated	n	n	n	"n" used in place of "?".
5. Deceased individual	⧄ d. 35	⊘ d. 4 mo	◇ d. 60's	Indicate cause of death if known. Do not use a cross (†) to indicate death to avoid confusion with evaluation positive (+).
6. Consultand	↗□	↗○		Individual(s) seeking genetic counseling/testing.
7. Proband	P↗■	P↗●		An affected family member coming to medical attention independent of other family members.
8. Stillbirth (SB)	⧄ SB 28 wk	⊘ SB 30 wk	◇ SB 34 wk	Include gestational age and karyotype, if known.
9. Pregnancy (P)	P LMP: 7/1/2007 47,XY,+21	P 20 wk 46, XX	P	Gestational age and karyotype below symbol. Light shading can be used for affected; define in key/legend.

Pregnancies not carried to term	Affected	Unaffected	
10. Spontaneous abortion (SAB)	▲ 17 wks female cyctic hygroma	△ <10 wks	If gestational age/gender known, write below symbol. Key/legend used to define shading.
11. Termination of pregnancy (TOP)	▲ 18 wks 47, XY,+18	△	Other abbreviations (e.g., TAB, VTOP) not used for sake of consistency.
12. Ectopic pregnancy (ECT)	△ ECT		Write ECT below symbol.

FIG. 97.1 Common pedigree symbols, definitions, and abbreviations. (From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors, *J Genet Couns* 17:424–433, 2008.)



1. Definitions

b. Adoption
in
out
by relative

If possible, male partner should be to left of female partner on relationship line.

Siblings should be listed from left to right in birth order (oldest to youngest).

A break in a relationship line indicates the relationship no longer exists. Multiple previous partners do not need to be shown if they do not affect genetic assessment.

If degree of relationship not obvious from pedigree, it should be stated (e.g., third cousins) above relationship line.

Biologic parents shown.

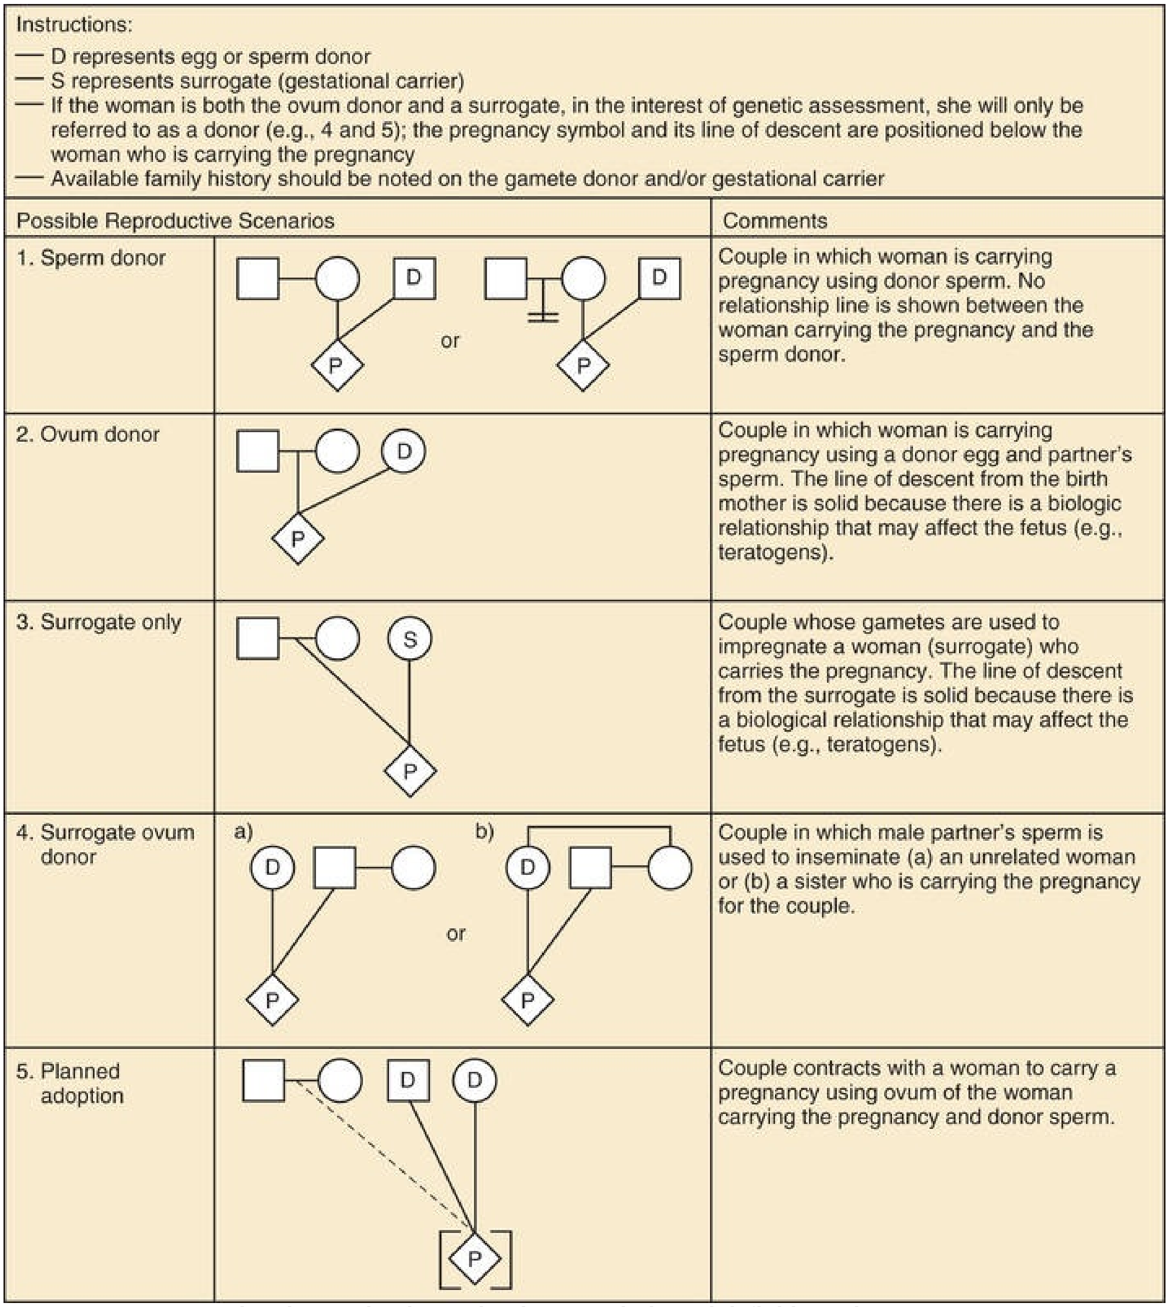
The horizontal line indicating monozygosity is placed between the individual's line and not between each symbol. An asterisk (*) can be used if zygosity proven.

Indicate reason, if known.

Indicate reason, if known.

Brackets used for all adoptions. Adoptive and biological parents denoted by dashed and solid lines of descent, respectively.

FIG. 97.2 Pedigree line definitions. (From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors, *J Genet Couns* 17:424–433, 2008.)

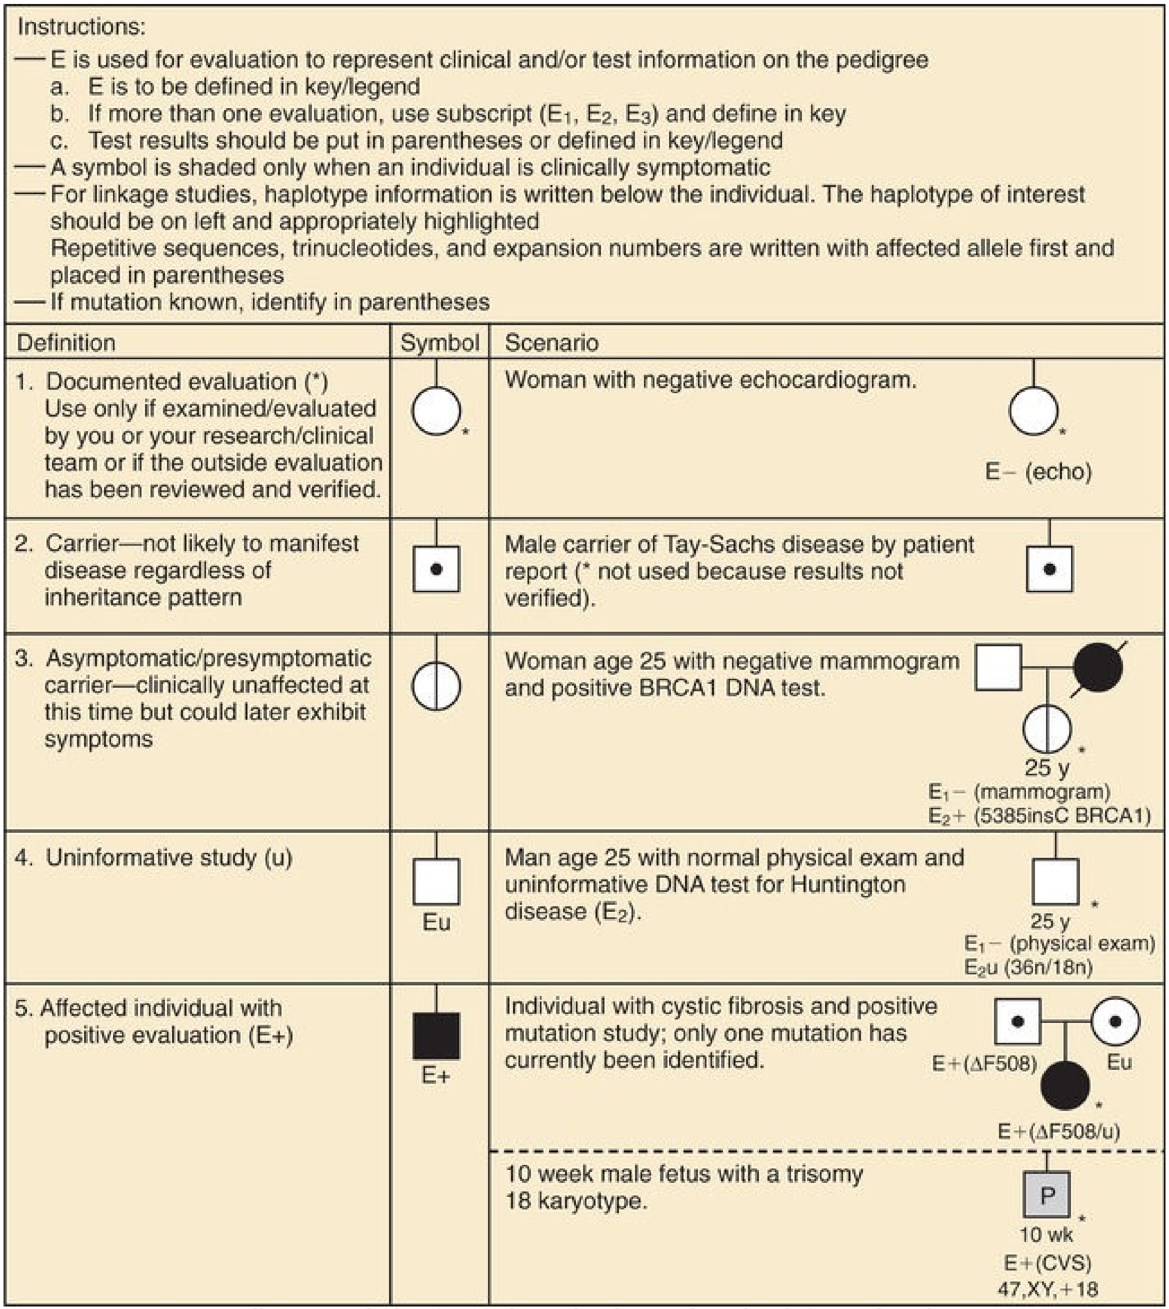


Instructions:

- D represents egg or sperm donor
- S represents surrogate (gestational carrier)
- If the woman is both the ovum donor and a surrogate, in the interest of genetic assessment, she will only be referred to as a donor (e.g., 4 and 5); the pregnancy symbol and its line of descent are positioned below the woman who is carrying the pregnancy
- Available family history should be noted on the gamete donor and/or gestational carrier

Possible Reproductive Scenarios		Comments
1. Sperm donor		Couple in which woman is carrying pregnancy using donor sperm. No relationship line is shown between the woman carrying the pregnancy and the sperm donor.
2. Ovum donor		Couple in which woman is carrying pregnancy using a donor egg and partner's sperm. The line of descent from the birth mother is solid because there is a biologic relationship that may affect the fetus (e.g., teratogens).
3. Surrogate only		Couple whose gametes are used to impregnate a woman (surrogate) who carries the pregnancy. The line of descent from the surrogate is solid because there is a biological relationship that may affect the fetus (e.g., teratogens).
4. Surrogate ovum donor		Couple in which male partner's sperm is used to inseminate (a) an unrelated woman or (b) a sister who is carrying the pregnancy for the couple.
5. Planned adoption		Couple contracts with a woman to carry a pregnancy using ovum of the woman carrying the pregnancy and donor sperm.

FIG. 97.3 **Assisted reproductive technology symbols and definitions. (From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors, *J Genet Couns* 17:424–433, 2008.)**



Instructions:

— E is used for evaluation to represent clinical and/or test information on the pedigree
  a. E is to be defined in key/legend
  b. If more than one evaluation, use subscript (E_1, E_2, E_3) and define in key
  c. Test results should be put in parentheses or defined in key/legend
— A symbol is shaded only when an individual is clinically symptomatic
— For linkage studies, haplotype information is written below the individual. The haplotype of interest should be on left and appropriately highlighted
  Repetitive sequences, trinucleotides, and expansion numbers are written with affected allele first and placed in parentheses
— If mutation known, identify in parentheses

Definition	Symbol	Scenario
1. Documented evaluation (*) Use only if examined/evaluated by you or your research/clinical team or if the outside evaluation has been reviewed and verified.	*	Woman with negative echocardiogram. * E− (echo)
2. Carrier—not likely to manifest disease regardless of inheritance pattern		Male carrier of Tay-Sachs disease by patient report (* not used because results not verified).
3. Asymptomatic/presymptomatic carrier—clinically unaffected at this time but could later exhibit symptoms		Woman age 25 with negative mammogram and positive BRCA1 DNA test. * 25 y E_1− (mammogram) E_2+ (5385insC BRCA1)
4. Uninformative study (u)	Eu	Man age 25 with normal physical exam and uninformative DNA test for Huntington disease (E_2). * 25 y E_1− (physical exam) E_2u (36n/18n)
5. Affected individual with positive evaluation (E+)	E+	Individual with cystic fibrosis and positive mutation study; only one mutation has currently been identified. E+(ΔF508) Eu * E+(ΔF508/u)
		10 week male fetus with a trisomy 18 karyotype. P * 10 wk E+(CVS) 47,XY,+18

FIG. 97.4 **Pedigree symbols of genetic evaluation and testing information. (From Bennett RL, French KS, Resta RG, et al: Standardized human pedigree nomenclature: update and assessment of the recommendations of the National Society of Genetic Counselors, *J Genet Couns* 17:424–433, 2008.)**

A 3 to 4–generation pedigree should be obtained for every new patient as an initial screen for genetic disorders segregating within the family. The pedigree can provide clues to the inheritance pattern of these disorders and can aid the clinician in determining the risk to the proband and other family members. The closer the relationship of the proband to the person in the family with the genetic disorder, the greater is the shared genetic complement. **First-degree** relatives, such as a parent, full sibling, or child, share one-half their genetic information on average; first cousins share one-eighth. Sometimes the person providing the family history may mention a distant relative who is affected with a genetic disorder. In such cases a more extensive pedigree may be needed to identify the risk to other family members. For example, a history of a distant maternally related cousin with intellectual disability caused by fragile X syndrome can still place a male proband at an elevated risk for this disorder.

Mendelian Inheritance

There are 3 classic forms of genetic inheritance: **autosomal dominant, autosomal recessive,** and **X-linked** . These are referred to as **mendelian inheritance** forms, after Gregor Mendel, the 19th-century monk whose experiments led to the laws of **segregation of characteristics, dominance,** and **independent assortment** . These remain the foundation of single-gene inheritance.

Autosomal Dominant Inheritance

Autosomal dominant inheritance is determined by the presence of one abnormal gene on one of the **autosomes** (chromosomes 1-22). Autosomal genes exist in pairs, with each parent contributing 1 copy. In an autosomal dominant trait, a change in 1 of the paired genes affects the phenotype of an individual, even though the other copy of the gene is functioning correctly. A **phenotype** can refer to a physical manifestation, a behavioral characteristic, or a difference detectable only through laboratory tests.

The pedigree for autosomal dominant disorders demonstrates certain characteristics. These disorders show a **vertical transmission** (parent-to-child) pattern and can appear in multiple generations. In Fig. 97.5 , this is illustrated by individual I.1 passing on the changed gene to II.2 and II.5. An affected individual has a 50% (1 in 2) chance of passing on the deleterious gene in *each* pregnancy and, therefore, of having a child affected by the disorder. This is referred to as the **recurrence risk** for the disorder. Unaffected individuals (family members who do not manifest the trait and do not harbor a copy of the deleterious gene) do not pass the disorder to their children. Males and females are equally affected.

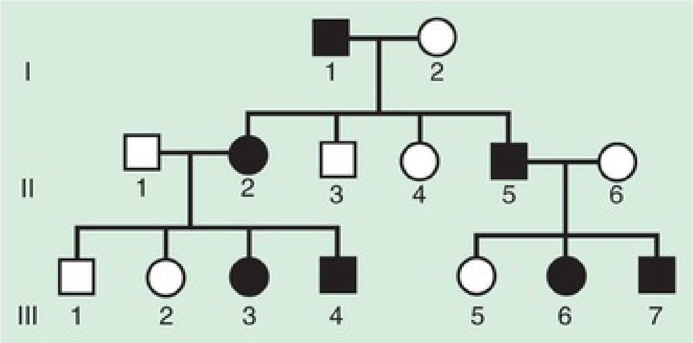


FIG. 97.5 **Autosomal dominant pedigree. Pedigree showing typical inheritance of a form of achondroplasia *(FGFR3)* inherited as an autosomal dominant trait. *Black,* Affected patients.**

Although not a characteristic per se, the finding of male-to-male transmission essentially confirms autosomal dominant inheritance. Vertical transmission can also be seen with X-linked traits. However, because a father passes on his Y chromosome to a son, male-to-male transmission cannot be seen with an X-linked trait. Therefore, male-to-male transmission eliminates X-linked inheritance as a possible explanation. Although male-to-male transmission can occur with Y-linked genes as well, there are very few **Y-linked** disorders, compared with thousands having the autosomal dominant inheritance pattern.

Although parent-to-child transmission is a characteristic of autosomal dominant inheritance, many patients with an autosomal dominant disorder have no history of an affected family member, for several possible reasons. First, the patient may have the disorder due to a **de novo** (new) mutation that occurred in the DNA of the egg or sperm that formed that individual. Second, many autosomal dominant conditions demonstrate **incomplete penetrance** , meaning that not all individuals who carry the mutation have phenotypic manifestations. In a pedigree this can appear as a **skipped generation** , in which an unaffected individual links 2 affected persons (Fig. 97.6). There are many potential reasons that a disorder might exhibit incomplete penetrance, including the effect of modifier genes, environmental factors, gender, and age. Third, individuals with the same autosomal dominant variant can manifest the disorder to different degrees. This is termed **variable expression** and is a characteristic of many autosomal dominant disorders. Fourth, some spontaneous genetic mutations occur not in the egg or sperm that forms a child, but rather in a *cell* in the developing embryo. Such events are referred to as **somatic mutations** , and because not all cells are affected, the change is said to be **mosaic** . The phenotype caused by a somatic mutation can vary but is usually milder than if all cells were affected by the mutation. In **germline mosaicism** the mutation occurs in cells that populate the germline that produces eggs or sperm. An individual who is germline mosaic might not have any manifestations of the disorder but may produce multiple eggs or sperm that are affected by the mutation.

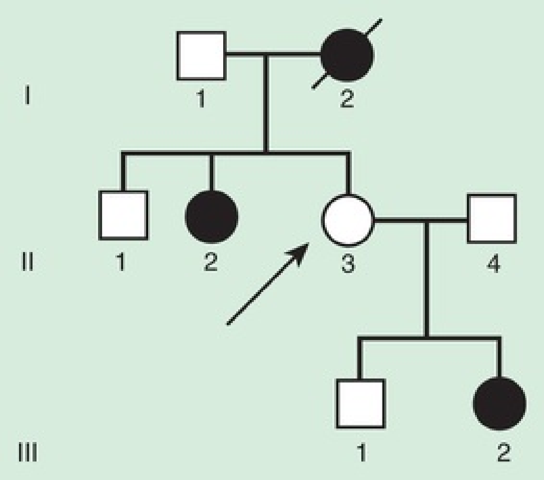

FIG. 97.6 **Incomplete penetrance. This family segregates a familial cancer syndrome, familial adenomatous polyposis. Individual II.3 is an obligate carrier, but there are no findings to suggest the disorder. This disorder is nonpenetrant in this individual. *Black,* Affected patients.**

Autosomal Recessive Inheritance

Autosomal recessive inheritance requires deleterious variants in both copies of a gene to cause disease. Examples include cystic fibrosis and sickle cell disease. Autosomal recessive disorders are characterized by **horizontal transmission** , the observation of multiple affected members of a kindred in the same generation, but no affected family members in other generations (Fig. 97.7). They are associated with a recurrence risk of 25% for carrier parents who have had a previous affected child. Male and female offspring are equally likely to be affected, although some traits exhibit differential expression between sexes. The offspring of consanguineous parents are at increased risk for rare, autosomal recessive traits due to the increased chance that that both parents may carry a gene affected by a deleterious mutation that they inherited from a common ancestor. **Consanguinity** between parents of a child with a suspected genetic disorder implies, but certainly does not prove, autosomal recessive inheritance. Although consanguineous unions are uncommon in Western society, in other parts of the world (southern India, Japan, and the Middle East) as high as 50% of all children may be conceived in consanguineous unions. The risk of a genetic disorder for the offspring of a first-cousin union (6–8%) is about double the risk in the general population (3–4%).

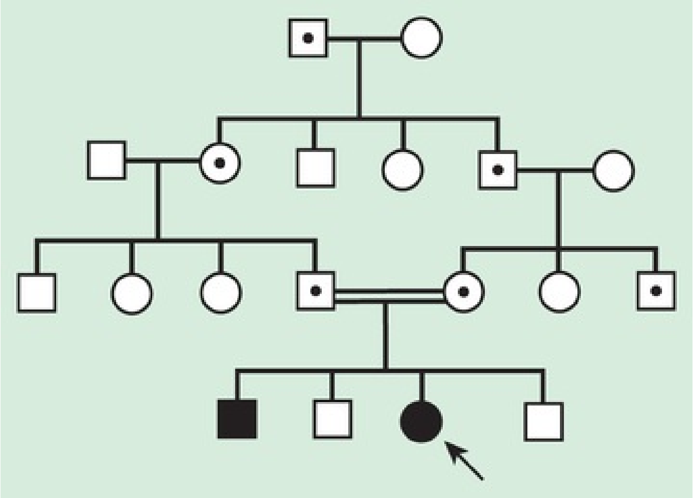

FIG. 97.7 **Autosomal recessive pedigree with parental consanguinity. *Central dot,* Carriers; *Black,* Affected patients.**

Every individual probably has several rare, deleterious recessive pathogenic sequence variants. Because most pathogenic variants carried in the general population occur at a very low frequency, it does not make economic sense to screen the entire population in order to identify the small number of persons who carry these variants. As a result, these variants typically remain undetected unless an affected child is born to a couple who both carry pathogenic variants affecting the same gene.

However, in some **genetic isolates** (small populations isolated by geography, religion, culture, or language), certain rare recessive pathogenic variants are much more common than in the general population. Even though there may be no known consanguinity, couples from these genetic isolates have a greater chance of sharing pathogenic alleles inherited from a common ancestor. Screening programs have been developed among some such groups to detect persons who carry common disease-causing variants and therefore are at increased risk for having affected children. A variety of autosomal recessive conditions are more common among Ashkenazi Jews than in the general population. Couples of Ashkenazi Jewish ancestry should be offered prenatal or preconception screening for Gaucher disease type 1 (carrier rate 1 : 14), cystic fibrosis (1 : 25), Tay-Sachs disease (1 : 25), familial dysautonomia (1 : 30), Canavan disease (1 : 40), glycogen storage disease type 1A (1 : 71), maple syrup urine disease (1 : 81), Fanconi anemia type C (1 : 89), Niemann-Pick disease type A (1 : 90), Bloom syndrome (1 : 100), mucolipidosis IV (1 : 120), and possibly neonatal familial hyperinsulinemic hypoglycemia.

The prevalence of carriers of certain autosomal recessive variants in some larger populations is unusually high. In such cases, **heterozygote advantage** is postulated. The carrier frequencies of sickle cell disease in the African population and of cystic fibrosis in the northern European population are much higher than would be expected from the rate of new mutations. In these populations, heterozygous carriers may have had an advantage in terms of survival and reproduction over noncarriers. In sickle cell disease the carrier state is thought to confer some resistance to malaria; in cystic fibrosis the carrier state has been postulated to confer resistance to cholera or enteropathogenic *Escherichia coli* infections. Population-based **carrier screening** for cystic fibrosis is recommended for persons of northern European and Ashkenazi Jewish ancestry; population-based screening for sickle cell disease is recommended for persons of African ancestry.

If the frequency of an autosomal recessive disease is known, the frequency of the heterozygote or carrier state can be calculated from the **Hardy-Weinberg formula:**

$$p^2 + 2pq + q^2 = 1$$

where *p* is the frequency of one of a pair of alleles and *q* is the frequency of the other. For example, if the frequency of cystic fibrosis among white Americans is 1 in 2,500 (p^2), then the frequency of the heterozygote (2pq) can be calculated: If $p^2 = 1/2{,}500$, then $p = 1/50$ and $q = 49/50$; $2pq = 2 \times (1/50) \times (49/50) = 98/2500$, or 3.92%.

Pseudodominant Inheritance

Pseudodominant inheritance refers to the observation of apparent dominant (parent to child) transmission of a known autosomal recessive disorder (Fig. 97.8). This occurs when a homozygous affected individual has a partner who is a heterozygous carrier. This is most likely to occur for relatively common recessive traits within a population, such as sickle cell anemia or nonsyndromic autosomal recessive hearing loss caused by deleterious mutations in the *GJB2* , the gene that encodes connexin 26.

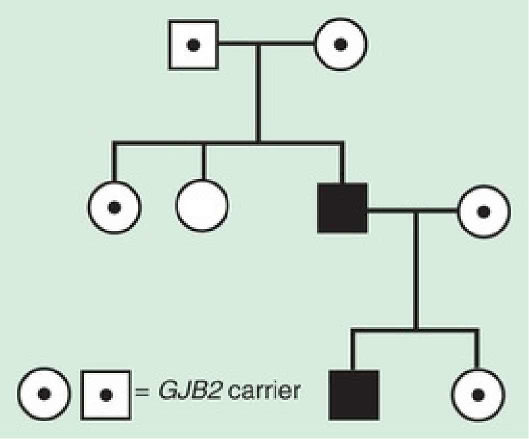

FIG. 97.8 **Pseudodominant inheritance. *Black,* Affected (deaf); *central dot* shows carrier who is asymptomatic (unaffected).**

X-Linked Inheritance

X-linked inheritance describes the inheritance pattern of most disorders caused by deleterious changes in genes located on the X chromosome (Fig. 97.9). In X-liked disorders, males are more commonly affected than females. Female carriers of these disorders are generally unaffected, or if affected, they are affected more mildly than males. In each pregnancy, female carriers have a 25% chance of having an affected son, a 25% chance of having a carrier daughter, and a 50% chance of having a child that does not inherit the mutated X-linked gene. Since affected males pass their X chromosome to all their daughters and their Y chromosome to all their sons, they have a 50% chance of having an unaffected son that does not carry the disease gene and a 50% chance of having a daughter who is a carrier. Male-to-male transmission excludes X-linked inheritance but is seen with autosomal dominant and Y-linked inheritance.

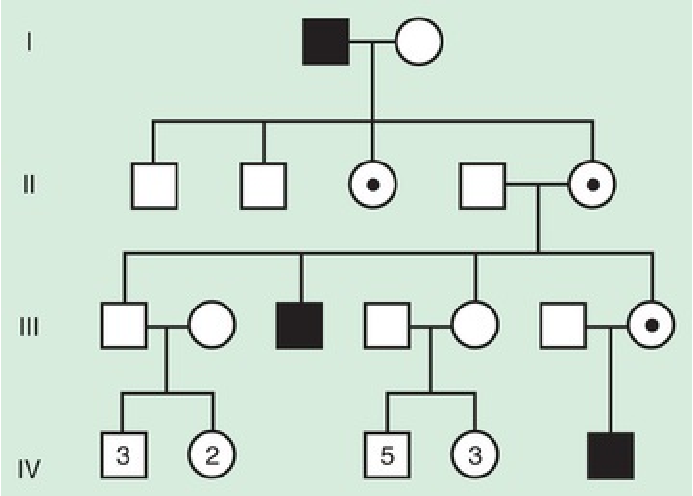

FIG. 97.9 Pedigree demonstrating X-linked recessive inheritance. *Central dot,* Carriers; *Black,* Affected patients.

A female occasionally exhibits signs of an X-linked trait similar to a male. This occurs rarely from homozygosity for an X-linked trait or the presence of a sex chromosome abnormality (45,X or 46,XY female) or skewed or nonrandom X-inactivation. **X chromosome inactivation** occurs early in development and involves the random and irreversible inactivation of most genes on one X chromosome in female cells (Fig. 97.10). In some cases, a preponderance of cells inactivates the same X chromosome, resulting in phenotypic expression of an X-linked pathogenic variant if it resides on the active chromosome. This can occur because of chance, selection against cells that have inactivated the X chromosome carrying the normal gene, or an X chromosome abnormality that results in inactivation of the X chromosome carrying the normal gene.

FIG. 97.10 X-inactivation. *Black* marks the active X chromosome. Color of the cell represents its active X chromosome is paternally (X_p , *blue*) or maternally (X_m , *pink*) derived.

In some X-linked disorders, both **hemizygous** males and heterozygous females who carry an affected X–linked gene have similar phenotypic manifestations. In these cases, an affected male will have a 50% chance of having an affected daughter and a 50% chance of having an unaffected son in each pregnancy, whereas half the male and female offspring of an affected woman will be affected (Fig. 97.11). Some X-linked conditions are lethal in a high percentage of males, such as **incontinentia pigmenti** (see Chapter 614.7). In such cases the pedigree typically shows only affected females and an overall female/male ratio of 2 : 1, with an increased number of miscarriages (Fig. 97.12).

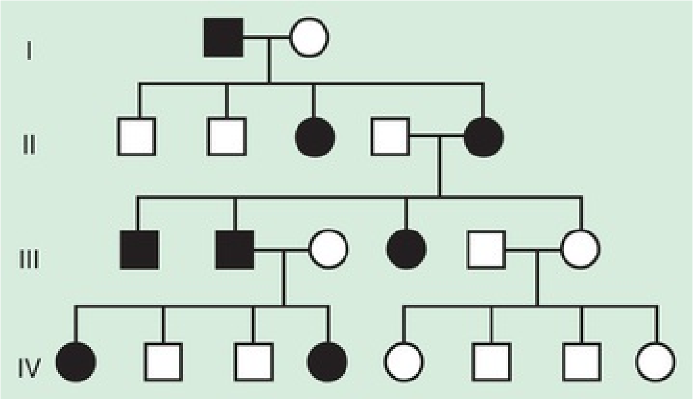

FIG. 97.11 Pedigree pattern demonstrating X-linked dominant inheritance. *Black,* Affected patients. Note there is no father-to-son transmission in this situation, and hemizygosity (i.e., X-linked gene in a male) is not lethal. In some X-linked dominant conditions, X-linked males have a more severe phenotype and might not survive. In that case, only females manifest the disease (see Fig. 97.12).

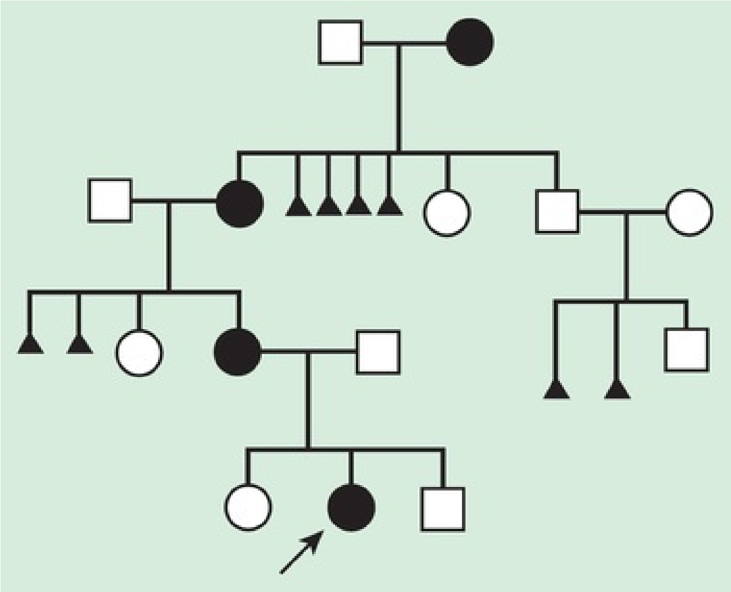

FIG. 97.12 Pedigree of an X-linked dominant disorder with male lethality, such as incontinentia pigmenti. *Black,* Affected patients.

Y-Linked Inheritance

There are few Y-linked traits. These demonstrate *only* male-to-male transmission, and only males are affected (Fig. 97.13). Most Y-linked genes are related to male sex determination and reproduction and are associated with infertility. Therefore, it is rare to see familial transmission of a Y-linked disorder. However, advances in assisted reproductive technologies might make it possible to have familial transmission of male infertility.

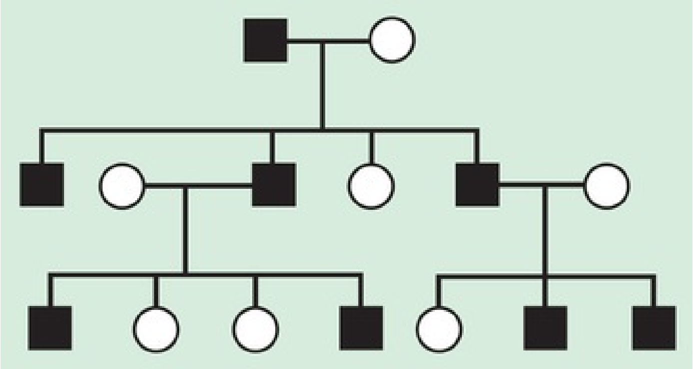

FIG. 97.13 Y-linked inheritance. *Black,* Affected patients.

Inheritance Associated With Pseudoautosomal Regions

Of special note are the pseudoautosomal regions on the X and Y chromosomes. Since these regions are made up of homologous sequences of nucleotides, genes that are located in these regions are present in equal numbers among both males and females. *SHOX* is one of the best-characterized disease genes located in these regions. Heterozygous *SHOX* mutations cause **Leri-Weil dyschondrosteosis** , a rare skeletal dysplasia that involves bilateral bowing of the forearms with dislocations of the ulna at the wrist and generalized short stature. Homozygous *SHOX* mutations cause the much more severe **Langer mesomelic dwarfism** .

Digenic Inheritance

Digenic inheritance explains the occurrence of **retinitis pigmentosa (RP)** in children of parents who each carry a pathogenic variant in a different RP-associated gene (Fig. 97.14). Both parents have normal vision, as would be expected, but their offspring who are **double heterozygotes** —having inherited both mutations—develop RP. Digenic pedigrees can exhibit characteristics of both autosomal dominant (vertical transmission) and autosomal recessive inheritance (1 in 4 recurrence risk). A couple in which the 2 unaffected partners are carriers for mutation in 2 different RP-associated genes that show digenic inheritance have a 1 in 4 risk of having an affected child, similar to what is seen in autosomal recessive inheritance. However, their affected children, and affected children in subsequent generations, have a 1 in 4 risk of transmitting both mutations to their offspring, who would be affected (vertical transmission).

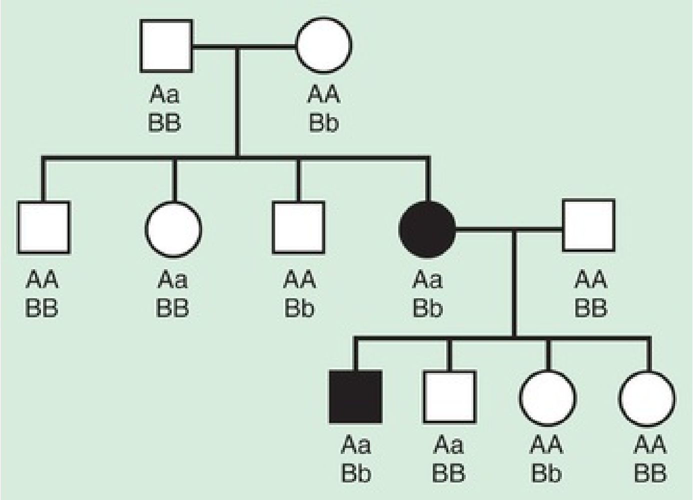

FIG. 97.14 **Digenic pedigree. Here, the disease alleles are *a* and *b* and they reside on distinct genetic loci or genes. For a person to have the disease, heterozygosity for mutant alleles in both genes (A/a; B/b) is required. *Black,* Affected patients.**

Pseudogenetic Inheritance and Familial Clustering

Sometimes nongenetic reasons for the occurrence of a particular disease in multiple family members can produce a pattern that mimics genetic transmission. These nongenetic factors can include identifiable environmental factors, teratogenic exposures, or as yet undetermined or undefined factors. Examples of identifiable factors might include multiple siblings in a family having asthma because of exposure to cigarette smoke from their parents or having failure to thrive, developmental delay, and unusual facial appearance caused by exposure to alcohol during pregnancy.

In some cases the disease is sufficiently common in the general population that some familial clustering occurs simply by chance. Breast cancer affects 11% of all women, and it is possible that several women in a family will develop breast cancer even in the absence of a genetic predisposition. However, hereditary breast cancer associated with mutations in *BRCA1* and *BRCA2* should be suspected in any individual who has a personal history of breast cancer with onset before age 50, early-onset breast and ovarian cancer at any age, bilateral or multifocal breast cancer, a family history of breast cancer or breast and ovarian cancer consistent with autosomal dominant inheritance, or a personal or family history of male breast cancer.

Nonetheless, such clustering within families may be caused by as yet undefined genetic factors or unidentified pathogenic sequence variants (nuclear or mitochondrial).

Nontraditional Inheritance

Some genetic disorders are inherited in a manner that does not follow classical mendelian patterns. Nontraditional inheritance is seen in mitochondrial disorders, triplet repeat expansion diseases, and imprinting defects.

Mitochondrial Inheritance

An individual's mitochondrial genome is entirely derived from the mother because sperm contain relatively few mitochondria, and these are degradated after fertilization. It follows that **mitochondrial inheritance** is essentially **maternal inheritance** . A woman with a mitochondrial genetic disorder can have affected offspring of either sex, but an affected father cannot pass on the disease to his offspring (Fig. 97.15). Mitochondrial DNA mutations are often deletions or point mutations; overall, 1 person in 400 has a maternally inherited pathogenic mitochondrial DNA mutation (see Chapter 106). In individual families, mitochondrial inheritance may be difficult to distinguish from autosomal dominant or X-linked inheritance, but in many cases, the sex of the transmitting and nontransmitting parents can suggest a mitochondrial basis (Table 97.1).

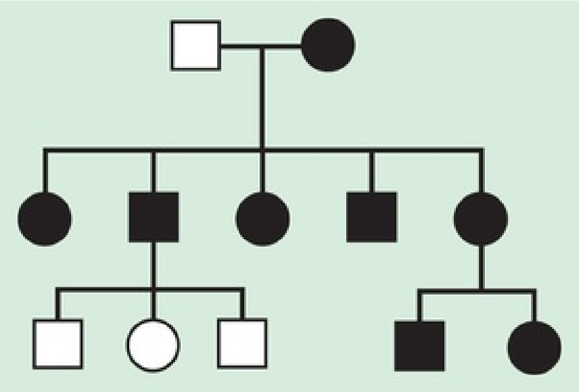

FIG. 97.15 Pedigree of a mitochondrial disorder, exhibiting maternal inheritance. *Black,* Affected patients.

Table 97.1

Representative Examples of Disorders Caused by Mutations in Mitochondrial DNA and Their Inheritance

DISEASE	PHENOTYPE	MOST FREQUENT MUTATION IN mtDNA MOLECULE	HOMOPLASMY vs HETEROPLASMY	INHERITANCE
Leber hereditary optic neuropathy	Rapid optic nerve atrophy, leading to blindness in young adult life; sex bias approximately 50% males with visual loss, only 10% females	Substitution p.Arg340His in *ND1* gene of complex I of electron transport chain; other complex I missense mutations	Homoplasmic (usually)	Maternal

The mitochondria are the cell's suppliers of energy, and it is not surprising that the organs that are most affected by the presence of abnormal mitochondria are those that have the greatest energy requirements, such as the brain, muscle, heart, and liver (see Chapters 105.4 , 388 , 616.2 , and 629.4) (Fig. 97.16). Common manifestations include developmental delay, seizures, cardiac dysfunction, decreased muscle strength and tone, and hearing and vision problems.

FIG. 97.16 The range of affected tissues and clinical phenotypes associated with mutations in mitochondrial DNA (mtDNA). (Modified from Chinnery PF, Turnbull DM: Mitochondrial DNA and disease, *Lancet* 345:SI17–SI21, 1999.)

Mitochondrial diseases can be highly variable in clinical manifestation. This is partly because cells can contain multiple mitochondria, each bearing several copies of the mitochondrial genome. Thus a cell can have a mixture of normal and abnormal mitochondrial genomes, which is referred to as **heteroplasmy** . In contrast, **homoplasmy** refers a state in which all copies of the mitochondrial genome carry the same sequence variant. Unequal segregation of mitochondria carrying normal and abnormal genomes and replicative advantage can result in varying degrees of heteroplasmy in the cells of an affected individual, including the individual ova of an affected female. Because of this, a mother may be asymptomatic yet have children who are severely affected. The level of heteroplasmy at which disease symptoms typically appear can also vary based on the type of mitochondrial variant. Detection of mitochondrial genome variants can require sampling of the affected tissue for DNA analysis. In some tissues, such as blood, testing for mitochondrial DNA variants may be inadequate because the variant may be found primarily in affected tissues such as muscle (Fig. 97.17).

Growth and differentiation factor 15 (GDF-15) and blood lactate levels are screening tests for mitochondrial disorders.

Triplet Repeat Expansion Disorders

Triplet repeat expansion disorders are distinguished by the special dynamic nature of the disease-causing variant. Triplet repeat expansion disorders include fragile X syndrome, myotonic dystrophy, Huntington disease, and spinocerebellar ataxias (Table 97.2 and Fig. 97.18). These disorders are caused by expansion in the number of 3-bp repeats. The fragile X gene, *FMR1*, normally has 5-40 CGG triplets. An error in replication can result in expansion of that number to a level in the gray zone between 41 and 58 repeats, or to a level referred to as **premutation** , which comprises 59-200 repeats. Some premutation carriers, more often males, develop fragile X–associated tremor/ataxia syndrome (FXTAS) as adults. Female premutation carriers are at risk for fragile X–associated primary ovarian insufficiency (*FXPOI*). Persons with a premutation are also at risk for having the repeat expand further in subsequent meiosis, thus crossing into the range of a **full mutation** (>200 repeats) in offspring. With this number of repeats, the *FMR1* gene becomes hypermethylated, and protein production is lost.

Table 97.2

Diseases Associated With Polynucleotide Repeat Expansions

DISEASE	DESCRIPTION	REPEAT SEQUENCE	NORMAL RANGE	ABNORMAL RANGE	PARENT IN WHOM EXPANSION USUALLY OCCURS	LOCATIO OF EXPANSI
CATEGORY 1						
Huntington disease	Loss of motor control, dementia, affective disorder	CAG	6-34	36-100 or more	More often through father	Exon
Spinal and bulbar muscular atrophy	Adult-onset motor-neuron disease associated with androgen insensitivity	CAG	11-34	40-62	More often through father	Exon
Spinocerebellar ataxia type 1	Progressive ataxia, dysarthria,	CAG	6-39	41-81	More often through father	Exon

	dysmetria					
Spinocerebellar ataxia type 2	Progressive ataxia, dysarthria	CAG	15-29	35-59	—	Exon
Spinocerebellar ataxia type 3 (Machado-Joseph disease)	Dystonia, distal muscular atrophy, ataxia, external ophthalmoplegia	CAG	13-36	68-79	More often through father	Exon
Spinocerebellar ataxia type 6	Progressive ataxia, dysarthria, nystagmus	CAG	4-16	21-27	—	Exon
Spinocerebellar ataxia type 7	Progressive ataxia, dysarthria, retinal degeneration	CAG	7-35	38-200	More often through father	—
Spinocerebellar ataxia type 17	Progressive ataxia, dementia, bradykinesia, dysmetria	CAG	29-42	47-55	—	Exon
Dentatorubral-pallidoluysian atrophy/Haw River syndrome	Cerebellar atrophy, ataxia, myoclonic epilepsy, choreoathetosis, dementia	CAG	7-25	49-88	More often through father	Exon
CATEGORY 2						
Pseudoachondroplasia, multiple epiphyseal dysplasia	Short stature, joint laxity, degenerative joint disease	GAC	5	6-7	—	Exon
Oculopharyngeal muscular dystrophy	Proximal limb weakness, dysphagia, ptosis	GCG	6	7-13	—	Exon
Cleidocranial dysplasia	Short stature, open skull sutures with bulging calvaria, clavicular hypoplasia, shortened fingers, dental anomalies	GCG, GCT, GCA	17	27 (expansion observed in 1 family)	—	Exon
Synpolydactyly	Polydactyly and syndactyly	GCG, GCT, GCA	15	22-25	—	Exon
CATEGORY 3						
Myotonic dystrophy (DM1; chromosome 19)	Muscle loss, cardiac arrhythmia, cataracts, frontal balding	CTG	5-37	100 to several thousand	Either parent, but expansion to congenital form through mother	3′ untransla region
Myotonic dystrophy (DM2; chromosome 3)	Muscle loss, cardiac arrhythmia,	CCTG	<75	75-11,000	—	3′ untransla region

	cataracts, frontal balding					
Friedreich ataxia	Progressive limb ataxia, dysarthria, hypertrophic cardiomyopathy, pyramidal weakness in legs	GAA	7-2	200-900 or more	Autosomal recessive inheritance, so disease alleles are inherited from both parents	Intron
Fragile X syndrome (FRAXA)	Intellectual impairment, large ears and jaws, macroorchidism in males	CGG	6-52	200-2,000 or more	Exclusively through mother	5′ untransla region
Fragile site (FRAXE)	Mild intellectual impairment	GCC	6-35	>200	More often through mother	5′ untransla region
Spinocerebellar ataxia type 8	Adult-onset ataxia, dysarthria, nystagmus	CTG	16-37	107-127	More often through mother	3′ untransla region
Spinocerebellar ataxia type 10	Ataxia and seizures	ATTCT	12-16	800-4,500	More often through father	Intron
Spinocerebellar ataxia type 12	Ataxia, eye movement disorders; variable age at onset	CAG	7-28	66-78	—	5′ untransla region
Progressive myoclonic epilepsy type 1	Juvenile-onset convulsions, myoclonus, dementia	12-bp repeat motif	2-3	30-75	Autosomal recessive inheritance, so transmitted by both parents	5′ untransla region

Transcriptional silencing = loss-of-function mutation
2 to 5-fold increase in FMR1 mRNA = ? gain-of-RNA function
Impaired transcriptional elongation = loss of frataxin function
Expanded polyglutamine tracts in the huntingtin protein confer novel properties on the protein
Expanded CUG repeats in the RNA confer novel properties on the RNA
Loss of RNA binding = impaired translational repression of target RNAs
Neuronal intranuclear inclusions
Increased Fe in mitochondria, reduced heme synthesis, reduced activity of Fe-S complex containing proteins
Increased and/or promiscuous protein:protein interactions with transcription factors → loss of their function
Expanded CUG repeats bind increased amounts of RNA-binding proteins → impaired RNA splicing of key proteins

FIG. 97.18 The locations of the trinucleotide repeat expansions and the sequence of each trinucleotide in 5 representative trinucleotide repeat diseases, shown on a schematic of a generic pre–messenger RNA (mRNA). The minimal number of repeats in the DNA sequence of the affected gene associated with the disease is also indicated, as well as the effect of the expansion on the mutant RNA or protein. (From Nussbaum RL, McInnes RR, Willard HF, editors: *Thompson & Thompson genetics in medicine,* ed 8, Philadelphia, 2016, Elsevier; based partly on an unpublished figure of John A. Phillips III, Vanderbilt University.)

Some triplet expansions associated with other genes can cause disease through a mechanism other than decreased protein production. In Huntington disease the expansion causes the gene product to have a new, toxic effect on the neurons of the basal ganglia. For most triplet repeat disorders, there is a clinical correlation to the size of the expansion, with a greater expansion causing more severe symptoms and having an earlier age of disease onset. The observation of increasing severity of disease and early age at onset in subsequent generations is termed **genetic anticipation** and is a defining characteristic of many triplet repeat expansion disorders (Fig. 97.19).

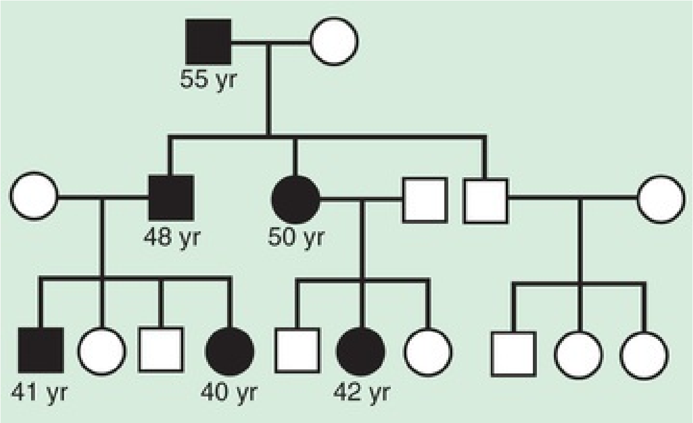

FIG. 97.19 Myotonic dystrophy pedigree illustrating genetic anticipation. In this case the age at onset for family members affected with an autosomal dominant disease is lower in more recent generations. *Black,* Affected patients.

Genetic Imprinting

The 2 copies of most autosomal genes are functionally equivalent. However, in some cases, only 1 copy of a gene is transcribed and the 2nd copy is silenced. This gene silencing is typically associated with methylation of DNA, which is an **epigenetic** modification, meaning it does not change the nucleotide sequence of the DNA (Fig. 97.20). In **imprinting** , gene expression depends on the parent of origin of the chromosome (see Chapter 98.8). Imprinting disorders result from an imbalance of active copies of a given gene, which can occur for several reasons. Prader-Willi and Angelman syndromes, two distinct disorders associated with developmental impairment, are illustrative. Both can be caused by microdeletions of chromosome 15q11-12. The microdeletion in **Prader-Willi syndrome** is always on the paternally derived chromosome 15, whereas in **Angelman syndrome** it is on the maternal copy. *UBE3A* is the gene responsible for Angelman syndrome. The paternal copy of *UBE3A* is transcriptionally silenced in the brain, and the maternal copy continues to be transcribed. If an individual has a maternal deletion, an insufficient amount of UBE3A protein is produced in the brain, resulting in the neurologic deficits seen in Angelman syndrome.

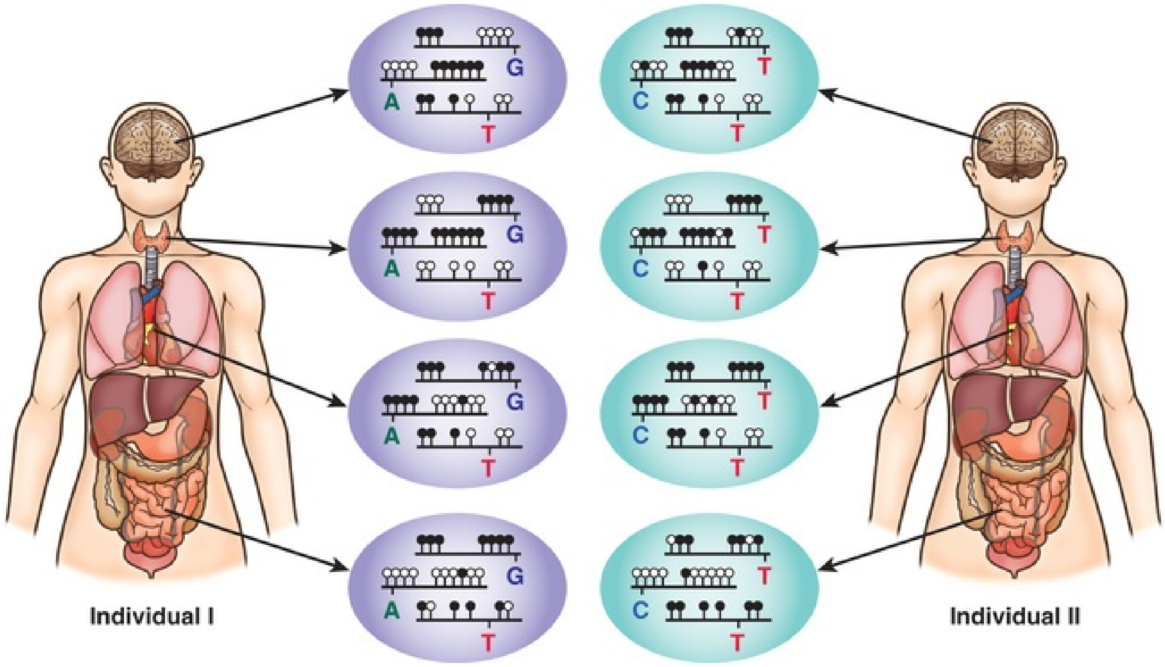

FIG. 97.20 **Tissue-specific DNA methylation and epigenetic heterogeneity among individuals. A subset of the DNA methylation patterns within a cell is characteristic of that cell type. Cell type–specific and tissue-specific DNA methylation patterns are illustrated by organ-to-organ variations in the clusters of methylated CpGs (cytosine-phosphate-guanine bases) within the same individual. Despite overall consistency in tissue-specific DNA methylation patterns, variations in these patterns exist among different individuals. Methylated CpGs are indicated by a *filled circle* and unmethylated CpGs by an *open circle* . Single nucleotide polymorphisms (SNPs) are indicated by the corresponding base. (Redrawn from Brena RM, Huang THM, Plass C: Toward a human epigenome, *Nat Genet* 38:1359–1360, 2006.)**

Uniparental disomy (UPD) , the rare occurrence of a child inheriting both copies of a chromosome from the same parent, is another genetic mechanism that can cause Prader-Willi and Angelman syndromes. Inheriting both chromosomes 15 from the mother is functionally the same as deletion of the paternal 15q12 and results in Prader-Willi syndrome. Approximately 30% of cases of Prader-Willi syndrome are caused by maternal UPD15, whereas paternal UPD15 accounts for only 3% of Angelman syndrome (see Chapter 98.8).

A mutation in an imprinted gene is another cause. Pathologic variants in *UBE3A* account for almost 11% of patients with Angelman syndrome and also result in familial transmission. The most uncommon cause is a mutation in the imprinting center, which results in an inability to correctly imprint *UBE3A* . In a woman, inability to reset the imprinting on her paternally inherited chromosome 15 imprint results in a 50% risk of passing on an incorrectly methylated copy of *UBE3A* to a child, who would then develop Angelman syndrome.

Besides 15q12, other imprinted regions of clinical interest include the short arm of chromosome 11, where the genes for Beckwith-Wiedemann syndrome and nesidioblastosis map, and the long arm of chromosome 7 with maternal UPD of 7q, which has been associated with some cases of idiopathic short stature and Russell-Silver syndrome.

Imprinting of a gene can occur during gametogenesis or early embryonic development (reprogramming). Genes can become inactive or active by various mechanisms including DNA methylation or demethylation or histone acetylation or deacetylation, with different patterns of (de)methylation noted on paternal or maternal imprintable chromosome regions. Some genes demonstrate tissue-specific imprinting (see Fig. 97.20). Several studies suggest a small but significantly increased incidence of imprinting disorders, specifically Beckwith-Wiedemann and Angelman syndrome, associated with assisted reproductive technologies such as in vitro fertilization and intracytoplasmic sperm injection. However, the overall incidence of these disorders in children conceived using assisted reproductive technologies is likely to be <1%.

Multifactorial and Polygenic Inheritance

Multifactorial inheritance refers to traits that are caused by a combination of inherited, environmental, and stochastic factors (Fig. 97.21). Multifactorial traits differ from **polygenic inheritance** , which refers to traits that result from the additive effects of multiple genes. Multifactorial traits segregate within families but do not exhibit a consistent or recognizable inheritance pattern. Characteristics include the following:

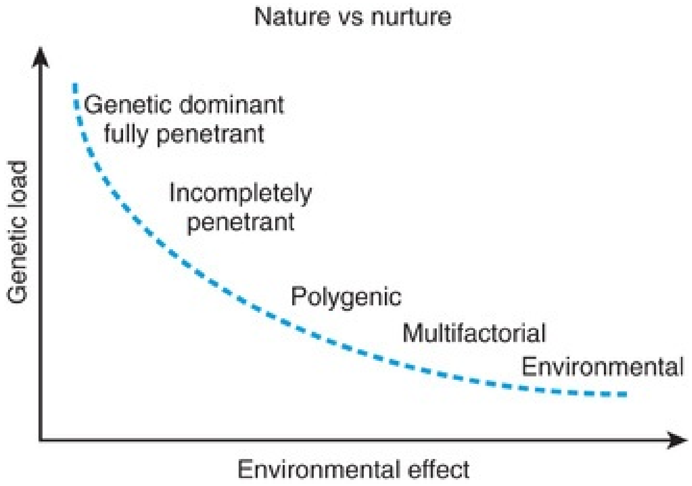

FIG. 97.21 The progressive decrease in the genetic load contributing to

the development of a disease creates a smooth transition in the distribution of illnesses on an etiologic diagram. In theory, no diseases are completely free from the influence of both genetic and environmental factors. (From Bomprezzi R, Kovanen PE, Martin R: New approaches to investigating heterogeneity in complex traits, *J Med Genet* 40:553–559, 2003. Reproduced with permission from the BMJ Publishing Group.)

◆ There is a similar rate of recurrence among all first-degree relatives (parents, siblings, offspring of affected child). It is unusual to find a substantial increase in risk for relatives related more distantly than second degree to the index case.

◆ The risk of recurrence is related to the incidence of the disease.

◆ Some disorders have a sex predilection, as indicated by an unequal male:female incidence. Pyloric stenosis, for example, is more common in males, whereas congenital dislocation of the hips is more common in females. With an altered sex ratio, the risk is higher for the relatives of an index case whose gender is less often affected than relatives of an index case of the more frequently affected gender. For example, the risk to the son of an affected female with infantile pyloric stenosis is 18%, compared with the 5% risk for the son of an affected male. An affected female presumably has a greater genetic susceptibility, which she can then pass on to her offspring.

◆ The likelihood that both identical twins will be affected with the same malformation is <100% but much greater than the chance that both members of a nonidentical twin pair will be affected. This contrasts with the pattern seen in mendelian inheritance, in which identical twins almost always share fully penetrant genetic disorders.

◆ The risk of recurrence is increased when multiple family members are affected. A simple example is that the risk of recurrence for unilateral cleft lip and palate is 4% for a couple with 1 affected child and increases to 9% with 2 affected children. It is sometimes difficult to distinguish between a multifactorial and mendelian etiology in families with multiple affected individuals.

◆ The risk of recurrence may be greater when the disorder is more severe. For example, an infant who has long-segment Hirschsprung disease has a greater chance of having an affected sibling than the infant who has short-segment Hirschsprung disease.

There are two types of multifactorial traits. One exhibits continuous variation, with “normal” individuals falling within a statistical range—often defined as having a value 2 standard deviations (SDs) above and/or below the mean—and “abnormals” falling outside that range. Examples include such traits as intelligence, blood pressure, height, and head circumference. For many of these traits, offspring values can be estimated based on a modified average of their parental values, with nutritional and environmental factors playing an important role.

With other multifactorial traits, the distinction between normal and abnormal is based on the presence or absence of a particular trait. Examples include pyloric stenosis, neural tube defects, congenital heart defects, and cleft lip and cleft palate. Such traits follow a **threshold model** (see Fig. 97.15). A distribution of liability because of genetic and nongenetic factors is postulated in the population. Individuals who exceed a threshold liability develop the trait, and those below the threshold do not.

The balance between genetic and environmental factors is demonstrated by neural tube defects. Genetic factors are implicated by the increased recurrence risk for parents of an affected child compared with the general population, yet the recurrence risk is about 3%, less than what would be expected if the trait was caused by a single, fully penetrant mutation. The role of nongenetic environmental factors is shown by the recurrence risk decreasing up to 87% if the mother-to-be takes 4 mg of folic acid daily starting 3 mo before conception.

Many adult-onset diseases behave as if caused by multifactorial inheritance. Diabetes, coronary artery disease, and schizophrenia are examples.

CHAPTER 98

Cytogenetics

Carlos A. Bacino, Brendan Lee

Clinical cytogenetics is the study of chromosomes: their structure, function, inheritance, and abnormalities. Chromosome abnormalities are very common and occur in approximately 1–2% of live births, 5% of stillbirths, and 50% of early fetal losses in the 1st trimester of pregnancy (Table 98.1). Chromosome abnormalities are more common among individuals with intellectual disability and play a significant role in the development of some neoplasias.

Table 98.1

Incidence of Chromosomal Abnormalities in Newborn Surveys

TYPE OF ABNORMALITY	NUMBER	APPROXIMATE INCIDENCE
SEX CHROMOSOME ANEUPLOIDY		
Males (43,612 newborns)		
47,XXY	45	1/1,000*
47,XYY	45	1/1,000
Other X or Y aneuploidy	32	1/1,350
Total	**122**	**1/360 male births**
Females (24,547 newborns)		
45,X	6	1/4,000
47,XXX	27	1/900
Other X aneuploidy	9	1/2,700
Total	**42**	**1/580 female births**
AUTOSOMAL ANEUPLOIDY (68,159 NEWBORNS)		
Trisomy 21	82	1/830
Trisomy 18	9	1/7,500
Trisomy 13	3	1/22,700
Other aneuploidy	2	1/34,000
Total	**96**	**1/700 live births**
STRUCTURAL ABNORMALITIES (68,159 NEWBORNS)		
Balanced Rearrangements		
Robertsonian	62	1/1,100

Other	77	1/885
Unbalanced Rearrangements		
Robertsonian	5	1/13,600
Other	38	1/1,800
Total	**182**	**1/375 live births**
All chromosome abnormalities	**442**	**1/154 live births**

[*] Recent studies show the prevalence is currently 1:580.

Data from Hsu LYF: Prenatal diagnosis of chromosomal abnormalities through amniocentesis. In Milunsky A, editor: *Genetic disorders and the fetus* , ed 4, Baltimore, 1998, Johns Hopkins University Press, pp 179–248.

Chromosome analyses are indicated in persons presenting with multiple congenital anomalies, dysmorphic features, and/or intellectual disability. The specific indications for studies include advanced maternal age (>35 yr), multiple abnormalities on fetal ultrasound (prenatal testing), multiple congenital anomalies, unexplained growth restriction in the fetus, postnatal problems in growth and development, ambiguous genitalia, unexplained intellectual disability with or without associated anatomic abnormalities, primary amenorrhea or infertility, recurrent miscarriages (≥3) or prior history of stillbirths and neonatal deaths, a first-degree relative with a known or suspected structural chromosome abnormality, clinical findings consistent with a known anomaly, some malignancies, and chromosome breakage syndromes (e.g., Bloom syndrome, Fanconi anemia).

98.1

Methods of Chromosome Analysis

Carlos A. Bacino, Brendan Lee

Cytogenetic studies are usually performed on peripheral blood lymphocytes, although cultured fibroblasts obtained from a skin biopsy may also be used. Prenatal (fetal) chromosome studies are performed with cells obtained from the amniotic fluid (amniocytes), chorionic villus tissue, and fetal blood or, in the case of preimplantation diagnosis, by analysis of a *blastomere* (cleavage stage) biopsy, polar body biopsy, or blastocyst biopsy. Cytogenetic studies of bone marrow have an important role in tumor surveillance, particularly among patients with leukemia. These are useful to determine induction of remission and success of therapy or in some cases the occurrence of relapses.

Chromosome anomalies include abnormalities of number and structure and are the result of errors during cell division. There are 2 types of cell division: mitosis, which occurs in most somatic cells, and meiosis, which is limited to the germ cells. In **mitosis,** 2 genetically identical daughter cells are produced from a single parent cell. DNA duplication has already occurred during **interphase** in the S phase of the cell cycle (DNA synthesis). Therefore, at the beginning of mitosis the chromosomes consist of 2 double DNA strands joined together at the centromere, known as *sister chromatids.* Mitosis can be divided into 4 stages: prophase, metaphase, anaphase, and telophase. **Prophase** is characterized by condensation of the DNA. Also during prophase, the nuclear membrane and the nucleolus disappear and the mitotic spindle forms. In **metaphase** the chromosomes are maximally compacted and are clearly visible as distinct structures. The chromosomes align at the center of the cell, and spindle fibers connect to the centromere of each chromosome and extend to centrioles at the 2 poles of the mitotic figure. In **anaphase** the chromosomes divide along their longitudinal axes to form 2 daughter chromatids, which then migrate to opposite poles of the cell. **Telophase** is characterized by formation of 2 new nuclear membranes and nucleoli, duplication of the centrioles, and cytoplasmic cleavage to form the 2 daughter cells.

Meiosis begins in the female oocyte during fetal life and is completed years to decades later. In males it begins in a particular spermatogonial cell sometime between adolescence and adult life and is completed in a few days. Meiosis is preceded by DNA replication so that at the outset, each of the 46 chromosomes consists of 2 chromatids. In meiosis, a **diploid cell** (2n = 46 chromosomes) divides to form **4 haploid cells** (n = 23 chromosomes). Meiosis consists of 2 major rounds of cell division. In **meiosis I** , each of the homologous chromosomes pair precisely so that **genetic recombination** , involving exchange between 2 DNA strands (**crossing over**), can occur. This results in reshuffling of the genetic information for the recombined chromosomes and allows further genetic diversity. Each daughter cell then receives 1 of each of the 23 homologous chromosomes. In oogenesis, one of the daughter cells receives most of the cytoplasm and becomes the egg, whereas the other smaller cell becomes the first polar body. **Meiosis II** is similar to a mitotic division but without a preceding round of DNA duplication (replication). Each of the 23 chromosomes divides longitudinally, and the homologous chromatids migrate to opposite poles of the cell. This produces 4 spermatogonia in males, or an egg cell and a 2nd polar body in females, each with a haploid (n = 23) set of chromosomes. Consequently, meiosis fulfills 2 crucial roles: It reduces the chromosome number from diploid (46) to haploid (23) so that on fertilization a diploid number is restored, and it allows genetic recombination.

Two common errors of cell division may occur during meiosis or mitosis, and either can result in an abnormal number of chromosomes. The 1st error is **nondisjunction** , in which 2 chromosomes fail to separate during meiosis and thus migrate together into one of the new cells, producing 1 cell with 2 copies of the chromosome and another with no copy. The 2nd error is **anaphase lag** , in which a chromatid or chromosome is lost during mitosis because it fails to move quickly enough during anaphase to become incorporated into 1 of the new daughter cells (Fig. 98.1).

(From Gardner RJM, Sutherland GR. *Chromosome abnormalities and genetic counseling,* ed 3 New York, 2003, Oxford University Press, p 33, Figure 43.1. By permission of Oxford University Press, Inc, www.oup.com .)**

For chromosome analysis, cells are cultured (for varying periods depending on cell type), with or without stimulation, and then artificially arrested in mitosis during metaphase (or prometaphase), later subjected to a hypotonic solution to allow disruption of the nuclear cell membrane and proper dispersion of the chromosomes for analysis, fixed, banded, and finally stained. The most commonly used banding and staining method is the **GTG banding** (G-bands trypsin Giemsa), also known as **G banding** , which produces a unique combination of dark (G-positive) and light (G-negative) bands that permits recognition of all individual 23 chromosome pairs for analysis.

Metaphase chromosome spreads are first evaluated microscopically, and then their images are photographed or captured by a video camera and stored on a computer for later analysis. Humans have 46 chromosomes or 23 pairs, which are classified as *autosomes* for chromosomes 1-22, and the *sex chromosomes* , often referred as *sex complement* : XX for females and XY for males. The homologous chromosomes from a metaphase spread can then be paired and arranged systematically to assemble a karyotype according to well-defined standard conventions such as those established by International System for Human Cytogenetic Nomenclature (ISCN), with chromosome 1 being the largest and 22 the smallest. According to nomenclature, the description of the karyotype includes the total number of chromosomes followed by the sex chromosome constitution. A normal karyotype is 46,XX for females and 46,XY for males (Fig. 98.2). Abnormalities are noted after the sex chromosome complement.

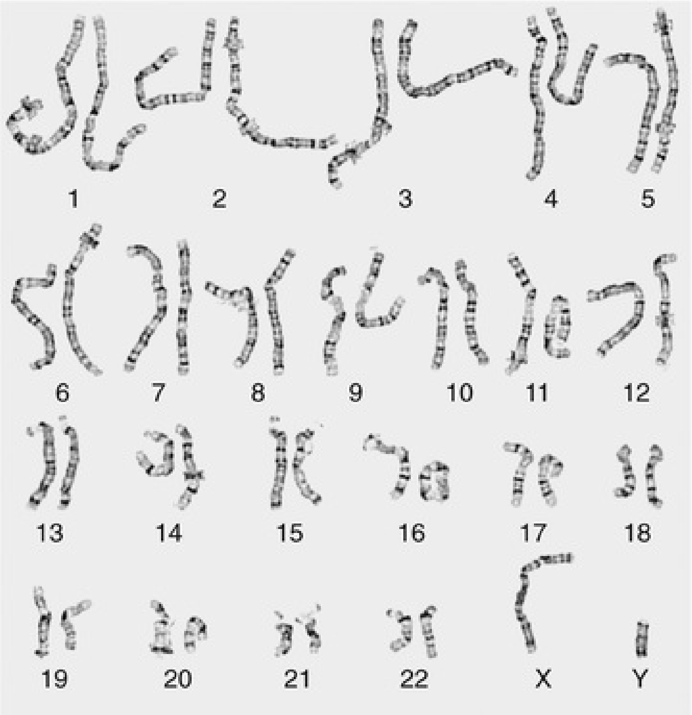

FIG. 98.2 **Karyotype of a normal male at the 550-600 band level. The longer the chromosomes are captured at metaphase or sometimes prometaphase, the more bands that can be visualized.**

Although the internationally accepted system for human chromosome classification relies largely on the length and banding pattern of each chromosome, the position of the centromere relative to the ends of the chromosome also is a useful distinguishing feature (Fig. 98.3). The centromere divides the chromosome in 2, with the short arm designated the **p arm** and the long arm designated the **q arm** . A plus or minus sign before the number of a chromosome indicates that there is an extra or missing chromosome, respectively. Table 98.2 lists some of the abbreviations used for the descriptions of chromosomes and their abnormalities. A metaphase chromosome spread usually shows 450-550 bands. Prophase and prometaphase chromosomes are longer, are less condensed, and often show 550-850 bands. High-resolution analysis may detect small chromosome abnormalities although has been mostly replaced by chromosome microarray studies (array CGH or aCGH).

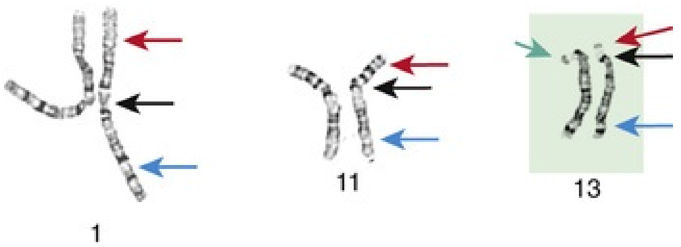

FIG. 98.3 Example of different chromosome types according to the position of the centromere. On the *left* is a chromosome 1 pair with the centromere equidistant from the short and long arm (also known as *metacentric*). In the center is a chromosome 11 pair that is submetacentric. On the *right* is a chromosome 13 pair that is an example of an acrocentric chromosome. Acrocentric chromosomes contain a very small short arm, stalks, and satellite DNA. The *black arrow* indicates the position of the centromere. The *blue arrow* shows the long arm of a chromosome. The *red arrow* shows the short arm of a chromosome. The *green arrow* highlights the satellite region, which is made of DNA repeats. The *light area* between the short arm and the satellite is known as the *stalk.*

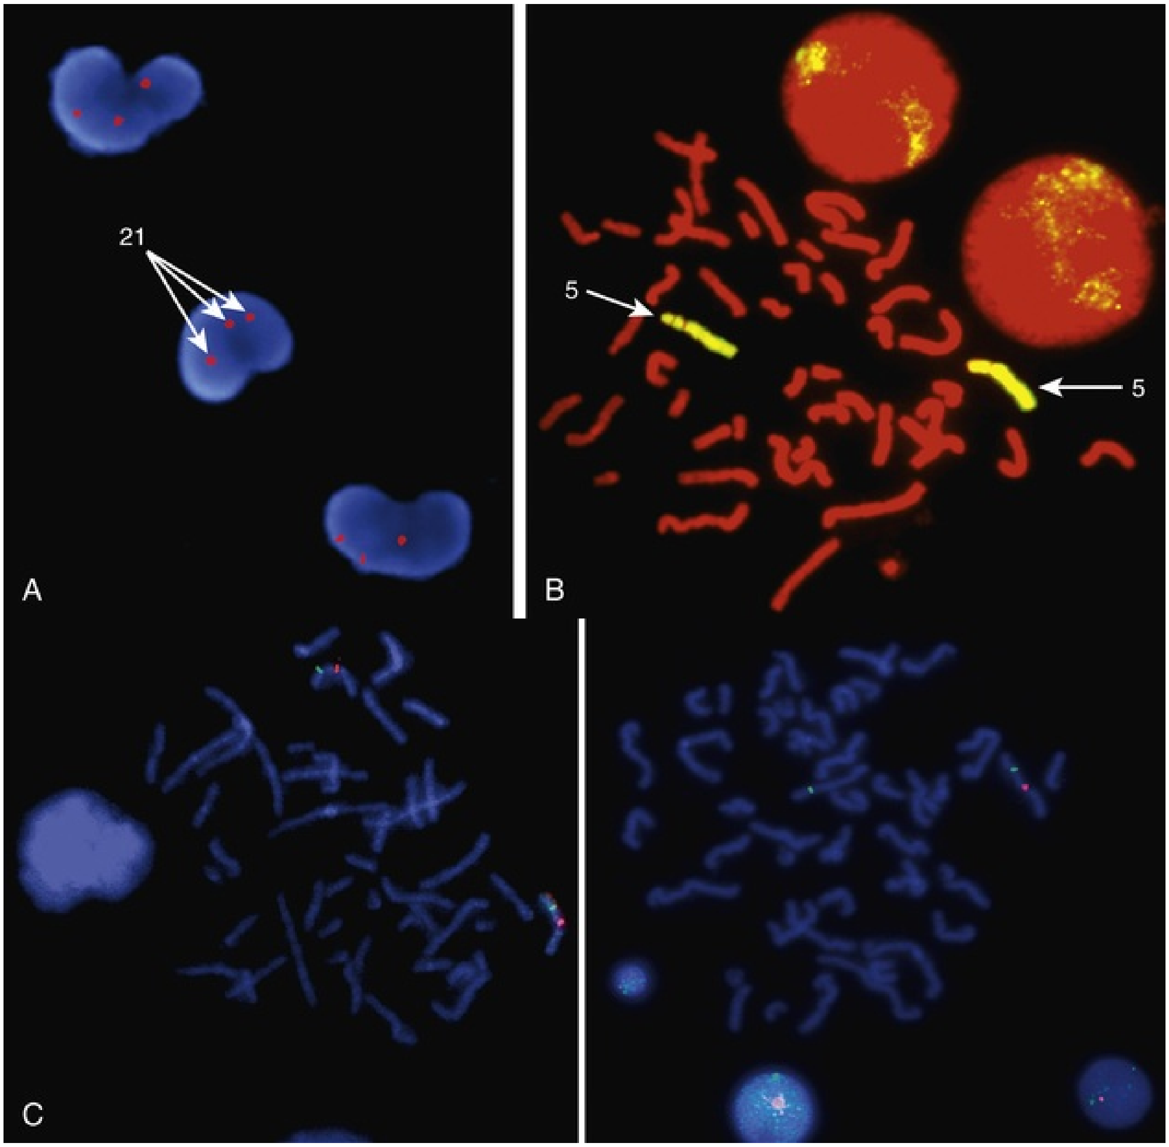
Table 98.2

Some Abbreviations Used for Description of Chromosomes and Their Abnormalities

ABBREV	MEANING	EXAMPLE	CONDITION
XX	Female	46,XX	Normal female karyotype
XY	Male	46,XY	Normal male karyotype
[##]	Number [#]	46,XY[12]/47,XXY[10]	Number of cells in each clone, typically inside brackets

	of cells		Mosaicism in Klinefelter syndrome with 12 normal cells and 10 cells with an extra X chromosome
cen	Centromere		
del	Deletion	46,XY,del(5p)	Male with deletion of chromosome 5 short arm
der	Derivative	46,XX,der(2),t(2p12;7q13)	Female with a structurally rearranged chromosome 2 that resulted from a translocation between chromosomes 2 (short arm) and 7 (long arm)
dup	Duplication	46,XY,dup(15)(q11-q13)	Male with interstitial duplication in the long arm of chromosome 15 in the Prader-Willi/Angelman syndrome region
ins	Insertion	46,XY,ins(3)(p13q21q26)	Male with an insertion within chromosome 3
			A piece between q21q26 has reinserted on p13
inv	Inversion	46,XY,inv(2)(p21q31)	Male with pericentric inversion of chromosome 2 with breakpoints at bands p21 and q31
ish	Metaphase FISH	46,XX.ish del(7)(q11.23q11.23)	Female with deletion in the Williams syndrome region detected by in situ hybridization
nuc ish	Interphase FISH	nuc ish(DXZ1 × 3)	Interphase in situ hybridization showing 3 signals for the X chromosome centromeric region
mar	Marker	47,XY,+mar	Male with extra, unidentified chromosome material
mos	Mosaic	mos 45,X[14]/46,XX[16]	Turner syndrome mosaicism (analysis of 30 cells showed that 14 cells were 45,X and 16 cells were 46,XX)
p	Short arm	46,XY,del(5)(p12)	Male with a deletion on the short arm of chromosome 5, band p12 (short nomenclature)
q	Long arm	46,XY,del(5)(q14)	Male with a deletion on the long arm of chromosome 5, band 14
r	Ring chromosome	46,X,r(X)(p21q27)	Female with 1 normal X chromosome and a ring X chromosome
t	Translocation	t(2;8)(q33;q24.1)	Interchange of material between chromosomes 2 and 8 with breakpoints at bands 2q33 and 8q24.1
ter	Terminal	46,XY,del(5)(p12-pter)	Male with a deletion of chromosome 5 between p12 and the end of the short arm (long nomenclature)
/	Slash	45,X/46,XY	Separate lines or clones Mosaicism for monosomy X and a male cell line
+	Gain of	47,XX,+21	Female with trisomy 21
−	Loss of	45,XY,−21	Male with monosomy 21

Molecular techniques (e.g., FISH, CMA, aCGH) have filled a significant void for the diagnosing cryptic chromosomal abnormalities. These techniques identify subtle abnormalities that are often below the resolution of standard cytogenetic studies. **Fluorescence in situ hybridization (FISH)** is used to identify the presence, absence, or rearrangement of *specific* DNA segments and is performed with gene- or region-specific DNA probes. Several FISH probes are used in the clinical setting: unique sequence or single-copy probes, repetitive-sequence probes (alpha satellites in the pericentromeric regions), and multiple-copy probes (chromosome specific or painting) (Fig. 98.4*A* and *B*). FISH involves using a unique, known DNA sequence or probe labeled with a fluorescent dye that is complementary to the studied region of disease interest. The labeled probe is exposed to the DNA on a microscope slide, typically metaphase or interphase chromosomal DNA. When the probe pairs with its complementary DNA sequence, it can then be visualized by fluorescence microscopy (Fig. 98.5). In metaphase chromosome spreads, the exact chromosomal location of each probe copy can be documented, and often the *number of copies* (deletions, duplications) of the DNA sequence as well. When the interrogated segments (as in genomic duplications) are close together, only interphase cells can accurately determine the presence of 2 or more copies or signals since in metaphase cells, some duplications might falsely appear as a single signal.



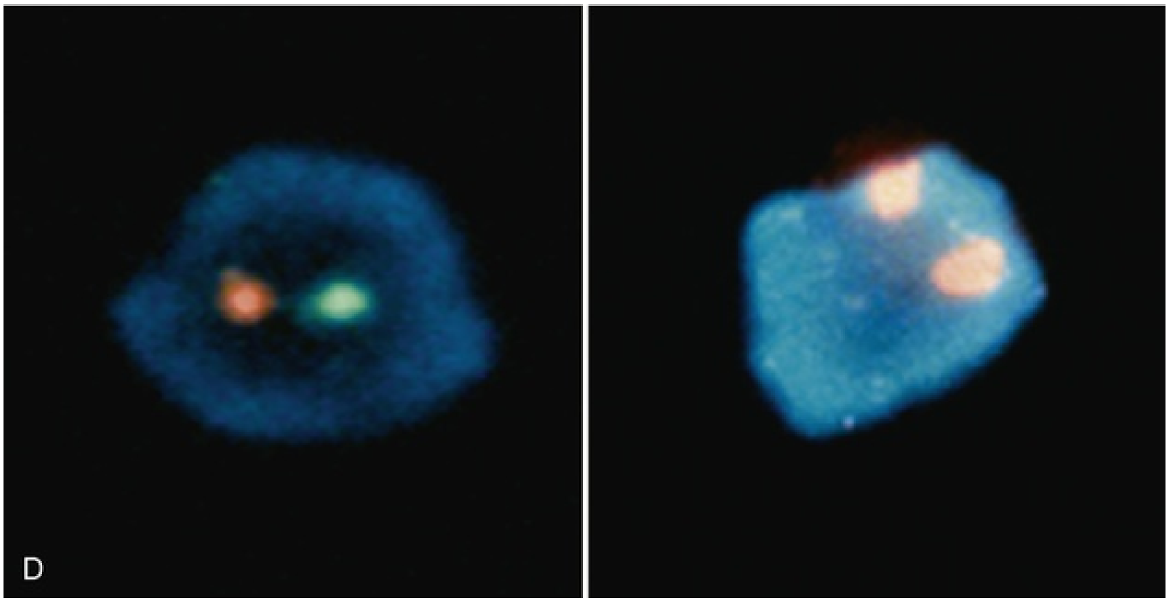


FIG. 98.4 **A,** FISH analysis of interphase peripheral blood cells from a patient with Down syndrome using a chromosome 21–specific probe. The 3 red signals mark the presence of 3 chromosomes 21. **B,** FISH analysis of a metaphase chromosome spread from a clinically normal individual using a whole chromosome paint specific for chromosome 5. Both chromosomes 5 are completely labeled *(yellow)* along their entire length. **C,** FISH on metaphase cells using a unique sequence probe that hybridizes to the elastin gene on chromosome 7q11.23, inside the Williams syndrome critical region. The elastin probe is labeled in *red* , and a control probe on chromosome 7 is labeled in *green* . The *left* image shows normal hybridization to chromosome 7, with 2 signals for the elastin region and 2 for the control probe. The *right* image shows a normal chromosome on the right with control and elastin signals, and a deleted chromosome 7 on the left, evidenced by a single signal for the control probe. This image corresponds to a patient with a Williams syndrome region deletion. **D,** FISH in interphase cells using DNA probes that hybridize to repetitive α-satellite sequences in the pericentromeric region for the sex chromosomes. *Left,* interphase cells with 2 signals, 1 labeled in *red* for the X chromosome and *green* for the Y chromosome, consistent with a normal male chromosome complement. *Right,* interphase cell showing 2 *red* signals for the X chromosome, compatible with a normal female chromosome complement.

FIG. 98.5 FISH involves denaturation of double-stranded DNA as present in metaphase chromosomes or interphase nuclei on cytogenetic slide preparations (**A**) into single-stranded DNA (**B**). The slide-bound (in situ) DNA is then renatured or reannealed in the presence of excess copies of a single-stranded, fluorochrome-labeled DNA base-pair sequence or probe (**C**). The probe anneals or "hybridizes" to sites of complementary DNA sequence (**D**) within the chromosomal genome. Probe signal is visualized and imaged on the chromosome by fluorescent microscopy. (From Lin RL, Cherry AM, Bangs CD, et al: FISHing for answers: the use of molecular cytogenetic techniques in adolescent medicine practice. In Hyme HE, Greydanus D, editors: *Genetic disorders in adolescents: state of the art reviews. Adolescent medicine,* Philadelphia, 2002, Hanley and Belfus, pp. 305–313.)

Chromosome rearrangements <5 million bp (5 Mbp) cannot be detected by conventional cytogenetic techniques. FISH was initially used to detect deletions as small as 50-200 kb of DNA and facilitated the early clinical characterization of a number of **microdeletion syndromes** . Some FISH probes hybridize to repetitive sequences located in the pericentromeric regions. Pericentromeric probes are still widely used for the rapid identification of certain trisomies in interphase cells of blood smears, or even in the rapid analysis of prenatal samples from cells obtained through amniocentesis. Such probes are available for chromosomes 13, 18, and 21 and for the sex pair X and Y (see Fig. 98.4*C* and *D*). With regard to the detection of genomic disorders, FISH is no longer the first line of testing, and its role has also mostly changed to the confirmation of microarray findings. In summary, FISH is reserved for (1) confirmation studies of abnormalities detected by CMA, (2) rapid prenatal screening on interphase amniotic fluid cells, and (3) interphase blood smear for sex assignment of newborns who present with ambiguous genitalia.

Array comparative genomic hybridization (aCGH) and **chromosomal microarray (CMA)** are molecular-based techniques that involve differentially labeling the patient's DNA with a fluorescent dye (green fluorophore) and a normal reference DNA with a red fluorophore (Fig. 98.6). Oligonucleotides (short DNA segments) encompassing the entire genome are spotted onto a slide or **microarray** grid. Equal amounts of the 2-label DNA samples are mixed, and the green:red fluorescence ratio is measured along each tested area. Regions of amplification of the patient's DNA display an excess of green fluorescence, and regions of loss show excess red fluorescence. If the patient's and the control DNA are equally represented, the green:red ratio is 1 : 1, and the tested regions appear yellow (see Chapter 96 , Fig. 96.5). The detection is currently possible at the single-exon resolution level, depending on the arrays used. In the near future, copy number detections may further evolve to be detected by next generation sequencing in the context of whole *genome* sequencing.

(From Li MM, Andersson HC: Clinical application of microarray-based molecular cytogenetics: an emerging new era of genomic medicine, *J Pediatr* 155:311–317, 2009, with permission of the authors and publisher.)

The many advantages of aCGH include its ability to test all critical disease-causing regions in the genome at once, detect duplications and deletions not currently recognized as recurrent disease-causing regions probed by FISH, and detect single-gene and contiguous gene deletion syndromes. Also, aCGH does not always require cell culture to generate sufficient DNA, which may be important in the context of prenatal testing because of timing. Limitations of aCGH are that it does not detect balanced translocations or inversions and may not detect low levels of chromosomal mosaicism. Among different types of aCGH, some are more targeted than others. **Targeted aCGH** can be an efficient way to detect clinically known cryptic chromosomal aberrations, which are typically associated with known disease phenotypes. **Whole genome arrays** target the entire genome and allow better and denser coverage in evenly spaced genomic regions. Its disadvantage is that interpretation of deletions or duplications may be difficult if it involves areas not previously known to be involved in disease.

A frequently used array in the clinical setting is the **single nucleotide polymorphism (SNP)** . SNPs are polymorphic variations between 2 nucleotides, and when analyzed in massive parallel fashion, they can provide valuable clinical information. Several million SNPs normally occur in the human genome. SNP arrays can help with the detection of **uniparental disomies** (i.e., genetic information derived from only 1 parent), as well as consanguinity in the family. Many arrays currently used in clinical practice combine the use of oligonucleotides for the detection of **copy number variations** in conjunction with SNPs. There are many copy number variations causing deletion or duplication in the human genome. Thus, most detected genetic abnormalities, unless associated with well-known clinical phenotypes, require *parental investigations* because a detected copy number variation that is inherited could be benign or an incidental polymorphic variant. A **de novo** abnormality (i.e., one found only in the child and not the parents) is often more significant if it is associated with an abnormal phenotype found only in the child, and if it involves genes with important functions.

aCGH is a very valuable technology alone or when combined with FISH and conventional chromosome studies (Fig. 98.7).

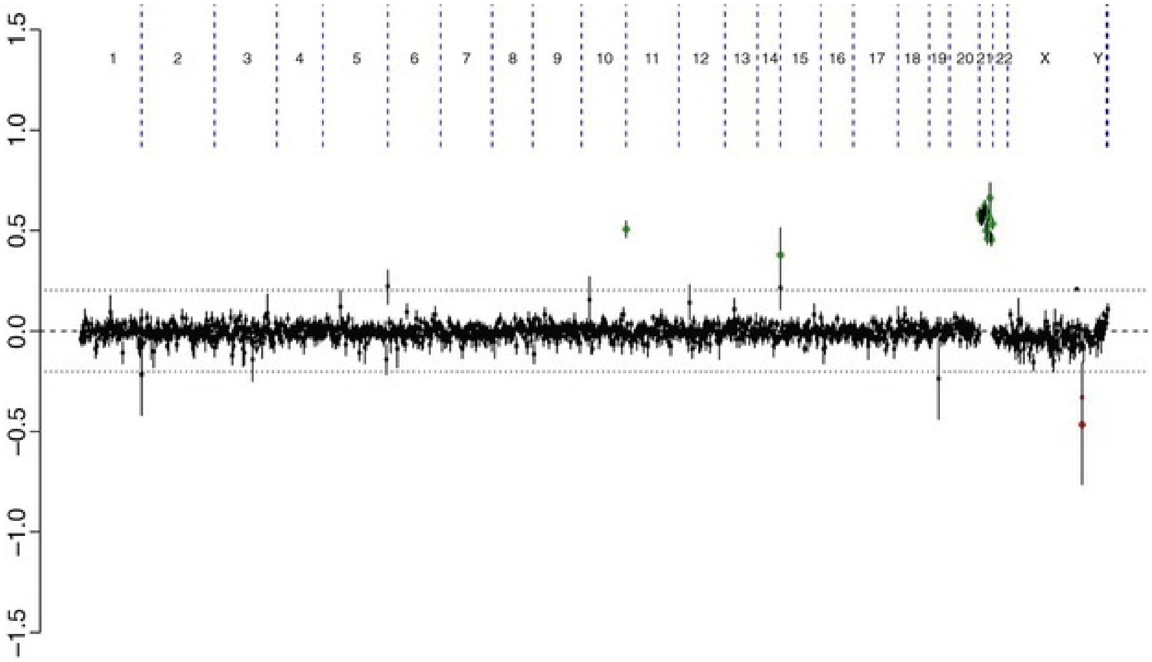

FIG. 98.7 aCGH in a female patient with Down syndrome. Each *black dot* represents a piece of DNA segment specific for different chromosome location. Most of the dots displayed between the 0.0 and 0.2 axis are considered within normal range. Exceptions are often a result of polymorphic variations. A group of dots colored in *green* clusters on chromosome 21 and above 0.5. These represent a *gain* in copy number of DNA segments for chromosome 21, as seen in Down syndrome and consistent with trisomy 21.

98.2

Down Syndrome and Other Abnormalities of Chromosome Number

Brendan Lee

Aneuploidy and Polyploidy

Human cells contain a multiple of 23 chromosomes (n = 23). A haploid cell (n) has 23 chromosomes (typically in the ovum or sperm). If a cell's chromosomes are an exact multiple of 23 (46, 69, 92 in humans), those cells are referred to as **euploid** . **Polyploid** cells are euploid cells with more than the normal **diploid** number of 46 (2n) chromosomes: 3n, 4n. Polyploid conceptions are usually not viable, but the presence of mosaicism with a karyotypically normal cell line can allow survival. **Mosaicism** is an abnormality defined as the presence of 2 or more cell lines in a single individual. **Polyploidy** is a common abnormality seen in 1st-trimester pregnancy losses. **Triploid cells** are those with 3 haploid sets of chromosomes (3n) and are only viable in a mosaic form. Triploid infants can be liveborn but do not survive long. Triploidy is often the result of fertilization of an egg by 2 sperm (dispermy). Failure of 1 of the meiotic divisions, resulting in a diploid egg or sperm, can also result in triploidy. The phenotype of a triploid conception depends on the origin of the extra chromosome set. If the extra set is of **paternal** origin, it results in a partial *hydatidiform mole* (excessive placental growth) with poor embryonic development, but triploid conceptions that have an extra set of **maternal** chromosomes results in severe embryonic restriction with a small, fibrotic placenta (insufficient placental development) that is typically spontaneously aborted.

Abnormal cells that do not contain a multiple of haploid number of chromosomes are termed **aneuploid** cells. **Aneuploidy** is the most common and clinically significant type of human chromosome abnormality, occurring in at least 3–4% of all clinically recognized pregnancies. **Monosomies** occur when only 1, instead of the normal 2, of a given chromosome is present in an otherwise diploid cell. In humans, most autosomal monosomies appear to be lethal early in development, and survival is possible in **mosaic forms** or by means of chromosome rescue (restoration of the normal number by duplication of single monosomic chromosome). An exception to this rule is monosomy for the X chromosome (45,X), seen in Turner syndrome; the majority of 45,X conceptuses are believed to be lost early in pregnancy for as yet unexplained reasons.

The most common cause of aneuploidy is **nondisjunction** , the failure of chromosomes to disjoin normally during meiosis (see Fig. 98.1). Nondisjunction can occur during meiosis I or II or during mitosis, although maternal meiosis I is the most common nondisjunction in aneuploidies (e.g., Down syndrome, trisomy 18). After meiotic nondisjunction, the resulting gamete either lacks a chromosome or has 2 copies instead of 1 normal copy, resulting in a monosomic or trisomic zygote, respectively.

Trisomy is characterized by the presence of 3 chromosomes, instead of the normal 2, of any particular chromosome. Trisomy is the most common form of aneuploidy. Trisomy can occur in all cells or it may be mosaic. Most individuals with a trisomy exhibit a consistent and specific phenotype depending on the chromosome involved.

FISH is a technique that can be used for rapid diagnosis in the prenatal detection of common fetal aneuploidies, including chromosomes 13, 18, and 21, as well as sex chromosomes (see Fig. 98.4*C* and *D*). Direct detection of fetal cell-free DNA from maternal plasma for fetal trisomy is a safe and highly effective screening test for fetal aneuploidy. The most common numerical abnormalities in liveborn children include trisomy 21 (Down syndrome), trisomy 18 (Edwards syndrome), trisomy 13 (Patau syndrome), and sex chromosomal aneuploidies: Turner syndrome (usually 45,X), Klinefelter syndrome (47,XXY), 47,XXX, and 47,XYY. By far the most common type of trisomy in liveborn infants is trisomy 21 (47,XX,+21 or 47,XY,+21) (see Table 98.1). Trisomy 18 and trisomy 13 are relatively less common and are associated with a characteristic set of congenital anomalies and severe intellectual disability (Table 98.3). The occurrence of trisomy 21 and other trisomies increases with advanced maternal age (≥35 yr). Because of this increased risk, women who are ≥35 yr old at delivery should be offered genetic counseling and prenatal diagnosis (including serum screening, ultrasonography, and cell-free fetal DNA detection, amniocentesis, or chorionic villus sampling; see Chapter 115).

Table 98.3

Chromosomal Trisomies and Their Clinical Findings

SYNDROME	INCIDENCE	CLINICAL MANIFESTATIONS
Trisomy 13, Patau syndrome	1/10,000 births	Cleft lip often midline; flexed fingers with postaxial polydactyly; ocular hypotelorism, bulbous nose; low-set, malformed ears; microcephaly; cerebral malformation, especially holoprosencephaly; microphthalmia, cardiac malformations; scalp defects; hypoplastic or absent ribs; visceral and genital anomalies
		Early lethality in most cases, with a median survival of 12 days; ~80% die by 1 year; 10-year survival ~13%. Survivors have significant neurodevelopmental delay.
Trisomy 18, Edwards syndrome	1/6,000 births	Low birthweight, closed fists with index finger overlapping the 3rd digit and the 5th digit overlapping the 4th, narrow hips with limited abduction, short sternum, rocker-bottom feet, microcephaly, prominent occiput, micrognathia, cardiac and renal malformations, intellectual disability
		~88% of children die in the 1st year; 10-year survival ~10%. Survivors have significant neurodevelopmental delay.
Trisomy 8, mosaicism	1/20,000 births	Long face; high, prominent forehead; wide, upturned nose, thick, everted lower lip; microretrognathia; low-set ears; high-arched, sometimes cleft, palate; osteoarticular anomalies common (camptodactyly of 2nd-5th digits, small patella); deep plantar and palmar creases; moderate intellectual disability

Down Syndrome

Trisomy 21 is the most common genetic etiology of moderate intellectual disability. The incidence of Down syndrome in live births is approximately 1 in 733; the incidence at conception is more than twice that rate; the difference is accounted for by early pregnancy losses. In addition to cognitive impairment, Down syndrome is associated with congenital anomalies and characteristic dysmorphic features (Figs. 98.8 and 98.9 and Table 98.4). Although there is variability in the clinical features, the constellation of phenotypic features is fairly consistent and permits clinical recognition of trisomy 21. Affected individuals are more prone to congenital heart defects (50%) such as atrioventricular septal defects, ventricular septal defects, isolated secundum atrial septal defects, patent ductus arteriosus, and tetralogy of Fallot. Pulmonary complications include recurrent respiratory infections, sleep-disordered breathing, laryngo- and tracheobronchochomalacia, tracheal bronchus, pulmonary hypertension, and asthma. Congenital and acquired gastrointestinal anomalies (celiac disease) and hypothyroidism are common (Table 98.5). Other abnormalities include megakaryoblastic leukemia, immune dysfunction, diabetes mellitus, seizures, alopecia, juvenile idiopathic arthritis, and problems with hearing and vision. Alzheimer disease–like dementia is a known complication that occurs as early as the 4th decade and has an incidence 2-3 times higher than sporadic Alzheimer disease. Most males with Down syndrome are sterile, but some females have been able to reproduce, with a 50% chance of having trisomy 21 pregnancies. Two genes (*DYRK1A, DSCR1*) in the putative critical region of chromosome 21 may be targets for therapy.

Additional Features of Down Syndrome That Can Develop or Become Symptomatic With Time

Neuropsychiatric

Developmental delay
Seizures
Autism spectrum disorders
Behavioral disorders (disruptive)
Depression
Alzheimer disease

Sensory

Congenital or acquired hearing loss
Serous otitis media
Refractive errors (myopia)
Congenital or acquired cataracts
Nystagmus
Strabismus

Glaucoma
Blocked tear ducts

Cardiopulmonary

Acquired mitral, tricuspid, or aortic valve regurgitation
Endocarditis
Obstructive sleep apnea

Musculoskeletal

Atlantoaxial instability
Hip dysplasia
Slipped capital femoral epiphyses
Avascular hip necrosis
Recurrent joint dislocations (shoulder, knee, elbow, thumb)

Endocrine

Congenital or acquired hypothyroidism
Diabetes mellitus
Infertility
Obesity
Hyperthyroidism

Hematologic

Transient myeloproliferative syndrome
Acute lymphocytic leukemia
Acute myelogenous leukemia

Gastrointestinal

Celiac disease
Delayed tooth eruption

Respiratory
Obstructed sleep apnea
Frequent infections (sinusitis, nasopharyngitis, pneumonia)

Cutaneous

Hyperkeratosis
Seborrhea
Xerosis
Perigenital folliculitis

Developmental delay is universal (Tables 98.6 and 98.7 and Fig. 98.10). Cognitive impairment does not uniformly affect all areas of development. Social development is often relatively spared, but autism spectrum disorder can occur. Children with Down syndrome have considerable difficulty using expressive language. Understanding the individual developmental strengths and challenges is necessary to maximize the educational process. Persons with Down syndrome often benefit from programs aimed at cognitive training, stimulation, development, and education. Children with Down syndrome also benefit from anticipatory guidance, which establishes the protocol for screening, evaluation, and care for patients with genetic syndromes and chronic disorders (Table 98.8). Up to 15% of children with Down syndrome have misalignment of the 1st cervical vertebra (C1), which places them at risk for spinal cord injury with neck hyperextension or extreme flexion. Special Olympics recommends sports participation and training but requires x-ray examination (full extension and flexion views) of the neck before participation in sports that may result in hyperextension or radical flexion or pressure on the neck or upper spine. Such sports include diving starts in swimming, butterfly stroke, diving, pentathlon, high jump, equestrian sports, gymnastics, football, soccer, alpine skinning, and warm-up exercises placing stress on the head and neck. If atlantoaxial instability is diagnosed, Special Olympics will permit participation if the parents or guardians request so and only after obtaining written certification from a physician and acknowledgment of the risks by the parent or guardian.

Table 98.8

Health Supervision for Children With Down Syndrome

CONDITION	TIME TO SCREEN	COMMENT
Congenital heart disease	Birth; by pediatric cardiologist	50% risk of congenital heart disease; increased risk for pulmonary hypertension
	Young adult for acquired valve disease	
Strabismus, cataracts, nystagmus	Birth or by 6 mo; by pediatric ophthalmologist	Cataracts occur in 15%, refractive errors in 50%
	Check vision annually	
Hearing impairment or loss	Birth or by 3 mo with auditory brainstem response or otoacoustic emission testing; check hearing q6mo up to 3 yr if tympanic membrane is not visualized; **annually thereafter**	Risk for congenital hearing loss plus 50–70% risk of serous otitis media
Constipation	Birth	Increased risk for Hirschsprung disease
Celiac disease	At 2 yr or with symptoms	Screen with IgA and tissue transglutaminase antibodies
Hematologic disease	At birth and in adolescence or if symptoms develop	Increased risk for neonatal polycythemia (18%), leukemoid reaction, leukemia (<1%)
Hypothyroidism	Birth; repeat at 6-12 mo and **annually**	Congenital (1%) and acquired (5%)
Growth and development	At each visit	Discuss school placement options
	Use Down syndrome growth curves	Proper diet to avoid obesity
Obstructive sleep apnea	Start at ~1 yr and at each visit	Monitor for snoring, restless sleep

Atlantoaxial subluxation or instability (incidence 10–30%)	At each visit by history and physical exam	Special Olympics recommendations are to screen for high-risk sports, e.g., diving, swimming, contact sports
	Radiographs at 3-5 yr or when planning to participate in contact sports	
	Radiographs indicated wherever neurologic symptoms are present even if transient (neck pain, torticollis, gait disturbances, weakness)	
	Many are asymptomatic	
Gynecologic care	Adolescent girls	Menstruation and contraception issues
Recurrent infections	When present	Check IgG subclass and IgA levels
Psychiatric, behavioral disorders	At each visit	Depression, anxiety, obsessive-compulsive disorder, schizophrenia seem in 10–17%
		Autism spectrum disorder in 5–10%
		Early-onset Alzheimer disease

IgA, Immunoglobulin A; IgG, immunoglobulin G.

Data from Committee on Genetics: Health supervision for children with Down syndrome, *Pediatrics* 107:442–449, 2001; and Baum RA, Spader M, Nash PL, et al: Primary care of children and adolescents with Down syndrome: an update, *Curr Probl Pediatr Adolesc Health Care* 38:235–268, 2008.

Compared with the general population, children with Down syndrome are at increased risk for behavior problems; psychiatric comorbidity is an estimated 18–38% in this population. Common behavioral difficulties that occur in children with Down syndrome include inattentiveness, stubbornness, and a need for routine and sameness. Aggression and self-injurious behavior are less common in this population than other children with similar degrees of intellectual disability from other etiologies. All these behaviors can respond to educational, behavioral, or pharmacologic interventions.

The life expectancy for children with Down syndrome is reduced and is approximately 50-55 yr. Little prospective information about the secondary medical problems of adults with Down syndrome is known. Retrospective studies have shown premature aging and an increased risk of Alzheimer disease in adults with Down syndrome. These studies have also shown unexpected negative (protective) associations between Down syndrome and comorbidities. Persons with Down syndrome have fewer-than-expected deaths caused by solid tumors and ischemic heart disease. This same study reported increased risk of adult deaths from congenital heart disease, seizures, and leukemia. In one large study, leukemias accounted for 60% of all cancers in people with Down syndrome and 97% of all cancers in children with Down syndrome. There was decreased risk of solid tumors in all age-groups with Down syndrome, including neuroblastomas and nephroblastomas in children and epithelial tumors in adults.

Most adults with Down syndrome are able to perform activities of daily living. However, most have difficulty with complex financial, legal, or medical decisions, and a guardian may be appointed.

The risk of having a child with trisomy 21 is highest in women who conceive after age 35 yr. Even though younger women have a lower risk, they represent half of all mothers with babies with Down syndrome because of their higher overall birth rate. *All women should be offered screening for Down syndrome* in their 2nd trimester by means of 4 maternal serum tests (free β-human chorionic gonadotropin [β-hCG], unconjugated estriol, inhibin, and α-fetoprotein). This is known as the *quad screen;* it can detect up to 80% of Down syndrome pregnancies vs 70% in the triple screen. Both tests have a 5% false-positive rate. There is a method of screening during the 1st trimester using fetal nuchal translucency (NT) thickness that can be done alone or in conjunction with maternal serum β-hCG and pregnancy-associated plasma protein-A (PAPP-A). In the 1st trimester, NT alone can detect ≤70% of Down syndrome pregnancies, but with β-hCG and PAPP-A, the detection rate increases to 87%. If both 1st- and 2nd-trimester screens are combined using NT and biochemical profiles (integrated screen), the detection rate increases to 95%. If only 1st-trimester quad screening is done, maternal serum α-fetoprotein (which is decreased in affected pregnancies) is recommended as a 2nd-trimester follow-up.

Detection of cell-free fetal DNA in maternal plasma is also diagnostic and replacing conventional 1st- and 2nd-trimester screens. The noninvasive detection of fetal trisomy 21 by analyzing cell-free fetal DNA in maternal serum is an important advance in prenatal diagnosis of Down syndrome. Next-generation DNA sequencing has reduced the cost of this procedure, which has a high degree of accuracy (98% detection rate) and applicability. The prenatal screens are also useful for other trisomies, although the detection rates may be different from those given for Down syndrome. Current tests can detect microdeletions including 22q11.2 deletion syndrome, Angelman syndrome, Prader Willi syndrome deletion, cri du chat syndrome, Williams syndrome, and 1p36.3 deletion syndrome. Importantly, especially for microdeletions, cell-free noninvasive prenatal testing (NIPT) should be considered primarily for screening tests and follow-up invasive testing (e.g., amniocentesis) pursued for definitive diagnosis.

In approximately 95% of the cases of Down syndrome, there are 3 copies of chromosome 21. The origin of the supernumerary chromosome 21 is maternal in

97% of the cases as a result of errors in meiosis. The majority of these occur in maternal meiosis I (90%). Approximately 1% of persons with trisomy 21 are mosaics, with some cells having 46 chromosomes, and another 4% have a **translocation** that involves chromosome 21. The majority of translocations in Down syndrome are fusions at the centromere between chromosomes 13, 14, 15, 21, and 22, known as *robertsonian translocations.* The translocations can be de novo or inherited. Very rarely is Down syndrome diagnosed in a patient with only a part of the long arm of chromosome 21 in triplicate (**partial trisomy**). Isochromosomes and ring chromosomes are other rarer causes of trisomy 21. Down syndrome patients without a visible chromosome abnormality are the least common. It is not possible to distinguish the phenotypes of persons with full trisomy 21 and those with a translocation. Representative genes on chromosome 21 and their potential effects on development are noted in Table 98.9 . Patients who are mosaic tend to have a milder phenotype.

Table 98.9

Genes Localized to Chromosome 21 That May Affect Brain Development, Neuronal Loss, and Alzheimer-Type Neuropathology

SYMBOL	NAME	POSSIBLE EFFECT IN DOWN SYNDROME	FUNCTION
SIM2	Single-minded homolog 2	Brain development	Required for synchronized cell division and establishment of proper cell lineage
DYRK1A	Dual-specificity tyrosine-(Y)-phosphorylation regulated kinase 1A	Brain development	Expressed during neuroblast proliferation Believed important homolog in regulating cell-cycle kinetics during cell division
GART	Phosphoribosylglycinamide formyltransferase Phosphoribosylglycinamide synthetase Phosphoribosylaminoimidazole synthetase	Brain development	Expressed during prenatal development of the cerebellum
PCP4	Purkinje cell protein 4	Brain development	Function unknown but found exclusively in the brain and most abundantly in the cerebellum
DSCAM	Down syndrome cell adhesion molecule	Brain development and possible candidate gene for congenital heart	Expressed in all molecule regions of the brain and believed to have a role in axonal outgrowth during development of the nervous system

		disease	
GRIK1	Glutamate receptor, ionotropic kainite1	Neuronal loss	Function unknown, found in the cortex in fetal and early postnatal life and in adult primates, most concentrated in pyramidal cells in the cortex
APP	Amyloid beta (A4) precursor protein (protease nexin-II, Alzheimer disease)	Alzheimer type neuropathy	Seems to be involved in plasticity, neurite outgrowth, and neuroprotection
S100B	S100 calcium binding protein β (neural)	Alzheimer type neuropathy	Stimulates glial formation
SOD1	Superoxide dismutase 1, soluble (amyotrophic lateral sclerosis, adult)	Accelerated aging?	Scavenges free superoxide molecules in the cell and might accelerate aging by producing hydrogen peroxide and oxygen

Chromosome analysis is indicated in every person suspected of having Down syndrome. If a translocation is identified, parental chromosome studies must be performed to determine whether one of the parents is a translocation carrier, which carries a high recurrence risk for having another affected child. That parent might also have other family members at risk. Translocation (21;21) carriers have a 100% recurrence risk for a chromosomally abnormal child, and other robertsonian translocations, such as t(14;21), have a 5–7% recurrence risk when transmitted by females. Genomic dosage imbalance contributes through direct and indirect pathways to the Down syndrome phenotype and its phenotypic variation.

Tables 98.10 and 98.11 provide more information on other aneuploidies and partial autosomal aneuploidies (Figs. 98.11 to 98.14).

Table 98.10

Other Rare Aneuploidies and Partial Autosomal Aneuploidies

DISORDER	KARYOTYPE	CLINICAL MANIFESTATIONS
Trisomy 8	47,XX/XY,+8	Growth and mental deficiency are variable.
		The majority of patients are mosaics.
		Deep palmar and plantar furrows are characteristic.
		Joint contractures
Trisomy 9	47,XX/XY,+9	The majority of patients are mosaics.
		Clinical features include craniofacial (high forehead, microphthalmia, low-set malformed ears, bulbous nose) and skeletal (joint contractures) malformations and heart defects (60%).
Trisomy 16	47,XX/XY,+16	The most commonly observed autosomal aneuploidy in spontaneous abortion; the recurrence risk is negligible.
Tetrasomy 12p	46,XX[12]/46,XX,+i(12p)[8] (mosaicism for an	Known as Pallister-Killian syndrome
		Sparse anterior scalp hair (more so temporal region), eyebrows, and eyelashes; prominent forehead; chubby cheeks; long philtrum with thin

isochromosome 12p)	upper lip and cupid-bow configuration; polydactyly; streaks of hyper- and hypopigmentation

98.3

Abnormalities of Chromosome Structure

Translocations

Translocations, which involve the transfer of material from one chromosome to another, occur with a frequency of 1 in 500 liveborn human infants. They may be inherited from a carrier parent or appear de novo, with no other affected family member. Translocations are usually reciprocal or robertsonian, involving 2 chromosomes (Fig. 98.15).

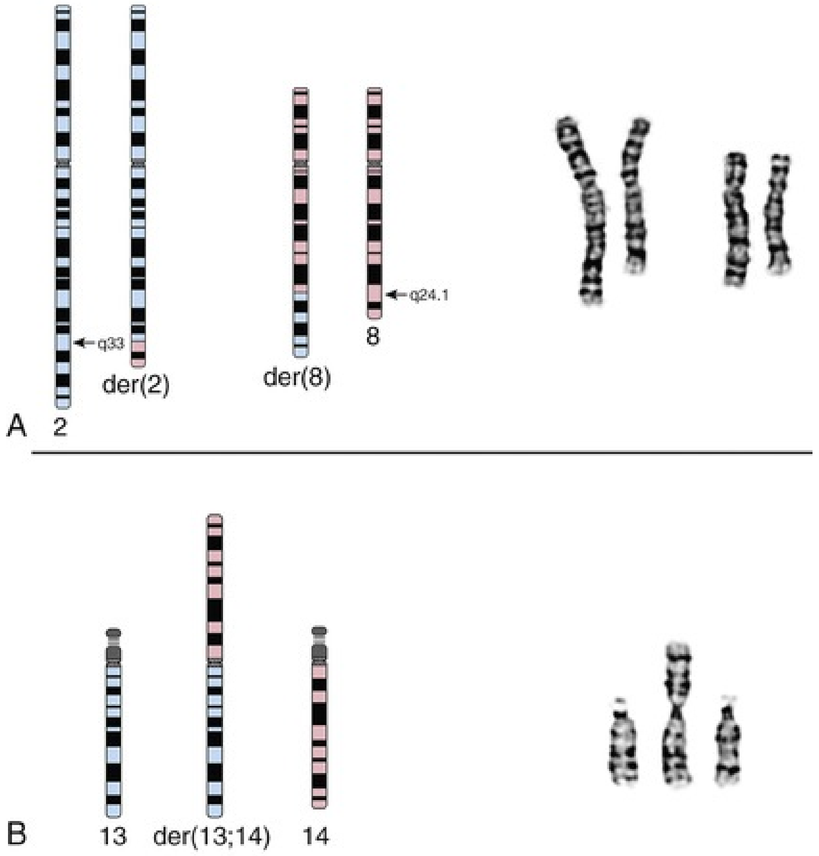

FIG. 98.15 **A,** Schematic diagram *(left)* and partial G-banded karyotype *(right)* of a reciprocal translocation between chromosome 2 *(blue)* and chromosome 8 *(pink).* The breakpoints are on the long *(q)* arm of both chromosomes at bands 2q33 and 8q24.1, with the reciprocal exchange of material between the derivative *(der)* chromosomes 2 and 8. This translocation is balanced, with no net gain or loss of material. The nomenclature for this exchange is t(2;8)(q33:q24.1). **B,** Schematic diagram

(left) and partial G-banded karyotype *(right)* of a robertsonian translocation between chromosomes 13 *(blue)* and 14 *(pink).* The breakpoints are at the centromere (band q10) of both chromosomes, with fusion of the long arms into a single derivative chromosome and loss of the short *(p)* arm material. The nomenclature for this exchange is der(13;14)(q10;q10).

Reciprocal translocations are the result of breaks in nonhomologous chromosomes, with reciprocal exchange of the broken segments. Carriers of a reciprocal translocation are usually phenotypically normal but are at an increased risk for miscarriage caused by transmission of unbalanced reciprocal translocations and for bearing chromosomally abnormal offspring. Unbalanced translocations are the result of abnormalities in the segregation or crossover of the translocation carrier chromosomes in the germ cells.

Robertsonian translocations involve 2 acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) that fuse near the centromeric region with a subsequent loss of the short arms. Because the short arms of all 5 pairs of acrocentric chromosomes have multiple copies of genes encoding for ribosomal RNA, loss of the short arm of 2 acrocentric chromosomes has no deleterious effect. The resulting karyotype has only 45 chromosomes, including the translocated chromosome, which consists of the long arms of the 2 fused chromosomes. Carriers of robertsonian translocations are usually phenotypically normal. However, they are at increased risk for miscarriage and unbalanced translocations in phenotypically abnormal offspring.

In some rare instances, translocations can involve 3 or more chromosomes, as seen in complex rearrangements. Another, less common type is the insertional translocation. **Insertional translocations** result from a piece of chromosome material that breaks away and later is reinserted inside the same chromosome at a different site or inserted in another chromosome.

Inversions

An inversion requires that a single chromosome break at 2 points; the broken piece is then inverted and joined into the same chromosome. Inversions occur in 1 in 100 live births. There are 2 types of inversions: pericentric and paracentric. In **pericentric inversions** the breaks are in the 2 opposite arms of the chromosome and include the centromere. They are usually discovered because they change the position of the centromere. The breaks in **paracentric inversions** occur in only 1 arm. Carriers of inversions are usually phenotypically normal, but they are at increased risk for miscarriages, typically in paracentric inversions, and chromosomally abnormal offspring in pericentric inversions.

Deletions and Duplications

Deletions involve loss of chromosome material and, depending on their location, can be classified as **terminal** (at the end of chromosomes) or **interstitial** (within the arms of a chromosome). They may be isolated or may occur along with a duplication of another chromosome segment. The latter typically occurs in unbalanced reciprocal chromosomal translocation secondary to abnormal crossover or segregation in a translocation or inversion carrier.

A carrier of a deletion is monosomic for the genetic information of the missing segment. Deletions are usually associated with intellectual disability and malformations. The most commonly observed deletions in routine chromosome preparations include 1p−, 4p−, 5p−, 9p−, 11p−, 13q−, 18p−, 18q−, and 21q− (Table 98.12 and Fig. 98.16), all distal or terminal deletions of the short or the long arms of chromosomes. Deletions may be observed in routine chromosome preparations, and deletions and translocations larger than 5-10 Mbp are usually visible microscopically.

Table 98.12

Common Deletions and Their Clinical Manifestations

DELETION	CLINICAL ABNORMALITIES
4p−	Wolf-Hirschhorn syndrome. The main features are a typical “Greek helmet” facies secondary to ocular hypertelorism, prominent glabella, and frontal bossing; microcephaly, dolichocephaly, hypoplasia of the orbits, ptosis, strabismus, nystagmus, bilateral epicanthic folds, cleft lip and palate, beaked nose with prominent bridge, hypospadias, cardiac malformations, and intellectual disability.
5p−	Cri du chat syndrome. The main features are hypotonia, short stature, characteristic shrill cry in the first few weeks of life (also called cat's cry syndrome), microcephaly with protruding metopic suture, hypertelorism, bilateral epicanthic folds, high arched palate, wide and flat nasal bridge, and intellectual disability.
9p−	The main features are craniofacial dysmorphic features with trigonocephaly, slanted palpebral fissures, discrete exophthalmos secondary to supraorbital hypoplasia, arched eyebrows, flat and wide nasal bridge, short neck with low hairline, genital anomalies, long fingers and toes with extra flexion creases, cardiac malformations, and intellectual disability.
13q−	The main features are low birthweight, failure to thrive, microcephaly, and severe intellectual disability. Facial features include high, wide nasal bridge; hypertelorism; ptosis; and micrognathia. Ocular malformations are common (retinoblastoma). The hands have hypoplastic or absent thumbs and syndactyly.
18p−	A few patients (15%) are severely affected and have cephalic and ocular malformations: holoprosencephaly, cleft lip and palate, ptosis, epicanthal folds, and varying degrees of intellectual

	disability. Most (80%) have only minor malformations and mild intellectual disability.
18q−	The main features are growth deficiency and hypotonia with a “froglike” position with the legs flexed, externally rotated, and in hyperabduction. The face is characteristic, with depressed midface and apparent protrusion of the mandible, deep-set eyes, short upper lip, and everted lower lip (“carplike” mouth); antihelix of the ears is very prominent. Varying degrees of intellectual disability and belligerent personality are present. Myelination abnormalities occur in the central nervous system.

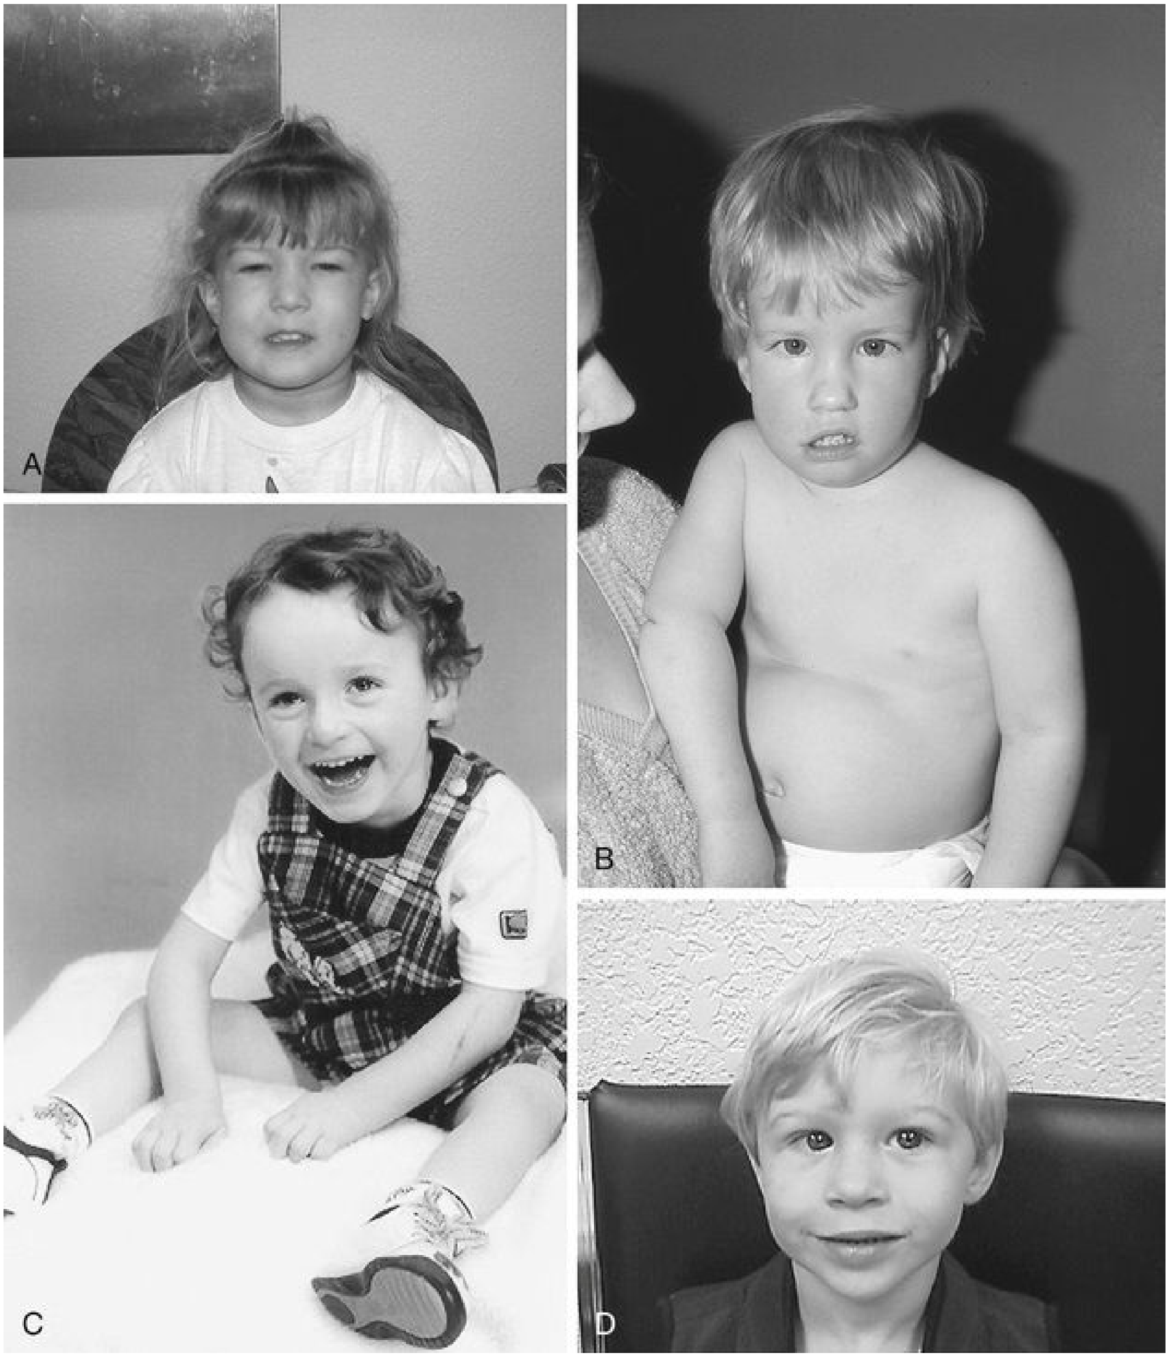

FIG. 98.16 **A,** Child with velocardiofacial syndrome (deletion 22q11.2). **B,** Child with Prader-Willi syndrome (deletion 15q11-13). **C,** Child with Angelman syndrome (deletion 15q11-13). **D,** Child with Williams syndrome (deletion 7q11.23). (From Lin RL, Cherry AM, Bangs CD, et al: FISHing for answers: the use of molecular cytogenetic techniques in adolescent medicine practice. In Hyme HE, Greydanus D, editors: *Genetic disorders in adolescents: state of the art reviews. Adolescent medicine,* Philadelphia, 2002, Hanley and Belfus, pp 305–313.)

High-resolution banding techniques, FISH, and molecular studies such as aCGH can reveal deletions that are too small to be seen in ordinary or routine chromosome spreads (see Fig. 98.7). **Microdeletions** involve loss of small chromosome regions, the largest of which are detectable only with prophase chromosome studies and molecular methods. For submicroscopic deletions, the missing piece can only be detected using molecular methodologies such as DNA-based studies (e.g., aCGH, FISH). The presence of extra genetic material from the same chromosome is referred to as **duplication** . Duplications can also be sporadic or result from abnormal segregation in translocation or inversion carriers.

Microdeletions and microduplications usually involve regions that include several genes, so the affected individuals can have a distinctive phenotype depending on the number of genes involved. When such a deletion involves more than a single gene, the condition is referred to as a **contiguous gene deletion syndrome** (Table 98.13). With the advent of clinically available aCGH, a large number of duplications, most of them microduplications, have been uncovered. Many of those **microduplication syndromes** are the reciprocal duplications of the known deletions or microdeletion counterparts and have distinctive clinical features (Table 98.14).

Table 98.13

Microdeletion and Contiguous Gene Syndromes and Their Clinical Manifestations

DELETION	SYNDROME	CLINICAL MANIFESTATIONS
1p36	1p deletion	Growth restriction, dysmorphic features with midface hypoplasia, straight thin eyebrows, pointy chin, sensorineural hearing loss, progressive cardiomyopathy, hypothyroidism, seizures, intellectual disability
5q35	Sotos (50% are deletions of *NSD1* gene in Asians but only 6% in whites)	Overgrowth, macrocephaly, prominent forehead, prominence of extraaxial fluid spaces on brain imaging, large hands and feet, hypotonia, clumsiness, mental disabilities
6p25	Axenfeld-Rieger	Axenfeld-Rieger malformation, hearing loss, congenital heart defects, dental anomalies, developmental delays, facial dysmorphism

7q11.23	Williams	Round face with full cheeks and lips, long philtrum, stellate pattern in iris, strabismus, supravalvular aortic stenosis and other cardiac malformations, varying degrees of intellectual disability, friendly personality
8p11	8p11	Kallmann syndrome type 2 (hypogonadotropic hypogonadism and anosmia), spherocytosis (deletions of ankyrin 1), multiple congenital anomalies, intellectual disability
8q24.1-q24.13	Langer-Giedion or trichorhinophalangeal type II	Sparse hair, multiple cone-shaped epiphyses, multiple cartilaginous exostoses, bulbous nasal tip, thickened alar cartilage, upturned nares, prominent philtrum, large protruding ears, mild intellectual disability
9q22	Gorlin	Multiple basal cell carcinomas, odontogenic keratocysts, palmoplantar pits, calcification falx cerebri
9q34	9q34 deletion	Distinct face with synophrys, anteverted nares, tented upper lip, protruding tongue, midface hypoplasia, conotruncal heart defects, intellectual disability
10p12-p13	DiGeorge type 2	Many of the DiGeorge type 1 and velocardiofacial type 1 features (conotruncal defects, immunodeficiency, hypoparathyroidism, dysmorphic features)
11p11.2	Potocki-Shaffer	Multiple exostoses, parietal foramina, craniosynostosis, facial dysmorphism, syndactyly, intellectual disability
11p13	WAGR	Hypernephroma (*W*ilms tumor), *a*niridia, male *g*enital hypoplasia of varying degrees, *g*onadoblastoma, long face, upward-slanting palpebral fissures, ptosis, beaked nose, low-set poorly formed auricles, intellectual disability (*r*etardation)
11q24.1-11qter	Jacobsen	Growth restriction, intellectual disability, cardiac and digit anomalies, thrombocytopenia
15q11-q13 (paternal)	Prader-Willi	Severe hypotonia and feeding difficulties at birth, voracious appetite and obesity in infancy, short stature (responsive to growth hormone), small hands and feet, hypogonadism, intellectual disability
15q11-q13 (maternal)	Angelman	Hypotonia, feeding difficulties, gastroesophageal reflux, fair hair and skin, midface hypoplasia, prognathism, seizures, tremors, ataxia, sleep disturbances, inappropriate laughter, poor or absent speech, severe intellectual disability
16p13.3	Rubinstein-Taybi	Microcephaly, ptosis, beaked nose with low-lying philtrum, broad thumbs and large toes, intellectual disability
17p11.2	Smith-Magenis	Brachycephaly, midfacial hypoplasia, prognathism, myopia, cleft palate, short stature, severe behavioral problems, intellectual disability
17p13.3	Miller-Dieker	Microcephaly, lissencephaly, pachygyria, narrow forehead, hypoplastic male external genitals, growth restriction, seizures, profound intellectual disability
20p12	Alagille	Bile duct paucity with cholestasis; heart defects, particularly pulmonary artery stenosis; ocular abnormalities (posterior embryotoxon); skeletal defects such as butterfly vertebrae; long nose
22q11.2	Velocardiofacial-DiGeorge	Conotruncal cardiac anomalies, cleft palate, velopharyngeal incompetence, hypoplasia or agenesis of thymus and parathyroid glands, hypocalcemia, hypoplasia of auricle, learning disabilities, psychiatric disorders
22q13.3 deletion		Hypotonia, developmental delay, normal or accelerated growth, severe expressive language deficits, autistic behavior
Xp21.2-p21.3		Duchenne muscular dystrophy, retinitis pigmentosa, adrenal hypoplasia, intellectual disability, glycerol kinase deficiency
Xp22.2-p22.3		Ichthyosis, Kallmann syndrome, intellectual disability, chondrodysplasia punctata
Xp22.3	MLS	*M*icrophthalmia, *l*inear *s*kin defects, poikiloderma, congenital heart defects, seizures, intellectual disability

Table 98.14

Microduplications and Their Clinical Manifestations

DUPLICATION CHROMOSOME REGION	DISEASE REGION	CLINICAL FEATURES
1q21.1		Macrocephaly, DD, learning disabilities
3q29		Mild to moderate MR, microcephaly
7q11.23	Williams syndrome	DD and severe expressive language disorder, autistic features, subtle dysmorphisms
15q13.3	Prader-Willi/Angelman syndrome	DD, MR, autistic features in duplications of maternal origin
15q24		Growth restriction, DD, microcephaly, digital anomalies, hypospadias, connective tissue abnormalities
16p11.2		FTT, severe DD, short stature, GH deficiency, dysmorphic features
17p11.2	Potocki-Lupski syndrome	Hypotonia, cardiovascular anomalies, FTT, DD, verbal apraxia, autism, anxiety
17q21.31		Severe DD, microcephaly, short and broad digits, dysmorphic features
22q11.2	Velocardiofacial-DiGeorge syndrome	Cardiovascular defects, velopharyngeal insufficiency
Xq28	*MECP2* gene (Rett syndrome)	In males: infantile hypotonia, immune deficiency, dysmorphic features, DD, speech delay, autistic behavior, regression in childhood

DD, Developmental delay; ID, intellectual disability; FTT, failure to thrive; GH, growth hormone; MR, mental retardation.

Subtelomeric regions are often involved in chromosome rearrangements that cannot be visualized using routine cytogenetics. *Telomeres*, which are the distal ends of the chromosomes, are gene-rich regions. The distal structure of the telomeres is essentially common to all chromosomes, but proximal to these are unique regions known as *subtelomeres,* which typically are involved in deletions and other chromosome rearrangements. Small subtelomeric deletions, duplications, or rearrangements (translocations, inversions) may be relatively common in children with nonspecific intellectual disability and minor anomalies. Subtelomeric rearrangements have been found in 3–7% of children with moderate to severe intellectual disability and 0.5% of those with mild intellectual disability and can be detected by aCGH studies.

Telomere mutations and length abnormalities have also been associated with dyskeratosis congenita and other aplastic anemia syndromes, as well as pulmonary or hepatic fibrosis. Both the subtelomeric rearrangements and the microdeletion and microduplication syndromes are typically diagnosed by molecular techniques such as aCGH and multiple ligation-dependent primer amplification studies. Recent studies show that aCGH can detect 14–18% of abnormalities in patients who previously had normal chromosome studies.

Insertions

Insertions occur when a piece of a chromosome broken at 2 points is incorporated into a break in another part of a chromosome. A total of 3 breakpoints are then required, and they can occur between 2 or within 1 chromosome. A form of nonreciprocal translocation, insertions are rare. Insertion carriers are at risk of having offspring with deletions or duplications of the inserted segment.

Isochromosomes

Isochromosomes consist of 2 copies of the same chromosome arm joined through a single centromere and forming mirror images of one another. The most commonly reported autosomal isochromosomes tend to involve chromosomes with small arms. Some of the more common chromosome arms involved in this formation include 5p, 8p, 9p, 12p, 18p, and 18q. There is also a common isochromosome abnormality seen in long arm of the X chromosome and associated with Turner syndrome. Individuals who have 1 isochromosome X within 46 chromosomes are monosomic for genes in the lost short arm and trisomic for the genes present in the long arm of the X chromosome.

Marker and Ring Chromosomes

Marker chromosomes are rare and are usually chromosome fragments that are too small to be identified by conventional cytogenetics; they usually occur in addition to the normal 46 chromosomes. Most are sporadic (70%); mosaicism is often (50%) noted because of the mitotic instability of the marker chromosome. The incidence in newborn infants is 1 in 3,300, and the incidence in persons with intellectual disability is 1 in 300. The associated phenotype ranges from normal to severely abnormal, depending on the amount of chromosome material and number of genes included in the fragment.

Ring chromosomes, which are found for all human chromosomes, are rare. A ring chromosome is formed when both ends of a chromosome are deleted and the ends are then joined to form a ring. Depending on the amount of chromosome material that is lacking or in excess (if the ring is in addition to the normal chromosomes), a patient with a ring chromosome can appear normal or nearly normal or can have intellectual disability and multiple congenital anomalies.

Marker and ring chromosomes can be found in the cells of solid tumors of children the cells of whose organs do not contain this additional chromosomal material.

98.4

Sex Chromosome Aneuploidy

Carlos A. Bacino, Brendan Lee

About 1 in 400 males and 1 in 650 females have some form of sex chromosome abnormality. Considered together, sex chromosome abnormalities are the most common chromosome abnormalities seen in liveborn infants, children, and adults. Sex chromosome abnormalities can be either structural or numerical and can be present in all cells or in a mosaic form. Those affected with these abnormalities might have few or no physical or developmental problems (Table 98.15).

Table 98.15

Sex Chromosome Abnormalities

DISORDER	KARYOTYPE	APPROXIMATE INCIDENCE
Klinefelter syndrome	47,XXY	1/580 males
	48,XXXY	1/50,000-1/80,000 male births
	Other (48,XXYY; 49,XXXYY; mosaics)	
XYY syndrome	47,XYY	1/800-1,000 males
Other X or Y chromosome abnormalities		1/1,500 males
XX males	46,XX	1/20,000 males
Turner syndrome	45,X	1/2,500-1/5,000 females
	Variants and mosaics	
Trisomy X	47,XXX	1/1,000 females
	48,XXXX and 49,XXXXX	Rare
Other X chromosome abnormalities		1/3,000 females
XY females	46,XY	1/20,000 females

Turner Syndrome

Turner syndrome is a condition characterized by complete or partial monosomy of the X chromosome and defined by a combination of phenotypic features (Table 98.16). Half the patients with Turner syndrome have a 45,X chromosome complement. The other half exhibit mosaicism and varied structural abnormalities of the X or Y chromosome. Maternal age is not a predisposing factor for children with 45,X. Turner syndrome occurs in approximately 1 in 5,000 female live births. In 75% of patients, the lost sex chromosome is of paternal origin (whether an X or a Y). 45,X is one of the chromosome abnormalities most often associated with spontaneous abortion. It has been estimated that 95–99% of 45,X conceptions are miscarried.

Table 98.16

Signs Associated With Turner Syndrome

- Short stature
- Congenital lymphedema
- Horseshoe kidneys
- Patella dislocation
- Increased carrying angle of elbow (cubitus valgus)
- Madelung deformity (chondrodysplasia of distal radial epiphysis)
- Congenital hip dislocation
- Scoliosis
- Widespread nipples
- Shield chest
- Redundant nuchal skin (in utero cystic hygroma)
- Low posterior hairline
- Coarctation of aorta
- Bicuspid aortic valve
- Cardiac conduction abnormalities
- Hypoplastic left heart syndrome and other left-sided heart abnormalities
- Gonadal dysgenesis (infertility, primary amenorrhea)
- Gonadoblastoma (increased risk if Y chromosome material is present)
- Learning disabilities (nonverbal perceptual motor and visuospatial skills) (in 70%)
- Developmental delay (in 10%)
- Social awkwardness
- Hypothyroidism (acquired in 15–30%)
- Type 2 diabetes mellitus (insulin resistance)

Strabismus
Cataracts
Red-green color blindness (as in males)
Recurrent otitis media
Sensorineural hearing loss
Inflammatory bowel disease
Celiac disease (increased incidence)

Clinical findings in the newborns can include small size for gestational age, webbing of the neck, protruding ears, and lymphedema of the hands and feet, although many newborns are phenotypically normal (Fig. 98.17). Older children and adults have short stature and exhibit variable dysmorphic features. Congenital heart defects (40%) and structural renal anomalies (60%) are common. The most common heart defects are bicuspid aortic valves, coarctation of the aorta, aortic stenosis, and mitral valve prolapse. The gonads are generally streaks of fibrous tissue (**gonadal dysgenesis**). There is primary amenorrhea and lack of secondary sex characteristics. These children should receive regular endocrinologic testing (see Chapter 604). Most patients tend to be of normal intelligence, but intellectual disability is seen in up to 6% of affected children. They are also at increased risk for behavioral problems and deficiencies in spatial and motor perception. Guidelines for health supervision for children with Turner syndrome are published by the American Academy of Pediatrics (AAP) and include pubertal induction, as well as treatment with growth hormone and oxandrolone.

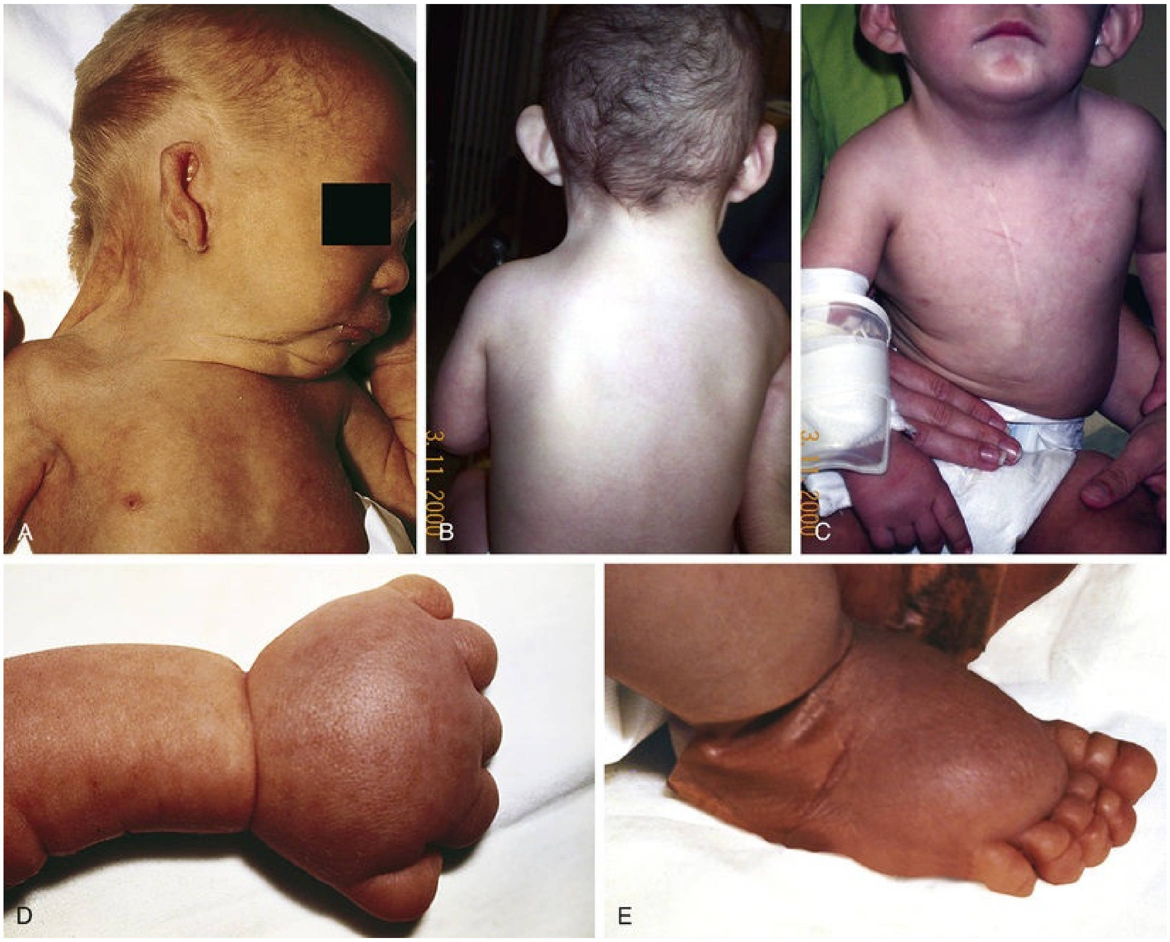

FIG. 98.17 Physical manifestations associated with turner syndrome. A, This newborn shows a webbed neck with low hairline, shield chest with widespread nipples, abnormal ears, and micrognathia. B, The low-set posterior hairline can be better appreciated in this older child, who also has protruding ears. C, In this frontal view, mild webbing of the neck and small, widely spaced nipples are evident, along with a midline scar from prior cardiac surgery. The ears are low set and prominent, protruding forward. D and E, The newborn shown in A also has prominent lymphedema of the hands and feet. (From Madan-Khetarpal S, Arnold G: Genetic disorders and dysmorphic conditions. In Zitelli BJ, McIntire SC, Nowalk AJ, editors: *Zitelli and Davis' atlas of pediatric physical diagnosis,* ed 6, Philadelphia, 2012, Elsevier, Fig 1.25.)

Patients with **45,X/46,XY mosaicism** can have Turner syndrome, although this form of mosaicism can also be associated with male pseudohermaphroditism, male or female genitalia in association with mixed gonadal dysgenesis, or a normal male phenotype. This variant is estimated to represent approximately 6% of patients with mosaic Turner syndrome. Some of the patients with Turner syndrome phenotype and a Y cell line exhibit masculinization. Phenotypic females with 45,X/46,XY mosaicism have a 15–30% risk of developing **gonadoblastoma** . The risk for the patients with a male phenotype and external testes is not so high, but tumor surveillance is nevertheless recommended. AAP has recommended the use of FISH analysis to look for Y chromosome mosaicism in all 45,X patients. If Y chromosome material is identified, laparoscopic gonadectomy is recommended.

Noonan syndrome shares many clinical features with Turner syndrome and was formerly called *pseudo-Turner syndrome* , although it is an autosomal dominant disorder resulting from mutations in several genes involved in the RAS-MAPK (mitogen-activated protein kinase) pathway. The most common of these is *PTPN11* (50%), which encodes a protein-tyrosine phosphatase (SHP-2) on chromosome 12q24.1. Other genes include *SOS1* in 10–13%, *RAF1* in 3–17%, *RITI* in 5%, *KRAS* <5%, *BRAF* <2%, *MAP2K* <2%, and *NRAS* (only few reported families). Overlapping phenotypes are seen in LEOPARD (lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, deafness) syndrome, cardiofaciocutaneous (CFC) syndrome, and Costello syndrome; these are Noonan-related disorders. Features common to Noonan syndrome include short stature, low posterior hairline, shield chest, congenital heart disease, and a short or webbed neck (Table 98.17). In contrast to Turner syndrome, Noonan syndrome affects both sexes and has a different pattern of congenital heart disease, typically involving right-sided lesions.

Table 98.17

Signs Associated With Noonan Syndrome

Short stature
Failure to thrive (best to use Noonan growth curve)
Tall forehead
Epicanthal folds
Ptosis
Blue-green irises
Hypertelorism
Low nasal bridge, upturned nose
Downward-slanting palpebral fissures
Myopia
Nystagmus
Low-set and posteriorly rotated auricles
Dental malocclusion
Low posterior hairline
Short, webbed neck (excessive nuchal skin), cystic hygroma

Shield chest
Pectus carinatum superiorly
Scoliosis
Pigmented villonodular synovitis (polyarticular)
Cubitus valgus
Pulmonary valve stenosis (dysplastic valve)
Hypertrophic cardiomyopathy
Atrial septal defect, ventricular septal defect
Lymphedema
Nevi, lentigines, café au lait spots
Cryptorchidism
Small penis
Delayed puberty
Bleeding disorders, including thrombocytopenia and coagulation factor deficiencies
Leukemia, myeloproliferative disorders, other malignancies
Cognitive delay (*KRAS* mutation)

Klinefelter Syndrome

Persons with Klinefelter syndrome are phenotypically male; this syndrome is the most common cause of hypogonadism and infertility in males and the most common sex chromosome aneuploidy in humans (see Chapter 601). Eighty percent of children with Klinefelter syndrome have a male karyotype with an extra chromosome X-47,XXY. The remaining 20% have multiple sex chromosome aneuploidies (48,XXXY; 48,XXYY; 49,XXXXY), mosaicism (46,XY/47,XXY), or structurally abnormal X chromosomes; the greater the aneuploidy, the more severe the mental impairment and dysmorphism. Early studies showed a birth prevalence of approximately 1 in 1,000 males, but more recent studies suggest that the prevalence of 47,XXY appears has increased to approximately 1 in 580 liveborn males; the reasons for this are still unknown but hypothesized to be the result of environmental factors acting in spermatogenesis. Errors in paternal nondisjunction in meiosis I account for half the cases.

Puberty commences at the normal age, but the testes remain small. Patients develop secondary sex characters late, and 50% ultimately develop gynecomastia. They have taller stature. Because many patients with Klinefelter syndrome are phenotypically normal until puberty, the syndrome often goes undiagnosed until they reach adulthood, when their infertility leads to identification. Patients with 46,XY/47,XXY have a better prognosis for testicular function. Their intelligence shows variability and ranges from above to below average. Persons with Klinefelter syndrome can show behavioral problems, learning disabilities, and deficits in language. Problems with self-esteem often occur in adolescents and adults. Substance abuse, depression, and anxiety have been reported in adolescents with Klinefelter syndrome. Those who have higher X chromosome counts show impaired cognition. It has been estimated that each additional X chromosome reduces the IQ by 10-15 points, when comparing these individuals with typical siblings. The main effect is seen in language skills and social domains.

47,XYY

The incidence of 47,XYY is approximately 1 in 800-1,000 males, with many cases remaining undiagnosed, because most affected individuals have a normal appearance and normal fertility. The extra Y is the result of nondisjunction at paternal meiosis II. Those with this abnormality have normal intelligence but are at risk for learning disabilities. Behavioral abnormalities, including hyperactive behavior, pervasive developmental disorder, and aggressive behavior, have been reported. Early reports that assigned stigmata of criminality to this disorder have long been disproved.

Fragile Chromosome Sites

Carlos A. Bacino, Brendan Lee

Fragile sites are regions of chromosomes that show a tendency for separation, breakage, or attenuation under particular growth conditions. They visually appear as a gap in the staining in chromosome studies. At least 120 chromosomal loci, many of them heritable, have been identified as fragile sites in the human genome (see Table 97.2).

A clinically significant fragile site is on the distal long arm of chromosome Xq27.3 associated with the **fragile X syndrome** . Fragile X syndrome accounts for 3% of males with intellectual disability. There is another fragile site on the X chromosome (FRAXE on Xq28) that has also been implicated in mild intellectual disability. The FRA11B (11q23.3) breakpoints are associated with **Jacobsen syndrome** (condition caused by deletion of the distal long arm of chromosome 11). Fragile sites can also play a role in tumorigenesis. In fragile X syndrome the CGG repeat expansion silences the gene producing **fragile X mental retardation protein (FMRP)** that regulates the translation of multiple mRNAs to specific proteins, thus affecting synaptic function. FMRP deficiency upregulates the metabotropic glutamate receptor (mGluR) 5 pathway. FMRP deficiency also alters the expression of matrix metalloproteinase (MMP) 9.

The main clinical manifestations of fragile X syndrome in affected males are intellectual disability, autistic behavior, postpubertal macroorchidism, hyperextensible finger joints, and characteristic facial features (Table 98.18). The facial features, which include a long face, large ears, and a prominent square jaw, become more obvious with age. Females affected with fragile X show varying degrees of intellectual disability and/or learning disabilities. Diagnosis of fragile X syndrome is possible by DNA testing that shows an expansion of a triplet DNA repeat inside the *FMR1* gene on the X chromosome >200 repeats. The expansion involves an area of the gene that contains a variable number of trinucleotide (CGG) repeats (typically <50 in unaffected individuals). The larger the triplet repeat expansion, the more significant is the intellectual disability. In cases where the expansion is large, females can also manifest different degrees of intellectual disability. Males with premutation triple repeat expansions (55-200 repeats) have been found to have an adult, late-onset, progressive neurodegenerative disorder known as **fragile X–associated tremor/ataxia syndrome** . Females with premutation triple repeat expansions are at high risk for developing premature ovarian failure (POF).

Table 98.18

Clinical Features of Full and Premutation *FMR1* Alleles

DISORDER	PHENOTYPE		ONSET	PENETRANCE
	Cognitive or Behavioral	Clinical and Imaging Signs		
FULL MUTATION (>200 repeats)				
FXS	Developmental delay: mean IQ = 42 in M; IQ is higher if significant residual FMRP is produced (e.g., females and mosaic males or unmethylated full mutations) Autism 20–30% ADHD 80% Anxiety 70–100%	Hypothalamic dysfunction: macroorchidism, 40%[*] Facial features, 60%,[*] large cupped ears, elongated face, high arched palate Connective tissue abnormalities: mitral valve prolapse, scoliosis, joint laxity, flat feet Others: seizures (20%), recurrent otitis media (60%), strabismus (8–30%)	Neonate	M 100%
PREMUTATION (55-200 repeats)				
Female reproductive symptoms		POF (<40 yr)	Adult/childhood	F 20% [†]
		Early menopause (<45 yr)		F 30% [†]
FXTAS	Cognitive decline, dementia, apathy, disinhibition, irritability, depression	Gait ataxia, intention tremor, parkinsonism, neuropathy, autonomic dysfunction	>50 yr	M 33% [‡] F unknown
Neurodevelopmental disorder	ADHD, autism, or developmental delay	Mild features of FXS	Childhood	8% (1/13)[*]

[*] Frequency of those signs in prepubertal boys; one third of boys with FXS are without classic facial features. Macroorchidism is present in 90% of men.

[†] Maximum penetrance reported for allele size approximately 80-90 CGG repeats.

[‡] Penetrance is correlated with age and repeat size.

ADHD, Attention-deficit/hyperactivity disorder; F, female; FMRP, fragile X mental retardation protein; FXS, fragile X syndrome; FXTAS, fragile X–associated tremor/ataxia syndrome; M, male; POF, premature ovarian failure.

98.6

Mosaicism

Carlos A. Bacino, Brendan Lee

Mosaicism describes an individual or tissue that contains ≥2 different cell lines typically derived from a single zygote and the result of mitotic nondisjunction (see Fig. 98.1). Study of placental tissue from chorionic villus samples collected at or before the 10th wk of gestation has shown that ≥2% of all conceptions are mosaic for a chromosome abnormality. With the exception of chromosomes 13, 18, and 21, complete autosomal trisomies are usually nonviable; the presence of a normal cell line might allow these other trisomic conceptions to survive to term. Depending on the point at which the new cell line arises during early embryogenesis, mosaicism may be present in some tissues but not in others. **Germline mosaicism** , which refers to the presence of mosaicism in the germ cells of the gonad, may be associated with an increased risk for recurrence of an affected child if the germ cells are affected with a chromosomal abnormality or with a specific gene mutation.

Pallister-Killian Syndrome

Pallister-Killian syndrome is characterized by coarse facies (prominent full cheeks), abnormal ear lobes, localized alopecia (sparse hair in the temporal regions), pigmentary skin anomalies, diaphragmatic hernia, cardiovascular anomalies, supernumerary nipples, seizures, and profound intellectual disability. The syndrome is caused by mosaicism for an isochromosome 12p. The presence of the isochromosome 12p in cells gives 4 functional copies for the short arm of chromosome 12 in the affected cells. The isochromosome 12p is preferentially cultured from fibroblasts that can be readily obtained from a skin punch biopsy and is seldom present in lymphocytes. The abnormalities seen in affected persons probably reflect the presence of abnormal cells during early embryogenesis.

Hypomelanosis of Ito

Hypomelanosis of Ito is characterized by unilateral or bilateral macular hypo- or hyperpigmented whorls, streaks, and patches (see Chapter 672). Sometimes these pigmentary defects follow the lines of Blaschko. Hair and tooth anomalies are common. Abnormalities of the eyes, musculoskeletal system (growth asymmetry, syndactyly, polydactyly, clinodactyly), and central nervous system (microcephaly, seizures, intellectual disability) may also be present. Patients with hypomelanosis of Ito might have two genetically distinct cell lines. The mosaic chromosome anomalies that have been observed involve both autosomes and sex chromosomes and have been demonstrated in about 50% of clinically affected patients. The mosaicism might not be visible in lymphocyte-derived chromosome studies; it is more likely to be found when chromosomes are analyzed from skin fibroblasts. The distinct cell lines might not always be caused by observable chromosomal anomalies but might result from single-gene mutations or other mechanisms.

98.7

Chromosome Instability Syndromes

Carlos A. Bacino, Brendan Lee

Chromosome instability syndromes, formerly known as *chromosome breakage syndromes,* are characterized by an increased risk of malignancy and specific phenotypes. They display autosomal recessive inheritance and have an increased frequency of chromosome breakage and/or rearrangement, either spontaneous or induced. Chromosome instability syndromes result from specific defects in DNA repair, cell cycle control, and apoptosis. The resulting chromosomal instability leads to the increased risk of developing neoplasms. The classic chromosome instability syndromes are Fanconi anemia, ataxia telangiectasia, Nijmegen syndrome, ICF (immunodeficiency, centromere instability, facial anomalies) syndrome, Roberts syndrome, Werner syndrome, and Bloom syndrome.

98.8

Uniparental Disomy and Imprinting

Carlos A. Bacino, Brendan Lee

Uniparental Disomy

Uniparental disomy (**UPD**) occurs when both chromosomes of a pair or areas from one chromosome in any individual have been inherited from a single parent. UPD can be of 2 types: uniparental isodisomy or uniparental heterodisomy. **Uniparental isodisomy** means that both chromosomes or chromosomal regions are identical (typically the result of monosomy rescue by duplication). **Uniparental heterodisomy** means that the 2 chromosomes are different members of a pair, both of which were still inherited from 1 parent. This results from a trisomy that is later reduced to disomy, leaving 2 copies from 1 parent. The phenotypic result of UPD varies according to the chromosome involved, the parent who contributed the chromosomes, and whether it is isodisomy or heterodisomy. Three types of phenotypic effects are seen in UPD: those related to imprinted genes (i.e., the absence of a gene that is normally expressed only when inherited from a parent of a specific sex), those related to the uncovering of autosomal recessive disorders, and those related to a vestigial aneuploidy producing mosaicism (see Chapter 97).

In uniparental isodisomy, both chromosomes or regions (and thus the genes) in the pair are identical. This is particularly important when the parent is a carrier of an autosomal recessive disorder. If the offspring of a carrier parent has UPD with isodisomy for a chromosome that carries an abnormal gene, the abnormal gene will be present in 2 copies, and the phenotype will be that of the autosomal recessive disorder; the child has an autosomal recessive disorder even though only 1 parent is a carrier of that recessive disorder. It is estimated that all humans carry approximately 20 abnormal autosomal recessive genes. Some autosomal recessive disorders, such as spinal muscular atrophy, cystic fibrosis, cartilage-hair hypoplasia, α- and β-thalassemias, and Bloom syndrome, have been reported in cases of UPD. The possibility of uniparental isodisomy should also be considered when a person is affected with >1 recessive disorder because the abnormal genes for both disorders could be carried on the same isodisomic chromosome. Uniparental isodisomy is a *rare* cause of recessively inherited disorders. Uniparental isodisomies can also be detected by SNP microarrays.

Maternal UPD involving chromosomes 2, 7, 14, and 15 and **paternal UPD** involving chromosomes 6, 11, 15, and 20 are associated with phenotypic abnormalities of growth and behavior. UPD of maternal chromosome 7 is associated with a phenotype similar to Russell-Silver syndrome with intrauterine growth restriction. These phenotypic effects may be related to imprinting (see later) (Fig. 98.18).

FIG. 98.18 Overview of the common clinical and molecular findings in the 8 known imprinting disorders, including specific features, frequencies, and major chromosomal localization. #6q24, Chromosome 6q24; EMG, exomphalos-macroglossia-gigantism; IUGR, intrauterine growth restriction; ID, intellectual disability; MLMDs, multilocus methylation defects. (From Eggermann T, Elbracht M, Schröder C, et al: Congenital imprinting disorders: a novel mechanism linking seemingly unrelated disorders, *J Pediatr* 163:1204, 2013).

UPD for chromosome 15 is seen in some cases of Prader-Willi syndrome and Angelman syndrome. In **Prader-Willi syndrome** , approximately 25–29% of cases have maternal UPD (missing the paternal chromosome 15) (Fig. 98.19). In **Angelman syndrome** , paternal UPD of chromosome 15 is rarer and is observed in approximately 5% of the cases (missing the maternal chromosome 15). The phenotype for Prader-Willi syndrome and Angelman syndrome in cases of UPD is thought to result from the lack of the functional contribution from a particular parent of chromosome 15. In Prader-Willi syndrome the paternal contribution is missing, and the maternal contribution is missing in Angelman syndrome. Prader-Willi syndrome may be caused by paternal deficiency of HB11-85 small nucleolar RNAs (snoRNAs). These findings suggest that there are differences in function of certain regions of chromosome 15, depending on whether it is inherited from the mother or from the father. Angelman syndrome is caused by absence of a maternally contributed gene known as *UBE3A* and can be the result of maternal deletion, maternal *UBE3A* mutation, paternal UPD, and abnormalities in the maternal imprinting center on chromosome 15q11-13 region.

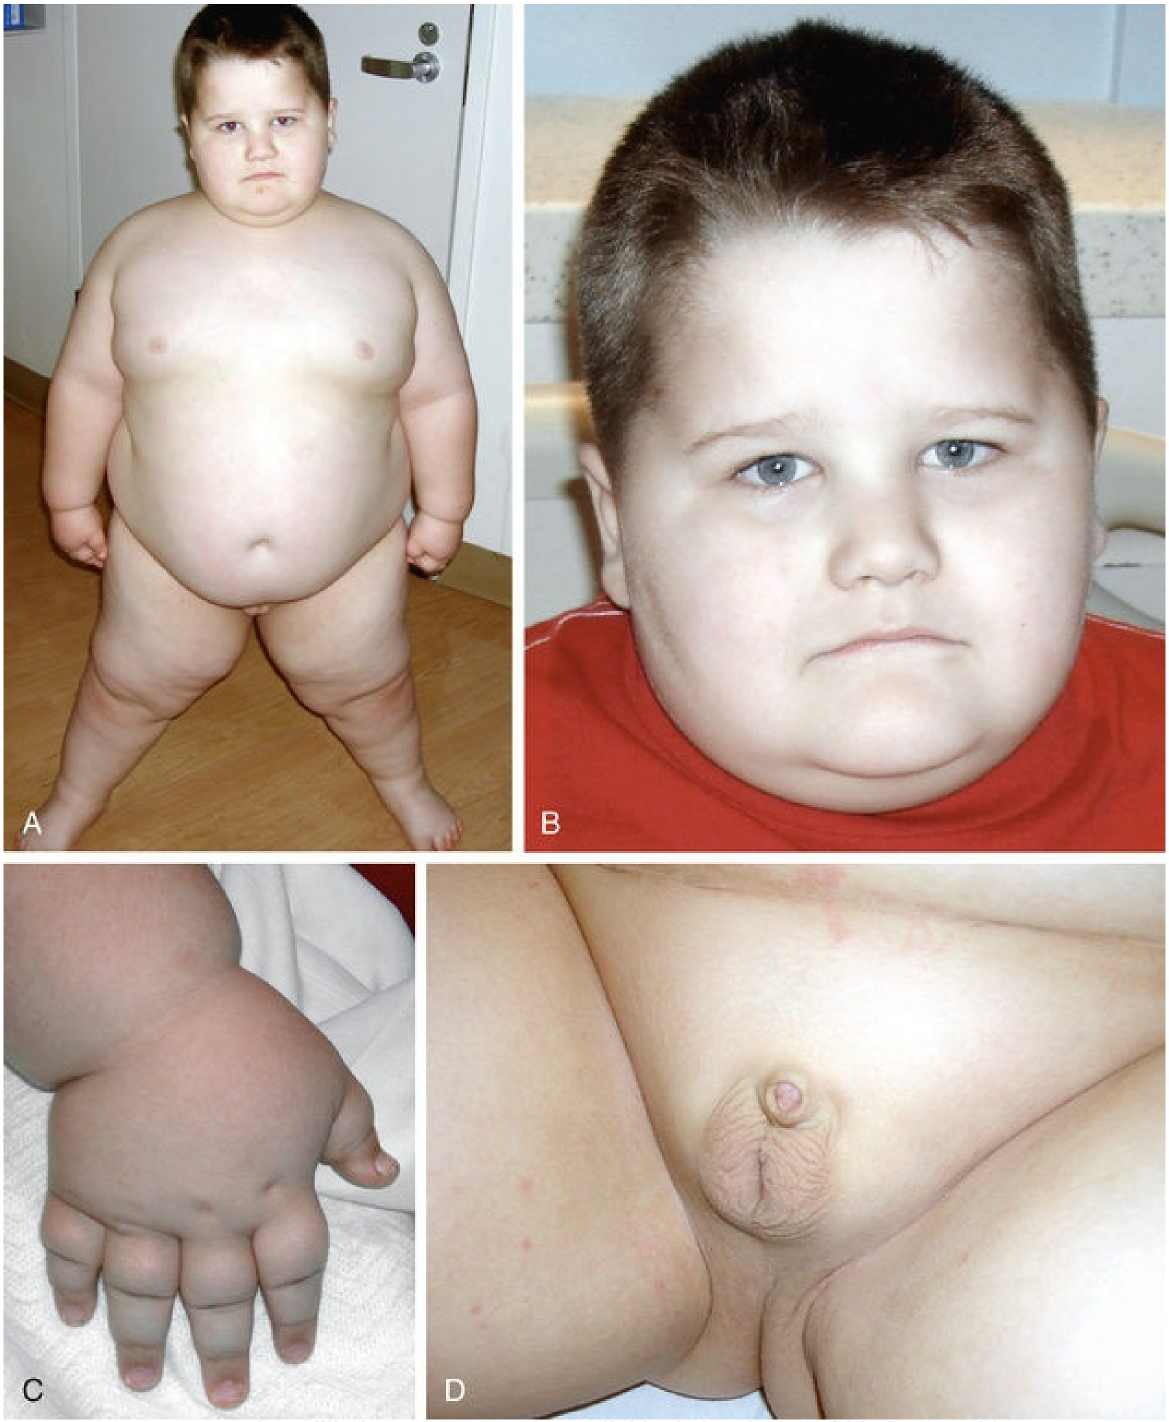

FIG. 98.19 Prader-Willi phenotype. A and B, Individual showing morbid obesity with facial features as shown. C, Upper extremities are notable for small hands relative to body size. D, External genitalia after laparoscopic orchiopexy at 13 mo. Parental informed consent, as approved by the Baylor College of Medicine Institutional Review Board, was obtained to publish the photographs. (From Sahoo T, del Gaudio D, German JR, et al: Prader-Willi phenotype caused by paternal deficiency for the HBII-85 C/D box small nucleolar RNA cluster, *Nat Genet* 40:719–721, 2008.)

UPD most frequently arises when a pregnancy starts off as a **trisomic**

conception followed by **trisomy rescue.** Because most trisomies are lethal, the fetus can only survive if a cell line loses 1 of the extra chromosomes to revert to the disomic state. One third of the time, the disomic cell line is uniparental. This is the typical mechanism for Prader-Willi syndrome, and it is often associated with advanced maternal age. The embryo starts off as trisomy 15 secondary to maternal meiosis I nondisjunction, followed by random loss of the paternal chromosome. In this case the disomic cell line becomes the more viable one and outgrows the trisomic cell line. When mosaic trisomy is found at prenatal diagnosis, care should be taken to determine whether UPD has resulted and whether the chromosome involved is one of the disomies known to be associated with phenotypic abnormalities. There must always be concern that some residual cells that are trisomic are present in some tissues, leading to malformations or dysfunction. The presence of aggregates of trisomic cells might account for the spectrum of abnormalities seen in persons with UPD.

Imprinting

Traditional genetics for many years has suggested that most genes are equally expressed when inherited from maternal vs paternal lineages. The only exception to this rule were genes on the X chromosome that are subject to inactivation, and the immunoglobulin genes subject to allelic exclusion, a phenomenon that results in monoallelic expression of a particular immunoglobulin chain by switching expression of parental alleles on and off. Genomic imprinting occurs when the phenotypic expression of a gene depends on the parent of origin for certain genes or in some cases entire chromosome regions. Whether the genetic material is expressed or not depends on the sex of the parent from whom it was derived. Genomic imprinting can be suspected in some cases on the basis of a pedigree. In these pedigrees the disease is always transmitted from one sex and could be passed on silently for several generations by the opposite sex (Figs. 98.20 and 98.21). Imprinting probably occurs in many different parts of the human genome and is thought to be particularly important in gene expression related to development, growth, cancer, and even behavior; >60 genes have been classified as imprintable. Imprinting disorders may arise from UPD, deletions or duplications, epigenetic aberrant methylation patterns, or point mutations in a specific gene.

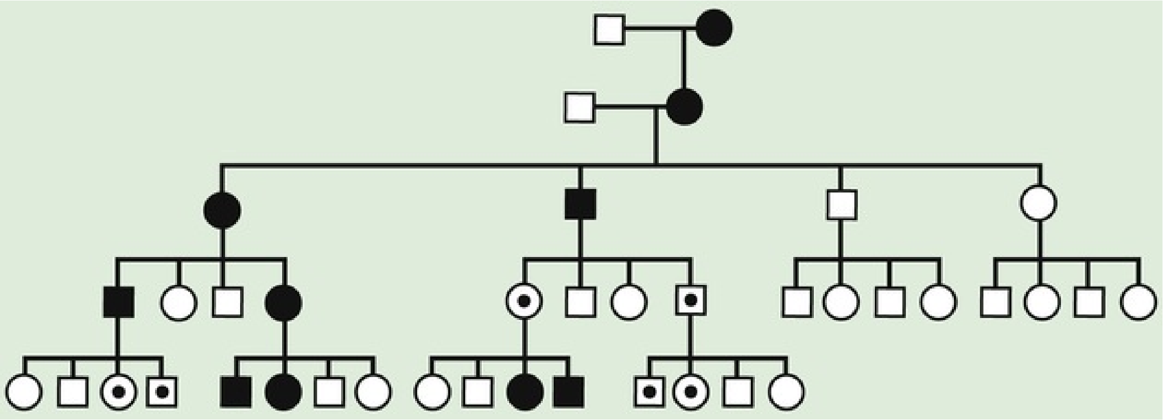

FIG. 98.20 In this hypothetical pedigree suggestive of imprinting, phenotypic effects occur only when the mutated gene is transmitted from the mother, but not when it is transmitted from the father, that is, maternal deficiency. Equal numbers of males and females can be affected and not affected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the sex of the parent who passes the expressed genetic information; that is, in maternal deficiency disorders (also termed *paternal imprinting*), there are "skipped" nonmanifesting females. This is theoretical, because in most clinical scenarios of maternal deficiency, such as Angelman syndrome, affected persons do not reproduce.

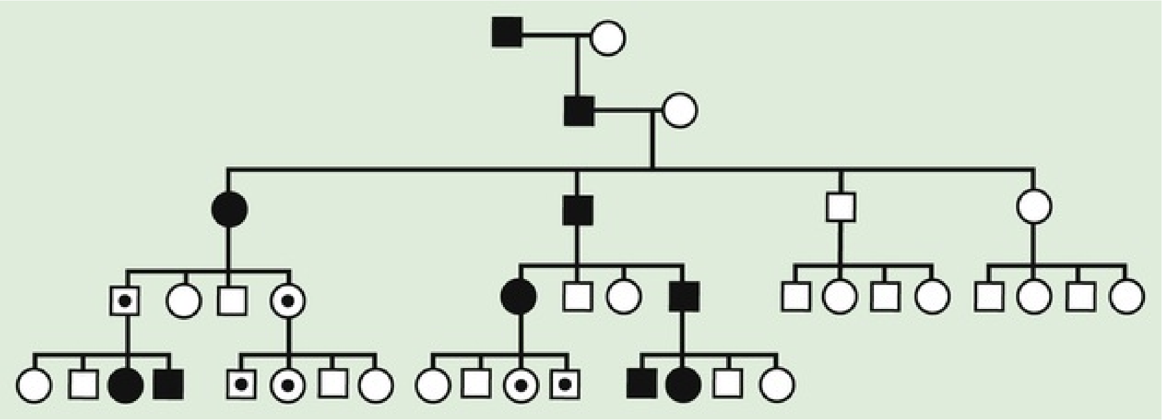

FIG. 98.21 In theoretical pedigrees suggestive of paternal deficiency (maternal imprinting), phenotypic effects occur only when the mutated gene is transmitted from the father, but not when transmitted from the mother. Equal numbers of males and females can be affected and not affected phenotypically in each generation. In a theoretical situation, a nonmanifesting transmitter gives a clue to the sex of the parent who passes on the expressed genetic information; that is, in paternal deficiency (also known as *maternal imprinting*), there are "skipped" nonmanifesting males. In real-life clinical cases of Prader-Willi syndrome, affected persons do not reproduce.

A classic example of imprinting disorder is seen in Prader-Willi syndrome and Angelman syndrome, 2 very different clinical conditions. These syndromes are usually associated with deletion of the same region in the proximal long arm of chromosome 15. A deletion on the paternally derived chromosome causes Prader-Willi syndrome, in which the maternally derived copy is still intact, but some of the imprinted genes within this region normally remain silent. Prader-Willi syndrome can be diagnosed clinically (Table 98.20) and confirmed with genetic testing. Additional clinical features and issues of weight gain are noted in Table 98.21 . The weight gain is difficult to control, but treatment with growth hormone has resulted in improvements in height, lean body mass, decreased adipose tissue, and improvement in cognitive function.

Table 98.20

Consensus Diagnostic Criteria for Prader-Willi Syndrome

	MAJOR CRITERIA (1 point each)	MINOR CRITERIA (1/2 point each)
1	Neonatal/infantile hypotonia	Decreased fetal movement and infantile lethargy
2	Feeding problems and failure to thrive as an infant	Typical behavior problems
3	Weight gain at 1-6 yr; obesity; hyperphagia	Sleep apnea
4	Characteristic dysmorphic facial features	Short stature for family by 15 yr
5	Small genitalia; pubertal delay and insufficiency	Hypopigmentation for the family
6	Developmental delay/intellectual disability	Small hands and feet for height
7		Narrow hands, straight ulnar border
8		Esotropia, myopia
9		Thick, viscous saliva
10		Speech articulation defects
11		Skin picking

Data from Cassidy SB, Schwartz S, Miller JL, Driscoll DJ: Prader-Willi syndrome, *Genet Med* 14(1):15, 2012, Table 2.

Table 98.21

Nutritional Phases in Prader-Willi Syndrome

PHASE	MEDIAN AGES	CLINICAL CHARACTERISTICS
0	Prenatal to birth	Decreased fetal movements and lower birthweight than siblings
1a	0-9 mo	Hypotonia with difficulty feeding and decreased appetite
1b	9-25 mo	Improved feeding and appetite and growing appropriately
2a	2.1-4.5 yr	Weight increasing without appetite increase or excess calories
2b	4.5-8 yr	Increased appetite and calories, but can feel full
3	8 yr to adulthood	Hyperphagic, rarely feels full
4	Adulthood	Appetite is no longer insatiable

Modified from Miller JL, Lynn CH, Driscoll DC, et al. Nutritional phases in Prader-Willi syndrome.

Am J Med Genet A 155A:1040–1049, 2011.

A maternal deletion of the same region as in Prader-Willi syndrome causes Angelman syndrome, leaving intact the paternal copy that in this case has genes that are also normally silent. In other situations, UPD can lead to the same diagnosis (Table 98.22). Many other disorders are associated with this type of parent-of-origin effect, as in some cases of Beckwith-Wiedemann syndrome, Russell-Silver syndrome, and neonatal diabetes.

Table 98.22

Molecular Mechanisms Causing Prader-Willi and Angelman Syndromes

	PRADER-WILLI SYNDROME	ANGELMAN SYNDROME
15q11-q13 deletion	~70% (paternal)	~70% (maternal)
Uniparental disomy	~30% (maternal)	~5% (paternal)
Single-gene mutation	None detected	E6-AP ubiquitin-protein ligase (11% of total but mostly in familial cases)
Imprinting center mutation	5%	1%
Unidentified	<1%	10–15%

Data from Nicholls RD, Knepper JL: Genome organization, function and imprinting in Prader-Willi and Angelman syndromes, *Annu Rev Genomics Hum Genet* 2:153–175, 2001; and Horsthemke B, Buiting K: Imprinting defects on human chromosome 15, *Cytogenet Genome Res* 113:292–299, 2006.

CHAPTER 99

Genetics of Common Disorders

Bret L. Bostwick, Brendan Lee

Common pediatric diseases are usually multifactorial. The combination of many genes and environmental factors contribute to a complex sequence of events leading to disease. The complexity of the combination of contributing factors increases the challenge of finding genetic variants that cause disease. Genetic tools include the completed human genome sequence, public databases of genetic variants, and the human haplotype map. In addition to public genetic databases, dramatic reduction in the cost of genotyping and DNA sequencing has allowed very large numbers of genetic variants to be efficiently tested in large numbers of patients. Most of these studies focus on common variants (those with frequencies >5%). Technologies for DNA sequencing are allowing whole exome sequencing in many individuals at very low cost. This technology is being used to investigate the role of rare coding sequence variants in common diseases. The incorporation of these tools into large, well-designed population studies is the field of **genetic epidemiology** . Many new methods for analyzing genetic data have been developed, stimulating a renaissance in applied population genetics.

99.1

Major Genetic Approaches to the Study of Common Pediatric Disorders

Millions of genetic variants are present in every person. Many of these variants have no impact on health, while others have a measureable influence. Sometimes, single-gene mutations consistently cause a disease, as with cystic fibrosis and sickle cell anemia. Other types of genetic variation, however, can contribute much less to the emergence of specific medical conditions, and these are best conceptualized as *modifiers* of disease risk. Fig. 99.1 demonstrates the relationship between variant frequency and the relative medical impact of the allele. The spectrum of variant impact is logarithmic, ranging widely from a slightly increased risk of illness to predetermined fully expressed disease. Studies aimed at discovering rare variants with outsized health effects only require small sample populations to achieve statistical significance, while those studying common variants require much larger sample sizes because of the small anticipated impact of each variant.

FIG. 99.1 Relationship between allele frequency and relative strength of genetic effect. Alleles with large effect tend to be very rare but can be studied with a small sample size because of the relative ease of allele detection when medical impact is high. Common variants tend to have a modest or low effect on health, requiring large datasets to visualize statistically small effects. The vast majority of disease-associated alleles

identified to date have the characteristics shown within the *diagonal dotted lines.* GWA, Genome-wide association. (Adapted from McCarthy MI, Abecasis GR, Cardon LR, et al: Genome-wide association studies for complex traits: consensus, uncertainty and challenges, *Nat Rev Genet* 9:356–369, 2008.)

The cumulative risk of many common variants determines genetic susceptibility. For common conditions, the genetic predisposition alone is not sufficient to cause disease. Everyone inherits a different degree of disease vulnerability, which is then augmented by exposure to certain environmental factors. Fig. 99.2 shows a model for the contribution of common genetic variants to individual health. One of the goals in medical genetics is to identify the genes that contribute to initial genetic susceptibility and to help prevent the occurrence of disease, either by avoiding inciting environmental factors or by instituting interventions that reduce risk. For persons who cross the threshold of disease, the goal is to better understand the pathogenesis in the hope that this will suggest better approaches to treatment. Common genetic variation can also influence response to medications and the risk of adverse drug reactions (see Chapter 72) and augment the health impacts of environmental toxins.

FIG. 99.2 Model for the influence of gene-environment interaction on genetic susceptibility to common diseases. Everyone inherits common variants that determine initial genetic liability for disease risk. For multifactorial disorders, the initial genetic susceptibility is insufficient to produce disease on its own. Over time, exposure to environmental factors increases the likelihood of a disease state. Identifying the gene

variants responsible for risk can lead to prevention strategies or treatments.

Complex traits may be inherently difficult to study if the precision of clinical diagnosis (phenotype) is problematic, as often occurs with neurobehavioral traits. A starting point in the genetic analysis of a complex trait is to obtain evidence in support of a genetic contribution and to estimate the relative strength of genetic and environmental factors. Complex traits typically exhibit familial clustering but are not transmitted in a regular pattern as is autosomal dominant or recessive inheritance. Complex traits often show variation among different ethnic or racial groups, possibly reflecting the differences in gene variants among these groups.

Assessing the potential genetic contribution begins by determining whether the trait is seen among related individuals more often than in the general population. A common measure of **familiality** is the first-degree relative risk (usually designated by the symbol λ_s), which is equal to the ratio of the prevalence rate in siblings and/or parents to the prevalence rate in the general population. The λ_s for type 1 diabetes is about 15. The relative strength of genetic and nongenetic risk factors can be estimated by variance components analysis. The **heritability** of a trait is the estimate of the fraction of the total variance contributed by genetic factors (Fig. 99.3).

$$\overset{\text{Phenotypic variance}}{V_P} = \overset{\text{Genetic variance}}{V_G} + \overset{\text{Environmental variance}}{V_E} + \overset{\text{Measurement variance}}{V_M}$$

$$\underset{\text{Heritability}}{h^2 = V_G / V_P}$$

FIG. 99.3 Heritability concept. The phenotypic variance of a particular trait can be partitioned between the contributions of the genetic variance, environmental variance, and measurement variance. This is usually empirically determined. Heritability is defined by the proportion of the phenotypic variance that is accounted for by the genetic variance. One can estimate the heritability from correlation of a quantitative trait between relatives.

A minority of cases of common diseases such as diabetes may be caused by single-gene mutations (mendelian inheritance), chromosomal disorders, and other genomic disorders. These *less common* causes of the disease can often provide important insight into the most important molecular pathways involved. Chromosomal regions with genes that might contribute to disease susceptibility could theoretically be located with **linkage mapping** , which locates regions of DNA that are inherited in families with the specific disease. In practical terms, however, this has become quite difficult for most complex traits either because of a dearth of families or because the effect of individual genetic loci is weak.

Genetic **association studies** are more powerful in identifying common gene variants (>5% in the population) that confer increased risk of disease, but they fail if the disease-causing gene variants are relatively rare. Detection of the modest effect of each variant and interactions with environmental factors requires well-powered studies that often include thousands of individuals. A number of parallel approaches for analyzing the aggregate effects of rare variants in genes have also been developed. Such rare variant association methods also seem to require large sample sizes because the gene effects have also proved to be relatively weak.

Linkage mapping and association studies require markers along the DNA that can be ascertained, or **genotyped** , with large-scale, high-throughput laboratory techniques. Markers that are typically used are in the forms of microsatellites and **single nucleotide polymorphisms** (**SNPs** ; Fig. 99.4). A sample of the same region of genome from 50 people will reveal that approximately 1 in every 200 bases varies from the more common form. Although most SNPs lack any obvious function, a few alter the amino acid sequence of the protein or affect regulation of gene expression. Some of these functional alterations directly affect susceptibility to disease. A complex clinical **phenotype** can be defined by the presence or absence of a disease as a **dichotomous trait** , or by selection of a clinically meaningful variable such as serum glucose in type 2 diabetes, which is a continuous or **quantitative trait** .

FIG. 99.4 **Different combinations of SNPs are found in different individuals. The locations of these SNPs can be pinpointed on maps of human genes. Subsequently, they can be used to create profiles that are associated with difference in response to a drug, such as efficacy and nonefficacy. (Adapted from Roses A: Pharmacogenetics and the practice of medicine, *Nature* 405:857–865, 2000. Copyright 2000. Reprinted by permission of Macmillan Publishers Ltd.)**

Although it might not be possible to define subgroups of patients in advance based on common disease mechanisms, the more uniform the phenotype, the more likely that a genetic study will be successful. **Locus heterogeneity** refers to the situation in which a trait results from the independent action of more than 1 gene. **Allelic heterogeneity** indicates that more than 1 variant in a particular gene can contribute to disease risk. The development of a trait or disease from a nongenetic mechanism results in a **phenocopy** . These 3 factors often contribute to the difficulty in identifying individual disease susceptibility genes, because they reduce the effective size of the study population.

A person bearing any variant or **allele** (inherited unit, DNA segment, or chromosome) in a gene has a certain probability of being affected with a specific gene variant–associated disease. This is called the **penetrance** . Some diseases manifest signs only later in life (age-related penetrance), which could lead to misclassifying children who actually have the disease-producing gene as unaffected. Single-gene disorders are typically caused by mutations with relatively high penetrance, but some common variants have very low penetrance because their overall contribution to the disease is small. Many such common variants can contribute to disease risk for a complex trait. Normal human height is influenced by >400 genes.

Ideally, important environmental exposures should be measured and accounted for in a population because there may be a dependent interaction between the environmental factor and specific genetic variant. An example is the likely requirement for a viral infection preceding onset of type 1 diabetes. Although **gene-environment interactions** are strongly suspected to play an important role in common diseases, it is difficult to identify and measure them. Very large studies with uniform collection of information about environmental exposures are rare. Methods, such as genome-wide analysis of DNA methylation, may show evidence of environmental effects—so-called developmental programming (see Chapter 100). This information might be used to discover and validate gene-environment interactions.

Linkage Mapping

Linkage studies were used in the past to isolate genes that cause rare genetic syndromes; modified methods have been used to identify chromosomal regions linked to more common diseases. Linkage studies involve tagging segments of a person's genome with markers that allow identification of segments that have been inherited through the family along with disease. The markers are typically **microsatellites** or SNPs that define and help to distinguish which type of an allele any person carries. **Genotype** refers to the combination of alleles at a locus in a diploid organism**.** Linkage analyses of common diseases have shown inconsistent results. Factors such as heterogeneity, pleiotropy, variable expressivity, and reduced penetrance, in addition to variability in environmental exposures, weaken the power of linkage studies in complex traits.

Genetic Association

For multifactorial common diseases, association analyses may be used to identify causally important genes. There are two types of association study: **direct association** , in which the causal variant itself is tested to see whether its presence correlates with disease, and **indirect association** , in which markers that are physically close to the biologically important variant are used as proxies. The correlation of markers with other genetic variants in a small region of the genome is called **linkage disequilibrium** . Indirect association is enabled by the construction of a detailed genetic map in 3 reference populations (Europeans, Asians, West Africans) through the International HapMap Project. SNPs that tag most of the genome have been identified and can be genotyped at low cost using specially designed microarrays.

Three basic study designs are used for association testing. In a case control design, the frequency of an allele in the affected group is compared with the unaffected group. In a family-based control design, parents or siblings of an affected individual are used as the controls. In a cohort design, large numbers of people are ascertained and then followed for the onset of any number of diseases. The cohort analysis is very expensive, and there are few true cohort studies.

Family-based control study designs are somewhat attractive for pediatric diseases because it is usually possible to enroll parents. These studies solve a major problem in testing for association because the parents are perfectly matched for genetic background. When parents are collected, the statistical test used for these studies is called the **transmission disequilibrium test** . TDT compares the transmitted genotype with the inferred nontransmitted genotype. The success of all association analysis depends on the design of a well-powered study and an accurately measured trait to avoid phenotypic misclassification. In large, population-based studies, confounding by ethnicity or **population stratification** could distort results. Some genetic variants are more common in people from a particular ethnic group, which could cause an apparent association of a variant with a disease, when the disease rate happens to be higher in that group. This association would not be a true association between an allele and a disease, because the association would be confounded by genetic background. The family-based tests using the TDT are immune to population stratification. However, TDT and related study designs are inherently less efficient than case control studies. Newer methods for measuring subtle mismatching between cases and controls using many thousands of markers routinely genotyped in genome-wide association studies allow researchers to account for this effect.

Association studies should be a powerful tool to find genetic variation that confers risk to an individual; the effect of any 1 genetic variant will be a very small contribution to the complex disease pathway. Genetic variants have been found that implicate a novel gene in a process, motivating more in-depth research into systems that will affect disease outcome. Associations such as the *APOE* ε4 variant with an increased risk of Alzheimer disease are noted by many studies. Many published association results are not reproducible; insufficient power and stratification might account for the inconsistencies. As of late 2016, 2,650 studies and 29,954 unique SNP-trait associations have been catalogued (https://www.ebi.ac.uk/gwas/).

Low-cost methods for sequencing the complete exomes *and* genomes of individuals will allow a more comprehensive evaluation of the full range of genetic variants involved in common diseases. Rare genetic variants, including small insertions or deletions, could turn out to be extremely important in explaining the impact of genetic factors in important pediatric diseases such as autism, cardiovascular malformations, and other birth defects. Common traits such as obesity, diabetes, and autoimmune diseases might also be affected by rare variants. In common severe disorders such as intellectual disability and complex heart malformations, de novo mutations (i.e., mutations not present in either parent) are known to play an important role.

CHAPTER 100

Epigenome-Wide Association Studies and Disease

John M. Greally

Pediatricians are asked to consider the possibility that certain conditions involve epigenetic mechanisms. The assumption is that **epigenetic** processes, generally defined as regulatory control of gene expression, are capable of overriding information encoded in the DNA sequence to increase or decrease the risk of a disease. Despite powerful genomic assays to test these regulators of gene expression, it has proved difficult to provide clear answers about how epigenetic mechanistic insights could improve patient care. Clarifying the fundamental concepts and definitions that underlie proposed epigenetic contributions to phenotypes should lead to valuable insights into their role in human health.

Epigenetic Mechanisms of Disease: Viable Yellow Mouse Model

The back-translated meaning of **epigenetics** (*epi,* above, upon; *genetic,* DNA sequence) implies that information encoded in the DNA sequence may be modifiable in some way by higher-order information that regulates the levels of activity of specific genes. Such a concept is attractive when trying to understand why monozygotic twins, who have identical DNA sequences, are sometimes discordant for certain heritable diseases, such as Alzheimer disease and type 1 diabetes mellitus. Genetic predisposition that fails to account fully for the development of a disease (or other) phenotype has been called “missing heritability,” a gap that epigenetic regulatory processes have been proposed to fill. Furthermore, because the environment influences the risk of certain disorders by modifying an underlying genetic predisposition, environmental stimuli may act through epigenetic regulatory processes of gene expression.

The most compelling evidence for the epigenetic, higher-level regulation of genes and predisposition to disease was the viable yellow mouse model (Fig. 100.1). This mouse was found to have a mutation involving an endogenous retrovirus, a component of the genome that can replicate itself and move to a new location. In the case of the viable yellow mouse, the endogenous retrovirus was the type called an **intracisternal A particle (IAP)** , which inserted upstream from a gene called *a* (*nonagouti*). The *nonagouti* gene encodes agouti-signaling protein precursor, which binds to and has a negative effect on melanocortin receptors. When it stimulates melanocytes in hair follicles, it causes the production of the yellow pheomelanin pigment rather than black eumelanin. Without the upstream IAP element, *nonagouti* would normally switch on for a very short burst of activity and stimulate a limited amount of yellow pigment production. The presence of the active IAP element upstream was found to create a new, constitutively active start site for the *nonagouti* gene, leading to the hair being produced with pheomelanin throughout its length, and a distinctive yellow fur phenotype. Because the agouti-signaling protein precursor is also expressed in other cell types, the extra activity of the *nonagouti* gene driven by the IAP element caused the yellow mice to become obese (due to actions on adipocytes), creating a syndrome comparable to human type 2 diabetes mellitus in these animals.

FIG. 100.1 The viable yellow mouse model of epigenetic modification of disease risk. The wild-type strain is depicted at the *top* ; the brown coat color is caused by a band of yellow pheomelanin within the shaft of the otherwise black hair, resulting from a pulse of expression during hair growth from the *a* (*nonagouti*) gene on chromosome 2. The lower examples represent what happens when the intracisternal A particle (IAP) transposable element inserts upstream from the *nonagouti* gene. These mice can be indistinguishable from wild-type mice when the IAP element is completely silenced (pseudoagouti phenotype), or the IAP element can be active in every cell (*bottom*), driving continuous transcription of the *nonagouti* gene and causing pheomelanin to be expressed throughout the growth of the hair, causing the yellow color of the fur (viable yellow phenotype). These mice are also obese because of the effect of agouti-signaling protein on adipocytes. When some cells express and others silence the IAP element, an intermediate fur phenotype, often described as “mottled,” is generated, accompanied by a less pronounced obesity. This demonstrates how the same genetic mutation (the IAP insertion) is variable in its association with a phenotype, depending on differences in transcriptional regulation at a specific locus in the genome.

These mice became an intriguing model of a potential epigenetic role in disease risk because of the unexpected observation that pups from the same litter, all containing the same IAP insertion mutation, differed strikingly in their amount of yellow fur and associated adult obesity. Some of the mice had so little yellow fur that they had no visible evidence of having a mutation at all. The IAP element in these littermates was active in the cells of the yellow mice, as expected, but had undergone **silencing** in the mice with the brown fur. The inactive IAP element was distinctive for having acquired **DNA methylation** , the modification of cytosines located immediately before guanines (CG or CpG dinucleotides) to 5-methylcytosine. Methylation of cytosines at CG dinucleotides is the default state throughout the genome, but it is usually absent at the sites regulating expression of nearby genes, so its acquisition at these sites indicates that the gene has undergone silencing. This suggested that an influence on how genes are expressed overrode innate genetic susceptibility, modifying the risk of acquiring a disease. Further, researchers modified the diets of mothers pregnant with a litter of pups with the IAP insertion by supplementing **folic acid** , a single-carbon donor that increased the availability of a cofactor needed for DNA methylation. The outcome was a higher proportion of pups born with DNA methylation and inactivation of the IAP mutation (Fig. 100.2).

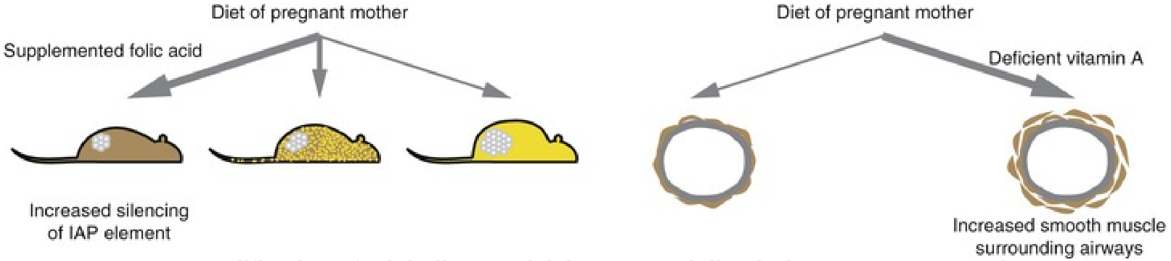

FIG. 100.2 Modification of adult disease risk by maternal diet during pregnancy. On the *left* is the pseudoagouti, intermediate, and viable yellow phenotypes associated with differences in silencing of the IAP element inserted upstream from the *nonagouti* gene. Increasing the amount of folic acid in the mother's diet during pregnancy is associated with an increased proportion of pups born with pseudoagouti and intermediate phenotypes, as well as less obesity during adulthood. On the *right* is the effect of vitamin A deficiency in the pregnant mother's diet during lung formation in the offspring. The lack of vitamin A during development is associated with the accumulation of smooth muscle (brown) around the airways and increased airway resistance during adulthood. The vitamin A deficiency results in a lack of retinoic acid in the developing embryos, leading to changes in gene expression regulation that alter cell fates and cause more smooth muscle cells to form. Both examples represent how dietary influences during pregnancy alter decisions made by cells during development, acting through regulation of gene expression, and predispose to adult diseases.

Therefore, a reason for the variability in whether the mice developed the yellow fur and obesity could be influences during pregnancy, such as maternal diet. This supported suggestions that intrauterine stresses were associated with increased risks of certain adult conditions, such as cardiovascular, renal, and metabolic diseases. This field of study is often known as the **Developmental Origins of Health and Disease (DOHaD)** , which asks how someone's cells remember an intrauterine stress years or decades later. The viable yellow mouse model suggested that such memory could be mediated by regulators of gene expression and influenced by environmental factors such as maternal diet during pregnancy.

Epigenetics and Regulation of Gene Expression

Two examples of gene regulation provide a model for locking in a regulatory pattern early in development and maintaining it indefinitely thereafter. The first is **X chromosome inactivation** . Because males have only 1 X chromosome, it does not undergo inactivation. However, a person with 2 X chromosomes will inactivate 1, a person with trisomy for the X chromosome will inactivate 2, and so on. The result is that males and females have 1 active X chromosome per cell, despite starting with different numbers of X chromosomes, a process referred to as **dosage compensation** .

X chromosome inactivation is generally a random event, choosing the maternal X for inactivation in half the cells of the body and the paternal X in the other half. The inactivation occurs very early during development, when the blastocyst is implanting itself into the uterine wall. However, once established in this small number of pluripotent cells, the inactivation persists in all the cells of the individual throughout life.

The other relevant model of gene regulation is **genomic imprinting** (see Chapter 97). Gene activation in a specific cell type usually switches on the copies present on both the paternal and the maternal chromosomes. However, an **imprinted locus** is distinctive because only the copy on the *paternal* chromosome is switched on for some imprinted genes, while other imprinted genes are distinctive for only switching on the maternal copy. The timing of this inactivation event is even earlier than X chromosome inactivation, occurring during the formation of the male or female gametes. Again, these patterns of inactivation persist throughout life into old age.

Evolution of the Term “Epigenetics”

Because the 2 previous examples both involved a gene regulation event (silencing) that occurred early in development and was maintained into adulthood, they were described as “epigenetic,” emphasizing how a cell retains a memory of past regulatory processes. This highlights that epigenetics has long been held to have a 2nd property, mediating cellular memory.

In the 1950s, Nanney interpreted the epigenetic landscape to define epigenetics as the property of a cell to remember past events. In the 1970s, Riggs and Holliday both noted that DNA methylation patterns could be propagated from parent to daughter cells, potentially providing a molecular mechanism of cellular memory, and described this as an “epigenetic property.” When DNA methylation was found to be a feature of the alleles silenced during X chromosome inactivation and genomic imprinting, this appeared to confirm the idea of a “heritable molecular mark” being involved in remembering a past silencing event during development, leading DNA methylation to be described as an “epigenetic regulator.” When the active and silenced alleles at X inactivated or imprinted loci were further studied, differences in chromatin states and long noncoding RNAs were found to distinguish the chromosomes, suggesting that they helped to mediate the long-term silencing at these loci.

There have been attempts to test whether chromatin states are heritable through cell division in the same way as DNA methylation. Despite the evidence for their heritability being less compelling, the field has tended to be *inclusive* rather than exclusive in labeling transcriptional regulators as epigenetic, but needed to redefine epigenetics as *epi* (above, upon) and *genetics* (DNA sequence), the back-translated definition. This definition is not only dissociated from the original ideas of cell fates and cellular memory, but now also encompasses all transcriptional regulatory processes. Because of the broadened definition of epigenetics, an experiment testing for differences in cellular memory is no different in design from an experiment testing for differences in transcriptional regulation, which may or may not mediate cellular memory.

Pediatric Diseases Involving Epigenetic Processes

Prime examples of epigenetics are those involving imprinted loci, exemplified by the Prader-Willi and Angelman syndromes (see Chapter 97). Each of these syndromes may be caused by the same deletion on chromosome 15, distinguished by the deletion occurring on the *paternal* chromosome 15 causing **Prader-Willi syndrome** and the *maternal* chromosome 15 causing **Angelman syndrome** . There are imprinted genes located within the 15q11-q13 region, some of which are expressed only on the paternal chromosome, some only on the maternal chromosome. When an individual is missing the region on the paternally inherited chromosome, the person still has a copy of the gene on the remaining maternal chromosome, but if it is silenced by imprinting, the individual effectively has *no functional copy* of the gene, leading to the Prader-

Willi phenotype. The converse happens for Angelman syndrome; a deletion of the maternal chromosome leaves a silenced copy of the gene on the paternal chromosome.

Although deletions cause these syndromes in the majority of affected individuals, a subset results from **uniparental disomy (UPD)** , in which there are 2 intact chromosomes 15, but both are inherited from *1 parent* . Maternal UPD has the same effect as a paternal deletion in that there is no contribution of a paternally inherited chromosome, causing Prader-Willi syndrome, with paternal UPD causing Angelman syndrome. UPD is thought to start with trisomy for that chromosome, with a 2nd event occurring early in development in which 1 of the 3 chromosomes is lost, occasionally leaving 2 chromosomes derived from the same parent. In a further, very small proportion of individuals, mutations within the 15q11-q13 region seem to affect the imprinted domain as a whole.

Prader-Willi and Angelman syndromes occur because of **genetic mutations** : large deletions, nondisjunction events leading to whole chromosomal gains or losses, or smaller DNA mutations. These mutations reveal the underlying pattern of genomic imprinting, a distinctive organization of gene regulation at chromosome 15q11-q13 that reflects a memory of the gamete of origin of each chromosome, described as epigenetic. What is *not* occurring in these individuals is an alteration of the normal epigenetic regulation of the locus, as exemplified by the yellow agouti mice. To find examples of altered epigenetic regulation associated with disease, researchers take advantage of assays that studied DNA methylation patterns throughout the genome. If we had never known about the IAP element insertion in the yellow agouti mice, for example, the locus would have revealed itself by having distinctive DNA methylation in the yellow, obese animals compared with the brown, lean, genetically identical littermates. This approach, referred to as an **epigenome-wide association study (EWAS)** , was initially applied to study individuals who had intrauterine perturbations, environmental exposures, or various types of cancer, to look for cellular reprogramming events.

Epigenome-Wide Association Studies: DNA Methylation

Because of the availability of genome-wide assays and its demonstrated heritability through mitosis, DNA methylation has been the primary focus for studies attempting to link altered epigenetic regulation with disease phenotypes. The *genome-wide association study* (GWAS) template was used for EWAS, but instead of linking variability in DNA sequences, the EWAS links variability in DNA methylation with the presence of a phenotype.

Interpretation of EWAS is more complex than foreseen partly because DNA methylation in a sample of cells reflects not only its reprogramming in these cells but also other influences. For example, if a sample of cells contains more than 1 subtype (each subtype of cells in the body has distinctive DNA methylation patterns), a change in proportion of *cell subtypes* between individuals will cause a change in the pattern of DNA methylation, at the loci where differences in DNA methylation distinguish the cell subtypes. In this way, DNA methylation changes can be found in an EWAS without any individual cells having altered their DNA methylation.

Another major influence, accounting for an estimated 22–80% of DNA methylation variation between individuals, is DNA sequence variability. Epigenetic regulation is defined as a level of information above that of DNA sequence, but the reciprocal influence of DNA sequence *variation* on DNA methylation is substantial. The typical EWAS to date has not taken genetic variation into account when interpreting its results, again suggesting misinterpretation of DNA methylation changes as reflective of reprogramming of cells, when in fact the differences in DNA methylation may reflect *sequence differences* in the individuals studied.

The typical design of an EWAS is cross-sectional: comparing a group of individuals with a condition against a group without the condition; by the time these people are studied, they have already developed the disorder of interest. This makes the study vulnerable to the effects of *reverse causation* , in which the condition studied alters DNA methylation, rather than reprogramming of DNA methylation causing the condition. This has been shown to occur in peripheral blood leukocytes in individuals with high body mass index. The results of all EWAS to date therefore should be interpreted with caution.

Cell Fate Variability as Model for Epigenetics and Disease

A universally held belief is that 1 or more cell types in the body undergo a change in the regulation of gene expression, a type of cellular reprogramming that alters the properties of the cell to contribute to the disease. However, another model to consider is a reprogramming occurring earlier, during cell fate decision-making, and changing the repertoire of cells in the organ in such a way that it predisposes to disease.

Studies are guided by a mouse model characterized by maternal **vitamin A deficiency** during pregnancy. Vitamin A is the dietary precursor of **retinoic acid** , which binds to a retinoic acid receptor that then finds its way to specific locations in the genome to regulate the expression of groups of genes. When vitamin A was restricted in the diet of pregnant female mice from embryonic days 9.5-14.5, the period when most lung formation occurs, the mice were born with increased amounts of smooth muscle around the airways, later in their lives shown to be associated with increased airway resistance. The mice were thus showing a component of the reactive airways disease (asthma) phenotype caused solely by a micronutrient deficiency during fetal life (see Fig. 100.2). The change in a cell fate decision to alter the proportion of 1 or more cell types in the mature organ is a strikingly attractive mechanism for DOHaD and highly consistent with the original definition of epigenetic events based on cell fate decisions, but it is not considered the outcome of interest in current EWAS.

The same model can be considered for the epigenetic response to toxins, in particular **endocrine disruptors** , defined by their interaction with the endocrine system, for which links with epigenetic regulatory processes have been frequently sought. One interesting class of endocrine-disrupting chemical is the *organotins*, biocides used in different types of manufacturing. The organotin tributyltin was found to cause obesity and to direct tissue stem cells preferentially toward the production of adipocytes, signaling through a transcriptional pathway involving PPAR gamma. Again, this is not an outcome generally sought in a typical EWAS at present, but it represents a perturbation acting to change cell fate through transcriptional regulatory mechanisms and leading to an altered repertoire of cells in the exposed individual.

Epigenetic Disease and Therapeutic Interventions

The question arises whether interventions can ameliorate or reverse a disease phenotype when it is caused by epigenetic processes. In cancer, involving somatic mutations that can target various mediators of transcriptional regulation, numerous therapeutic avenues have emerged that show promise. An interesting noncancer example is the genetic condition called **Kabuki syndrome** , which is caused by mutations in either a histone methyltransferase (*KMT2D*) or a histone demethylase (*KDM6A*) gene, each of which has a role in creating accessible chromatin to allow genes to be expressed appropriately (Fig. 100.3 and Table 100.1). With the idea that increasing the amount of histone acetylation could help to compensate for the inappropriate histone methylation, mice with Kabuki syndrome were placed on a ketogenic diet, which increases the amount of β-hydroxybutyrate, an endogenous inhibitor of histone deacetylases. Mice on this diet showed improved neurogenesis and memory, suggesting that such an intervention in children with Kabuki syndrome may also have beneficial effects.

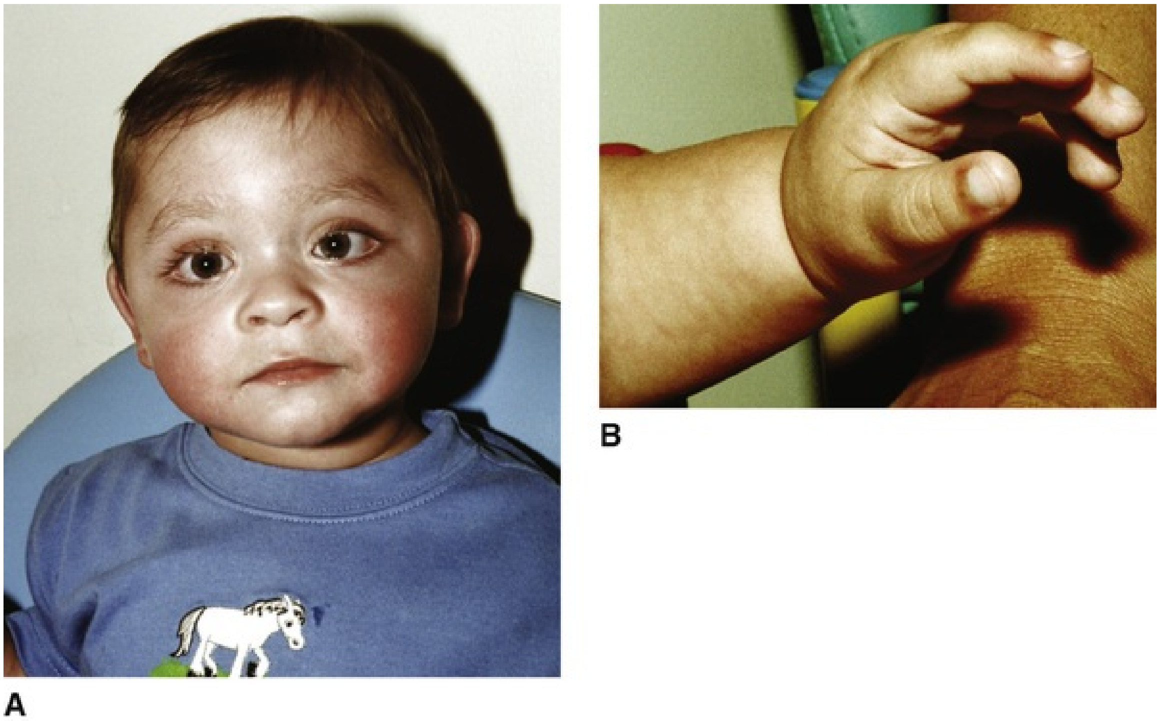

FIG. 100.3 Kabuki syndrome in 18 mo old boy. A, Long palpebral fissures and eversion of lateral portion of lower eyelids. B, Prominent fingertip pads. (From Jones, KL, Jones MC, Del Campo, M, editors: Smith's recognizable patterns of human malformation, ed 7, Philadelphia, 2013, Elsevier, p 158.)

Table 100.1

Clinical Manifestations of Kabuki Syndrome

Facial

Long palpebral tissues and eversions of lateral third of lower eyelids
Ptosis
Broad, arched eyebrows with sparse hair on lateral third
Long eyelashes
Blue sclerae
Protuberant ears
Short nasal columella (depressed nasal tip)

Neurodevelopmental

Hypotonia
Developmental delay (IQ about 60; >80 in 10%)
Low birthweight
Postnatal growth deficiency
Microcephaly
Seizures
Autism

Extremity/Skeletal

Short, incurved 5th finger
Brachydactyly
Kyphosis
Joint hyperextensibility
Persistent fetal fingertip pads
Hypoplastic finger nails

Cardiovascular

Multiple forms of congenital heart disease

Other

Nonimmune hydrops
Hypothyroidism
Precocious puberty
Delayed puberty
Lymphatic malformations
Feeding difficulties

CHAPTER 101

Genetic Approaches to Rare and Undiagnosed Diseases

William A. Gahl, David R. Adams, Thomas C. Markello, Camilo Toro, Cynthia J. Tifft

Rare and novel disorders often present in childhood and represent a diagnostic challenge that can be addressed using advanced genetic techniques. In the United States, **rare disorders** are defined as those affecting <200,000 people (about 1 in 1,500 persons), but no single definition has been agreed on internationally.

Scope of Genetic Disease

An estimated 8000 rare disorders are recognized, and the existence of approximately 23,000 human genes suggests that many more genetic diseases will be discovered in the future. Potential reasons patients may remain undiagnosed despite extensive prior investigation include:

- The genetic variant had not previously been associated with the disease phenotype.
- There is genetic *pleiotropy* (same gene but different variant producing a different phenotype).
- There is genetic *heterogeneity* (different genes producing similar phenotype).
- Presentation is known but atypical features for a known disease.

◆ Multiple diseases are contributing to the presenting set of disease features.

◆ Somatic mosaicism

NIH Undiagnosed Diseases Program

One approach toward investigating undiagnosed diseases was taken by the National Institutes of Health (NIH) Undiagnosed Diseases Program (**UDP**), which was expanded to a nationwide Undiagnosed Diseases Network (UDN). For the >4,000 patient applications to the UDP, prior investigations are recounted in a summary letter from the referring clinician and documented with medical records that include photos, videos, imaging, and histologic slides of biopsy material. Specialty consultants review the records, and the UDP directors determine the next steps. Accepted patients come to the NIH Clinical Center for a week-long inpatient admission. Approximately half the patients with undiagnosed diseases have neurologic disease; cardiovascular, rheumatology, immunology, and pulmonary problems are also common. Approximately 40% of accepted patients are children, who often have congenital anomalies and neurologic disorders.

Clinical Evaluation

Patients remain without a definitive diagnosis after an extensive workup in part because every individual has a unique genetic and environmental background, and diseases have variable expression. Undiagnosed conditions include those never before seen, unusual presentations of otherwise recognizable conditions, and combinations of conditions that obfuscate each other's identities. A thorough clinical investigation allows the clinician to broaden the differential diagnosis through research, consultation, and clinical testing. Extensive phenotyping, imaging, and other tests provide better documentation of the presentation and allow for association with diseases not yet discovered, genetic variants, and patient cohorts.

A complete history anchors the data and includes prenatal and neonatal findings, developmental milestones, growth pattern, onset and progression of symptoms and signs, precipitating influences, response to medications, and a pedigree to determine which family members are possibly affected. Pertinent physical findings include dysmorphisms, organomegaly, neurologic impairment, bone involvement, and dermatologic findings. Because many rare and novel disorders are *multisystemic*, consultants play a critical role in every diagnostic evaluation. Typical studies performed to address possible diagnoses are listed in Table 101.1 ; neurodevelopmental or neurodegenerative phenotypes require even more extensive studies (Table 101.2).

Table 101.1

Initial Studies to Generate New Diagnostic Hypotheses

TEST	RELATED DISORDERS/DISORDER GROUPS
Electrolytes, lactate, pyruvate	Energy metabolism defects, including mitochondrial disorders
Plasma amino acids	Renal disorders, amino acid disorders
Urine organic acids	Renal disorders, organic acid disorders, energy metabolism disorders, vitamin deficiencies
Aldolase, creatine phosphokinase	Muscle disorders
Carnitine (free, total, acyl, panel)	Fatty acid oxidation disorders, carnitine metabolism disorders
Cerebrospinal fluid (CSF) analysis	Neurotransmitter disorders, inborn errors of metabolism, select disorders that may present only in the CSF
Brain MRI/magnetic resonance spectroscopy	Structural and morphologic clues to disorders affecting central nervous system
Mass spectrometry to detect *N* - and *O* -linked proteoglycan abnormalities	Congenital disorders of glycosylation
Lysosomal enzyme testing	Lysosomal storage diseases
White cell and skin electron microscopy	Lysosomal storage diseases; neuronal lipofuscinoses
Pathologic evaluation of affected tissues with special stains, DNA hybridization	Any
Echocardiogram, electrocardiogram	Structural and functional abnormalities of the heart
Nerve conduction velocity, electromyogram	Dysfunction of anterior horn cells, nerves, neuromuscular junction, or muscle
Fibroblast cell line	Any
Single nucleotide polymorphism, exome/genome/karyotype	Any
Erythrocyte sedimentation rate, C-reactive protein	Inflammatory disorders

Table 101.2

Diagnostic Evaluation of the Neurologically Impaired Child

Consultations

- Genetics/genetic counseling
- Neurology

Ophthalmology
Endocrinology
Immunology
Rheumatology
Dermatology
Cardiology
Neuropsychology
Nutrition
Rehabilitative medicine
    Physical therapy
    Occupational therapy
    Speech therapy

Procedures

Swallow study for aspiration
Abdominal ultrasound (hepatosplenomegaly)
Skeletal survey (dysostosis)
Bone density scan (nonambulatory or growth failure patients)
Bone age
Electroencephalogram, evoked responses, electroretinogram (ERG)
Muscle biopsy for electron transport chain function, histology, immunohistochemistry
Neuropsychometric testing
Nerve biopsy

Laboratory Evaluations

Complete blood count with differential and peripheral smear
Comprehensive metabolic panel
Prothrombin time/partial thromboplastin time (for anesthesia sedation)
Thyroid-stimulating hormone, thyroxine
Vitamins A and E, 1,25-dihydroxyvitamin D
Lactate, pyruvate
Ammonia
Amino acids (plasma and urine)

Organic acids (urine)
Acylcarnitine profile
Total and free carnitine
Lysosomal enzyme analysis in leukocytes/fibroblasts
White blood cell coenzyme Q
Purines and pyrimidines (urine)
α-Glucosidase (plasma and urine)
Peroxisomal panel
Oxysterols
Methylmalonic acid and homocysteine (plasma)
Copper/ceruloplasmin
Transferrin isoelectric focusing
N - and *O* -glycans (plasma)
Oligosaccharides and free glycans (urine)
Glycosaminoglycans (urine)

Additional Testing if Clinically Indicated

Electron microscopy of white blood cell buffy coat for inclusion bodies
Electron microscopy of skin biopsy for evidence of storage
Stool for ova and parasites, occult blood, fecal fat, or fecal calprotectin
Autoimmune antibodies
Vaccine response titers
C3/C4
Quantitative immunoglobulins
T-cell subsets
Conjunctival or salivary gland biopsy

Research Specimens

Cerebrospinal fluid
Serum
Plasma
Skin biopsy for fibroblasts and/or melanocytes
Isolated DNA/RNA
Urine

Studies Under Sedation

3T MRI/magnetic resonance spectroscopy of brain (and spine if indicated)
Skin biopsy
Ophthalmologic exam
Brainstem auditory evoked response
Electroretinogram
Lumbar puncture for biopterin, neopterin, neurotransmitters, folate, and inflammatory markers
Dental exam
Large blood draws
Catheterization for urine
Any part of the physical exam difficult to do in an awake child, including dysmorphology measurements and genital and rectal exam
Electromyography and nerve conduction studies

An inpatient admission allows for close interaction among experts in different fields, informs the evaluation of complex cases, and often leads to new disease discovery. In the last situation, other family members require evaluation to ascertain whether they are affected with the disorder.

Commercial Genetic Studies

Once **phenotyping** is complete, a list of candidate genetic disorders can be compiled. Laboratory testing is available for an increasingly large number of molecular disorders. Examples of genetic panels include those for X-linked cognitive impairment, hereditary spastic paraplegia, spastic paraplegia and gait disorders, spinocerebellar ataxias, dystonias, and mitochondrial disorders. Some of these are expensive and may exceed the cost of **exome sequencing** . On the other hand, exome and genome sequencing are not useful for detecting diseases caused by many types of genetic disorder, including from DNA repeats. In addition, exome sequencing may provide less certainty for excluding genetic diseases than a disease-specific test panel.

Single Nucleotide Polymorphism Arrays

Single nucleotide polymorphism (**SNP**) arrays and next-generation sequencing (NGS) provide valuable genome-wide structural information. The human genome's 3.2 billion bases include many that are **polymorphic,** customarily defined as differing between any 2 people >1% of the time. In most human populations, about 4 million differences exist between any 2 unrelated individuals (about 1 polymorphism for every 1,000 bases in the genome on average). Within a single ethnic population, about 1 common SNP occurs per 3,000-7,000 bases, where *common* means a >10% chance that the base will differ between 2 unrelated people. Approximately 1 million of these common SNPs can be included on a DNA hybridization array and examined simultaneously, revealing copy number variants, mosaicism, and regions of identity by descent. These results complement NGS results; one example is the pairing of sequence variants detected by exome or genome sequencing with *trans* -oriented deletions detected by SNP assay.

Exome Sequencing

Technical advances have allowed for massive, inexpensive DNA sequencing, making it feasible to determine the sequence of the coding regions of almost all the human genes. Because this involves 1.9% of the 3.2 billion bases in the human genome, exome sequences comprise approximately 60,000,000 bases. Using current technology, clinical exome sequencing adequately sequences >80% of known genes and >90% of genes that have been associated with human disease. The average exome sequencing produces about 35,000 bases (0.06%) that differ from the “reference” sequence and from any other unrelated human sequence of the same ethnic group. These variants include some laboratory and computational errors. In practice, most variants are inconsequential polymorphisms and minor polynucleotide repeats that occur near intron/exon boundaries. However, each of the 35,000 variants of unknown significance is a *potential* disease-causing variant, yet only 1 (or 2 for compound heterozygous recessive cases) is *the* disease-causing mutation for a monogenic disorder (with perhaps 2 or 3 additional loci modifying severity). The clinician and bioinformatician must reduce the number of candidate variants to a tractable number, which is challenging. For instance, a variant causing an adult-onset disease may look just as damaging as a different variant causing congenital-onset disease. However, the likelihood of the presence of the associated diseases is much different in an adult vs a child.

Certain rules are used to separate *likely-interesting variants* from likely-uninteresting variants. For example, variants that segregate in a family consistent with a given inheritance model (e.g., dominant or recessive) are retained, while those that segregate in an inconsistent manner are set aside. This segregation filter requires careful clinical data collection and experimental design, since it depends on correct assignment of affected vs unaffected statuses in the family and collection of sequencing data for family members besides the proband.

A 2nd technique used to evaluate sequence variants is **pathogenicity assessment** . Bioinformaticians estimate the likelihood that a given DNA sequence variant will have biologic consequences (e.g., change protein function or gene expression). Factors such as nucleotide conservation and differences in coded amino acids are used to create a pathogenicity estimate, or score. Various software programs take different, often overlapping, approaches. PolyPhen-2, SIFT, and MutationTaster rate the pathogenicity of amino acid changes. Computer modeling programs such as CADD, Eigen, and M-CAP, trained on model genetic changes that are already validated, predict effects on gene expression of noncoding variants. These filters are very powerful because of large population datasets that are publically available, including the 1000Genomes project, ExAC, and the UK's 10K genome project. In the next 1 or 2 yr, datasets with genome populations in the 100,000 to 1 million range (e.g., GnomAD database) will further improve these filters and provide better subpopulation frequencies. Ultimately, a multiethnic, graph theory-based alignment should allow successful filtering of variants in currently incomplete genomic regions such as the HLA region. Overall, computational pathogenicity assessment has false-positive and false-negative rates of 10–20%.

Some filters compare variants to databases that contain previously measured or asserted properties of variants found in human populations, such as population frequency information (e.g., ExAC), or curated evidence for association with human disease (e.g., CLINVAR). The latter, while potentially useful, is quite incomplete for many genes, but this is improving. One common pitfall of database-derived filters is an inaccurate designation of certain variants as rare. This typically happens when the database is missing information from human populations in whom the variant is seen more often than in the included populations.

Several points need to be considered when employing genome-scale sequencing for clinical diagnostics. **Positive predictive value** gives the likelihood that a positive test is a true positive. This is higher in a population in whom a disease is common and lower in a population in whom the disease is rare. A person being tested with exome sequencing will show no clinical signs or symptoms of most of the genetic diseases for which the exome sequencing tests. Therefore, many apparently positive findings will be *false positives*, variants associated with phenotypes that do not match the person being tested.

Individual vs family studies are relevant because family data allow for the proband's variants to be substantially filtered. This advantage must be weighed against the financial costs of studying families vs individuals. Furthermore, family studies are useless if an affected person is called unaffected, or vice versa. Therefore, *phenotyping family members is critical.* For later-onset conditions, younger siblings may not be suitable for inclusion in an exome sequencing study unless their affected status can be determined unambiguously. Datasets with large numbers of young individuals may have many pathologic variants that cause disease in elderly persons and are inappropriate for filtering variants in late-onset adult diseases or for prenatal counseling about late-onset disease inheritance risks.

Data revisiting policies must be addressed. Genome-scale sequencing generates data for many genes besides those involved in the current diagnostic effort; these data may be useful in the future care of the patient. Some unreported mutated genes, not currently associated with disease, may be implicated in the future as disease risk factors or even as protective factors. In the current testing environment, time-limited data reuse policies and storage and reuse fees are increasingly common. In fact, the storage of data is now becoming more expensive than the cost of re-generating the data.

Early discussion with a genetic specialist is critical. Genetic counseling should be sought before an exome sequencing study is sent. Proper consent for exome sequencing studies is an involved process, including discussions of disease risk factors, unrelated medical conditions, carrier states, and cancer susceptibility. Consented individuals should be asked which types of results they would like to receive.

Anticipating findings that are difficult to use clinically is an important part of counseling. Variants of unknown significance (VUS) are problematic, and genome-scale sequencing amplifies the problem by including variable numbers of results that are difficult to use for medical decision-making. Discussing such variants with families can be challenging; counseling families about the likelihood of receiving this type of result before testing is performed can help the family to cope when the report is returned (see Chapter 94).

When used as a gene panel, exome sequencing rules *in* but does not rule *out* . An exome study is a cost-effective way to test many genes simultaneously, but coverage of any given exon varies. Therefore, exome studies cannot always exclude **variants** in a panel of genes. With careful analysis involving laboratory validation performed on many similarly processed individuals, the exome coverage of any given gene can be assessed. However, commercial/clinical testing facilities may be unwilling to perform such an analysis when a large set of genes needs to be considered. Therefore, a gene panel can be useful when the index of suspicion is high for a disorder caused by a large group of genes. Cerebellar ataxia and hereditary spastic paraplegia are examples (see Chapters 615.1 and 631).

Providing information to the testing facility improves the chance of diagnosis. Exome sequencing interpretation benefits substantially from the incorporation of an accurate and detailed phenotype. The more clinical information provided to the testing lab, the more specific and useful will be the clinical report.

The role of whole *genome* sequencing (WGS) is not yet defined in clinical practice but remains a consideration when *exome* sequencing yields no diagnosis. The fundamental issue is whether the VUS findings in an exome will be more meaningful than any additional variants discovered by WGS, rather than a clinical conclusion that there is no germline genetic/molecular cause for the undiagnosed patient. WGS tools have less confidence because of net lower coverage, take more time to process, and generate variants in noncoding regions of the genome that are much more difficult to filter and interpret.

Gene Function Studies

Despite filtering for frequency and predicted deleteriousness, a variant identified by exome or genome sequencing cannot be interpreted as the cause of an individual's disease unless it has been previously demonstrated to cause a disease with a similar phenotype. To prove causality, medical genetics relies on **association** (the recurrence of mutations within a gene among individuals with a similar phenotype). For rare diseases, there may be too few affected patients to demonstrate a statistically significant association, and other evidence from phenotype ontologies, metabolomics, glycomics, proteomics, and lipidomics may be required. In addition, models (e.g., mice, zebrafish, fruit flies, yeast, cultured cells) can be developed to recapitulate the disease. The variant in question can also be linked to a biologic process or pathway that is known to cause a similar phenotype when disturbed. Finally, standardized and correlated phenotypic and genomic data are deposited into a database to identify other individuals with a similar phenotype and mutations in the same gene.

Physicians may apply their past biases to a group of variants that could be disease causing, but this is often misleading. A standardized computational approach is preferable. For example, the Human Phenotype Ontology standardizes the description of a disease and, because the descriptors have been mapped to other human diseases and to mutant model organisms, identifies possible candidate genes and genetic networks for causing the disease. Similarly, untargeted laboratory screening tests provide an unbiased survey of patient cellular biology and physiology and a more informed prioritization of candidate variants.

The ultimate proof of causality is to ameliorate the disease process by correcting the genetic defect; this might be demonstrable in a model system that recapitulates the human disease. Alternatively, a search for other patients with a similar phenotype and mutations in the same gene can be performed using public databases established using strict statistical and biologic standards.

Pediatric Issues

Of the UDP's 1st 500 pediatric applications, >10% had more than 1 family member (usually a sibling) similarly affected. The age distribution had peaks at 4-5 yr (reflecting patients with congenital disorders) and at 16-18 yr (representing disorders with symptom onset at early school age). Most applicants had been on a diagnostic odyssey for >5 yr. Of the 200 pediatric cases accepted, 25% received a diagnosis; half were obtained using conventional diagnostic methods, including clinical suspicion, biochemical testing with molecular confirmation, or radiographic interpretation. Otherwise, SNP analysis and NGS yielded the diagnosis; all involved rare diseases.

Pediatric medical records require attention to what has and what has not been completed previously. The electronic medical record is an important tool, but “copy forward” functions can perpetuate errors, such as reports of normal testing when in fact the test was recommended or ordered but not performed. Repetitive copying also fosters sloppiness in critical thinking, failure to take an adequate history, and missing the nuances of symptom progression. A history and physical examination should be performed anew and all prior testing results confirmed through copies of original laboratory reports.

Prolonged and painful procedures should be performed under sedation, but the risks associated with sedation must be weighed against the value of information and samples obtained.

Considerations for Families of Undiagnosed Children

When a child comes to a genetics clinic for evaluation, the parents ask these questions:

- What does my child have? (diagnosis)
- Why did it happen? (etiology/inheritance)
- What will happen in the future? (natural history; prognosis)
- Is there a treatment? (therapy)
- Could the same thing happen to other family members? (recurrence risk)

The answers all require an accurate diagnosis. The lack of a diagnosis makes both the family and the physician uncomfortable, raises suspicion among relatives and acquaintances, and creates feelings of guilt about not having worked hard enough to obtain a diagnosis. Families often consult more and more specialists, becoming frustrated with the lack of coordination among providers. Families should save copies of every test and every visit from each institution in a binder for travel among institutions. A 2- to 3-page narrative summarizing the child's history, medications, list of healthcare providers with contact information, main medical issues, level of functioning on well days and sick days, and interventions that worked in the past can be invaluable in an emergency room setting. An electronic copy is easily updated. Parents can always be the best advocates for their child, particularly an undiagnosed child.

Recommendations to parents of an undiagnosed child are similar to those that apply to any child with chronic illness:

◆ Organize copies of all records, especially original reports from “send-out” laboratories.

◆ Carry an updated emergency letter.

◆ Establish a medical home even if you obtain many second opinions.

◆ Find a physiatrist (rehabilitation medicine physician) to coordinate rehabilitative care.

◆ Strongly advocate with the school system for needed services (see Chapter 48), using a legal advocate if necessary;

◆ Explore parent support groups for unknown disorders (Syndromes Without a Name, National Organization for Rare Disorders).

◆ Periodically check with providers (especially geneticists) for new diagnoses reported in the medical literature.

◆ Carve out time for yourselves as caregivers by engaging extended family members or respite care services.

◆ Work at supporting and being attentive to well children in the family.

◆ For the dying child, consider an autopsy to establish a diagnosis, especially when there is a possibility of future pregnancies.

The Diagnostic Spectrum

Rare and new genetic disorders can present at any age; a gene's “severe” mutations may manifest early in life while “mild” mutations present later. Diagnoses of known disorders can have very different bases, such as the extent of recognition of a clinical entity, a molecular confirmation, or biochemical evidence. Some variants identified by SNP and exome sequencing analyses may represent new diseases.

One example of the use of these technologies to discover a new diagnosis involves 2 brothers whose parents were first cousins. The brothers had an early-onset spastic ataxia-neuropathy syndrome, with lower-extremity spasticity, peripheral neuropathy, ptosis, oculomotor apraxia, dystonia, cerebellar atrophy, and progressive myoclonic epilepsy. A homozygous missense mutation (c.1847G>A; p.Y616C) in *AFG3L2* , which encodes a subunit of a mitochondrial protease, was identified by exome sequencing. The AFG3L2 protein can bind to another AFG3L2 molecule or to paraplegin. UDP collaborators in Germany used a yeast model system to demonstrate that the patients' mutation affects the specific amino acid involved in the formation of both these complexes. As a result, the brothers exhibited the signs and symptoms of a known AFG3L2 defect, autosomal dominant spinocerebellar ataxia type 28 (SCA28), and also deficits attributable to a paraplegin defect, hereditary spastic paraplegia type 7 (SPG7). Other features of a mitochondrial disorder (oculomotor apraxia, extrapyramidal dysfunction, myoclonic epilepsy) were also present. The 2 brothers represent the 1st such cases in the world and expand the phenotype of AFG3L2 disease.

A 2nd example involves 2 siblings ages 5 and 10 yr with hypotonia, developmental delays, facial dysmorphisms, hearing loss, nystagmus, seizures, and atrophy on brain MRI. In this case the leading clue was biochemical in nature, and genetic analysis confirmed the diagnosis. Urine thin-layer chromatography for oligosaccharides identified a strong band determined by mass spectrometry to consist of a tetrasaccharide containing 3 glucoses and 1 mannose. This suggested a defect of glucosidase I, the 1st enzyme involved in endoplasmic reticulum trimming of *N* -linked glycoproteins from a high-mannose to a complex form. Mutation analysis confirmed compound heterozygous variants in the glucosidase I gene, establishing the diagnosis of congenital disorder of glycosylation IIb. The 2 siblings were the 2nd and 3rd patients in the world with this disorder.

Occasionally an autosomal dominant disorder, typically presenting in adulthood, can manifest as a completely different and more severe disorder when pathologic variants in the same gene are inherited from each parent; the child is a *compound heterozygote*. This was the case in a 3 yr old child who inherited 2 variants in *GARS*, the gene causing autosomal dominant Charcot-Marie-Tooth disease (CMT) 2D. The child had severe intrauterine and postnatal growth retardation, microcephaly, developmental delay, optic nerve atrophy and retinal pigment changes, as well as an atrial septal defect. Neither parent was symptomatic at the time the child was evaluated; the parents had normal electromyography and nerve conduction studies. This case emphasizes the need to consent families before any genetic testing as to the possibility of receiving unexpected results in additional family members. In this case, genetic counseling was expanded to include possible CMT2D in the parents.

CHAPTER 102

An Approach to Inborn Errors of Metabolism

Oleg A. Shchelochkov, Charles P. Venditti

Many childhood conditions are caused by single-gene mutations that encode specific proteins. These mutations can change primary protein structure or the amount of protein synthesized. The function of a protein, whether it is an enzyme, receptor, transport vehicle, membrane component, transcriptional co-regulator, or structural element, may be compromised or abolished. Hereditary diseases that disrupt normal biochemical processes are termed **inborn errors of metabolism** or **inherited metabolic diseases** .

Most genetic changes are clinically inconsequential and represent *benign* variants. However, pathogenic variants produce diseases that range in severity of presentation and time of onset. Severe metabolic disorders usually become clinically apparent in the newborn period or shortly thereafter, whereas milder forms may present later in childhood and even in adulthood. With some exceptions, the presenting symptoms of most metabolic conditions lack the specificity to enable a definitive diagnosis without further evaluation. The combination of *low specificity* of presenting symptoms and *low prevalence* of metabolic disorders makes determination of the diagnosis difficult. Progressive symptoms, the lack of plausible non-genetic diagnosis after detailed evaluation, history of overlapping symptoms in patient's relatives, or consanguinity should alert a pediatrician to seek a consultation with a geneticist and consider metabolic testing early in the evaluation.

Correct diagnosis is often only the beginning of a long medical journey for most families affected by metabolic conditions (see Chapter 95). Although each inherited metabolic disorder is individually rare, improved diagnosis and increasing survival of patients with metabolic conditions virtually ensure that a pediatrician will encounter and provide care to affected patients. Pediatricians can play a critical role in establishing the continuity of care, managing some aspects of treatment, fostering adherence, and delivering routine pediatric interventions such as immunizations, referrals to specialists, and elements of genetic counseling (see Chapter 94.1).

The greater awareness of metabolic conditions, wider availability of biochemical laboratories, global metabolomic analysis, and routine application of exome sequencing dramatically increased the detection rate of the known disorders and contributed to the discovery of new metabolic disorders. Nonetheless, collection and analysis of family history remains a critical screening test that a healthcare provider can use to identify an infant or child at risk for a metabolic disorder. The identification of consanguinity or a particular ethnic background with an unusually high incidence of inborn errors of metabolism can be important to direct further studies. For example, tyrosinemia type 1 is more common among French-Canadians of Quebec, maple syrup urine disease is seen with higher frequency in the U.S. Amish population, and Canavan disease in patients of the Ashkenazi Jewish ancestry.

Newborn Screening

The individual rarity of inborn errors of metabolism, the importance of early diagnosis, and the ensuing genetic counseling ramifications make a strong argument for the universal screening all newborn infants. **Tandem mass spectrometry** of metabolites and **digital microfluidics analysis** of enzyme activities form the foundation of newborn screening today. Both methods require a few drops of blood to be placed on a filter paper and delivered to a central laboratory for assay. Many genetic conditions can be identified by these methods, and the list of disorders continues to grow (Tables 102.1 and 102.2). Pediatricians need to be aware of the general screening procedure and limitations of screening. As a screening method, a positive result may require a repeat newborn screen or confirmatory testing to secure the diagnosis. Time required to return the results vary from country to country and even within states in the same country. Some metabolic conditions can be severe enough to cause clinical manifestations before the results of the newborn screening become available. Conversely, diagnostic metabolites in milder forms of screened disorders may not reach a set threshold to trigger secondary studies, thus leading to a negative newborn screen results and delayed diagnosis. *Therefore, negative newborn screening in a patient with symptoms suggestive of a metabolic disorder* *warrants a referral to genetics center for further evaluation.*

Table 102.1

Disorders Recommended by the American College of Medical Genetics Task Force for Inclusion in Newborn Screening (“Primary Disorders”)*

Disorders of Organic Acid Metabolism

Isovaleric acidemia
Glutaric aciduria type I
3-Hydroxy-3-methylglutaric aciduria
Multiple carboxylase deficiency
Methylmalonic acidemia (methylmalonyl-CoA mutase deficiency)
Methylmalonic acidemia (*cbl* A and *cbl* B defects)
Propionic acidemia
3-Methylcrotonyl-CoA carboxylase deficiency
β-Ketothiolase deficiency

Disorders of Fatty Acid Metabolism

Medium-chain acyl-CoA dehydrogenase deficiency
Very-long-chain acyl-CoA dehydrogenase deficiency
Long-chain 3-hydroxy-acyl-CoA dehydrogenase deficiency
Trifunctional protein deficiency
Carnitine uptake defect

Disorders of Amino Acid Metabolism

Phenylketonuria
Maple syrup urine disease
Homocystinuria
Citrullinemia type 1
Argininosuccinic acidemia

Tyrosinemia type I

Hemoglobinopathies

Sickle cell anemia (hemoglobin SS disease)
Hemoglobin S/β-thalassemia
Hemoglobin S/C disease

Other Disorders

Congenital hypothyroidism
Biotinidase deficiency
Congenital adrenal hyperplasia
Galactosemia
Hearing loss
Cystic fibrosis
Severe combined immunodeficiency (SCID) [†]
Critical congenital heart disease [†]

cbl A, Cobalamin A defect; *cbl* B, cobalamin B defect; CoA, coenzyme A.

---

[*] As of November 2014, there is state-to-state variation in newborn screening; a list of the disorders that are screened for by each state is available at http://genes-r-us.uthscsa.edu/sites/genes-r-us/files/nbsdisorders.pdf .

[†] The inclusion of SCID and critical congenital heart disease received support of the American College of Medical Genetics and Genomics.

Table 102.2

Secondary Conditions Recommended by American College of Medical Genetics[*] Task Force for Inclusion in Newborn Screening

Organic Acid Metabolism Disorders

Methylmalonic acidemia (*cbl* C and *cbl* D defects)
Malonic acidemia
2-Methyl-3-hydroxybutyric aciduria
Isobutyryl-CoA dehydrogenase deficiency
2-Methylbutyryl-CoA dehydrogenase deficiency
3-Methylglutaconic aciduria

Fatty Acid Oxidation Disorders

Short-chain acyl-CoA dehydrogenase deficiency
Glutaric acidemia type 2
Medium/short-chain 3-hydroxy-acyl-CoA dehydrogenase deficiency
Medium-chain ketoacyl-CoA thiolase deficiency
Carnitine palmitoyltransferase IA deficiency
Carnitine palmitoyltransferase II deficiency
Carnitine:acylcarnitine translocase deficiency
Dienoyl-CoA reductase deficiency

Amino Acid Metabolism Disorders

Hyperphenylalaninemia, benign (not classic phenylketonuria)
Tyrosinemia type II
Tyrosinemia type III
Defects of biopterin cofactor biosynthesis
Defects of biopterin cofactor regeneration
Argininemia
Hypermethioninemia
Citrullinemia type II (citrin deficiency)

Hemoglobinopathies

Hemoglobin variants (including hemoglobin E)

Others

Galactose epimerase deficiency
Galactokinase deficiency

cbl C, Cobalamin C defect; *cbl* D, cobalamin D defect; CoA, coenzyme A.

---

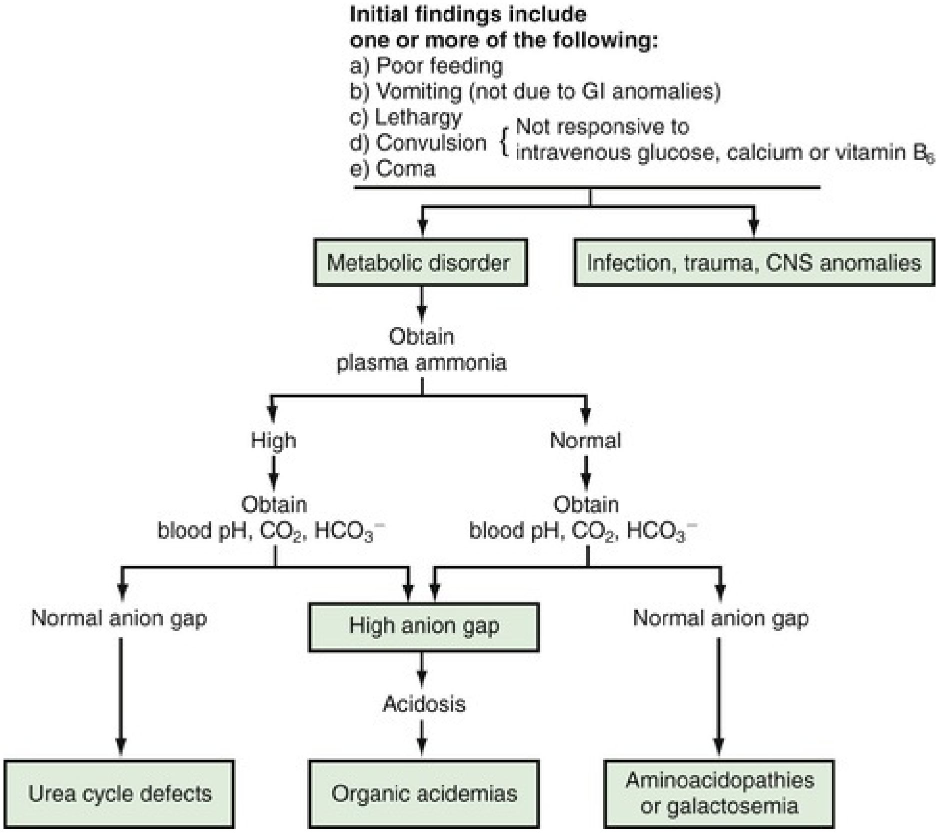
[*] The American College of Medical Genetics Newborn Screening Expert Group (May 2006) recommended reporting, in addition to the primary disorders, 25 disorders (“secondary targets”) that can be detected through screening but that do not meet the criteria for primary disorders (https://www.acmg.net/resources/policies/nbs/NBS_Main_Report_01.pdf).

Universal newborn screening may also identify mild forms of inherited metabolic conditions, some of which may never cause clinical manifestations in the lifetime of the individual. For example, short-chain acyl-CoA dehydrogenase deficiency has been identified with unexpectedly high frequency in screening programs using tandem mass spectrometry, but most of these children have remained asymptomatic. This highlights the need for an ongoing evaluation of metabolite cutoff values and approaches to confirmatory testing to maximize the diagnostic yield and minimize potential psychosocial and economic implications of such findings. Premature infants represent a special patient population in whom the incidence of false-positive or false-negative test results can be especially high.

With the advent of genetic therapy for spinal muscular atrophy (SMA) and enzyme replacement therapy for some lysosomal storage diseases (e.g., Pompe disease, Fabry disease, Gaucher disease, and mucopolysaccharidosis type 1), pilot newborn screening programs have demonstrated initial success in identifying SMA or lysosomal storage disorders, often before severe symptoms develop.

Clinical Manifestations of Genetic Metabolic Diseases

Physicians and other healthcare providers who care for children should familiarize themselves with early manifestations of genetic metabolic disorders, because (1) severe forms of some of these conditions may cause symptoms before the results of screening studies become available, and (2) the current screening methods, although quite extensive, identify a small number of all inherited metabolic conditions. In the newborn period, the clinical findings are usually nonspecific and similar to those seen in infants with sepsis. A genetic disorder of metabolism should be considered in the differential diagnosis of a severely ill newborn infant, and special studies should be undertaken if the index of suspicion is high (Fig. 102.1).



Initial findings include
one or more of the following:
a) Poor feeding
b) Vomiting (not due to GI anomalies)
c) Lethargy
d) Convulsion
e) Coma
Not responsive to intravenous glucose, calcium or vitamin B6
Metabolic disorder
Infection, trauma, CNS anomalies
Obtain plasma ammonia
High
Normal
Obtain blood pH, CO2, HCO3−
Obtain blood pH, CO2, HCO3−
Normal anion gap
High anion gap
Normal anion gap
Acidosis
Urea cycle defects
Organic acidemias
Aminoacidopathies or galactosemia

FIG. 102.1 **Initial clinical approach to a full-term newborn infant with a suspected genetic metabolic disorder. This schema is a guide to elucidate some of the metabolic disorders in newborn infants. Although some exceptions to this schema exist, it is appropriate for most cases affected by disorders or intermediate metabolism. CNS, Central nervous system; GI, gastrointestinal; HCO_3^- , bicarbonate.**

Signs and symptoms such as lethargy, hypotonia, hypothermia, convulsions (Table 102.3), poor feeding, and vomiting may develop as early as a few hours after birth. Occasionally, vomiting may be severe enough to suggest the diagnosis of pyloric stenosis, which is usually not present, although it may occur simultaneously in such infants. Lethargy, poor feeding, seizures, and coma may also be seen in infants with hypoglycemia (Table 102.4) (see Chapters 111 and 127), hypocalcemia (Chapters 64 and 589), and hyperammonemia (Table 102.5) (Chapter 103). Measurements of blood concentrations of glucose and calcium and response to intravenous injection of glucose or calcium help establish these diagnoses. Every organ system can be affected by metabolic disorders. However, *physical examination* usually reveals nonspecific findings; most signs are related to the central nervous system such as opisthotonus in the case of maple syrup urine disease (MSUD). Hepatomegaly is a common finding in a variety of inborn errors of metabolism (Table 102.6). Cardiomyopathy (Table 102.7), dysmorphology (Table 102.8), and fetal hydrops (Table 102.9) are additional potential manifestations of a metabolic disorder (Table 102.10). Occasionally, a peculiar odor may offer an invaluable aid to the diagnosis (Table 102.11).

Table 102.3

Select Inborn Errors of Metabolism Associated With Neurologic and Laboratory Manifestations in Neonates

DETERIORATION IN CONSCIOUSNESS
Metabolic Acidosis
Organic acidemias
Disorders of pyruvate metabolism
Fatty acid oxidation defects
Fructose-1,6-bisphosphatase deficiency
Glycogen storage diseases
Mitochondrial respiratory chain defects
Disorders of ketone metabolism
***Hypoglycemia* ***
Fatty acid oxidation defects
Disorders of gluconeogenesis
Disorders of fructose and galactose metabolism
Glycogen storage diseases
Disorders of ketogenesis
Organic acidemias
Hyperinsulinemic hypoglycemias
Mitochondrial respiratory chain defects
Neonatal intrahepatic cholestasis caused by citrin deficiency

Pyruvate carboxylase deficiency
Carbonic anhydrase VA deficiency
Hyperammonemia [**]
Urea cycle disorders
Organic acidemias
Fatty acid oxidation disorders
Disorders of pyruvate metabolism
GLUD1 -related hyperinsulinemic hypoglycemia
Carbonic anhydrase VA deficiency
SEIZURES AND HYPOTONIA
Antiquitin deficiency (pyridoxine-dependent epilepsy)
Pyridoxamine 5'-phosphate oxidase (PNPO) deficiency (pyridoxal phosphate-responsive epilepsy)
Folate metabolism disorders
Multiple carboxylase deficiency (holocarboxylase synthetase deficiency and biotinidase deficiency)
Urea cycle disorders
Organic acidemias
Fatty acid oxidation disorders
Disorders of creatine biosynthesis and transport
Disorders of neurotransmitter metabolism
Molybdenum cofactor deficiency and sulfite oxidase deficiency
Serine deficiency disorders
Glycine encephalopathy
Asparagine synthetase deficiency
Mitochondrial respiratory chain defects
Zellweger spectrum disorders
Congenital disorders of glycosylation
Purine and pyrimidine metabolism defects
NEONATAL APNEA
Glycine encephalopathy
Asparagine synthetase deficiency
Urea cycle disorders
Organic acidemias
Disorders of pyruvate metabolism
Fatty acid oxidation defects
Mitochondrial respiratory chain defects

[*] Refer to Table 102.4 for more details on the metabolic disorders associated with neonatal hypoglycemia.

** Refer to Table 102.5 for more details on the differential diagnosis of neonatal and infantile hyperammonemia.

Modified from El-Hattab AW: Inborn errors of metabolism, Clin Perinatol 42:413-439, 2015 (Box 1, p 415).

Table 102.4

Select Inborn Errors of Metabolism Associated With Neonatal Hypoglycemia

CATEGORY OF DISORDERS	DISORDERS
Fatty acid oxidation disorders	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase Ia deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency/trifunctional protein deficiency Medium-chain acyl-CoA dehydrogenase deficiency Very-long-chain acyl-CoA dehydrogenase deficiency Multiple acyl-CoA dehydrogenase deficiency
Disorders of gluconeogenesis	Fructose-1,6-diphosphatase deficiency Phosphoenolpyruvate carboxykinase deficiency
Disorders of fructose and galactose metabolism	Hereditary fructose intolerance Classic galactosemia
Glycogen storage diseases (GSD)	GSD type Ia (glucose-6-phosphatase deficiency) GSD type Ib (impaired glucose-6-phosphate exchanger) GSD type III (glycogen debrancher enzyme deficiency) GSD type VI (liver glycogen phosphorylase deficiency) GSD type IX (phosphorylase kinase deficiencies)
Disorders of ketogenesis	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency Mitochondrial 3-hydroxy-3-methylglutaryl-CoA synthase deficiency
Organic acidemias	Propionic acidemia Methylmalonic acidemia Isovaleric acidemia Maple syrup urine disease Multiple carboxylase deficiency (holocarboxylase synthetase deficiency and biotinidase deficiency)
Hyperinsulinemic hypoglycemia	*HADH* -related disorder (3-alpha-hydroxyacyl-CoA dehydrogenase deficiency) *GLUD1* -related disorder (hyperammonemia-hyperinsulinism syndrome, HIHA)
Other	Mitochondrial respiratory chain defects Neonatal intrahepatic cholestasis caused by citrin deficiency Pyruvate carboxylase deficiency Carbonic anhydrase VA deficiency

Modified from Zinn AB: Inborn errors of metabolism. In *Fanaroff & Martin's neonatal-perinatal medicine: diseases of the fetus and infant,* ed 10, vol 2, Philadelphia, 2015, Elsevier (Table 99.17, p 1605).

Table 102.5

Differential Diagnosis of Hyperammonemia

INBORN ERRORS OF METABOLISM
Urea Cycle Enzyme Defects
N-acetylglutamate synthase (NAGS) deficiency
Carbamoyl phosphate synthetase 1 (CPS1) deficiency
Ornithine transcarbamylase (OTC) deficiency
Argininosuccinate synthetase (ASS) deficiency (citrullinemia type 1)
Argininosuccinate lyase (ASL) deficiency (argininosuccinic aciduria)
Arginase 1 deficiency
Transport and Synthesis Defects of Urea Cycle Intermediates
Hyperornithinemia-hyperammonemia-homocitrullinemia (HHH syndrome)
Citrullinemia type 2 caused by citrin deficiency
Lysinuric protein intolerance
Ornithine aminotransferase deficiency
Carbonic anhydrase VA deficiency
Organic Acidemias
Propionic acidemia
MUT **-**related methylmalonic acidemia and cobalamin metabolism disorders
Isovaleric acidemia
Fatty Acid Oxidation Disorders
Long-chain fatty acid oxidation defects
Systemic primary carnitine deficiency
Other
Pyruvate carboxylase deficiency
GLUD1 **-**related hyperinsulinemic hypoglycemia
Neonatal iron overload disorders (e.g. hereditary hemochromatoses)
ACQUIRED DISORDERS
Transient Hyperammonemia of the Newborn
Diseases of the Liver and Biliary Tract
Liver failure
Biliary atresia
Severe Systemic Neonatal Illness
Neonates sepsis
Heart failure
Medications

Valproic acid

Cyclophosphamide

5-Pentanoic acid

Asparaginase

Other

Reye syndrome

ANATOMIC VARIANTS

Vascular bypass of the liver (e.g. a portosystemic anastomosis)

TECHNICAL

Inappropriate sample collection (e.g., capillary blood or prolonged placement of a tourniquet)

Sample not immediately analyzed

Modified from El-Hattab AW: Inborn errors of metabolism, Clin Perinatol 42:413-439, 2015 (Box 8, p 428).

Table 102.6

Select Metabolic Disorders Associated With Hepatic Dysfunction

CATEGORY OF DISORDERS	DISORDERS
Disorders of amino acid metabolism	Tyrosinemia type I Citrullinemia type II caused by citrin deficiency Disorders of methionine metabolism Urea cycle disorders
Biliary tract disorders and disorder of bile acid synthesis	See Chapter 383
Disorders of fructose and galactose metabolism	Hereditary fructose intolerance Classic galactosemia Epimerase deficiency galactosemia
Congenital disorders of glycosylation	Multiple types
Fatty acid oxidation disorders	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase Ia deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency/trifunctional protein deficiency Very-long-chain acyl-CoA dehydrogenase deficiency Multiple acyl-CoA dehydrogenase deficiency
Glycogen storage disorders (GSD)	GSD type III (glycogen debrancher enzyme deficiency) GSD type IV (glycogen branching enzyme deficiency) GSD type VI (liver glycogen phosphorylase deficiency)
Peroxisomal disorders	Zellweger spectrum disorders Disorders of peroxisomal β-oxidation
Mitochondrial respiratory chain (RC) defects	*Mitochondrial DNA (mtDNA) or nuclear DNA (nDNA) defects* Specific single nucleotide pathogenic variants in mtDNA Large-scale mtDNA re-arrangements (Pearson syndrome)

	Disorders of mitochondrial translation (e.g., tRNA^{Glu}) Disorder of protein synthesis of RC complexes Disorders affected the assembly or stabilization of RC complexes (e.g., *BCS1L*) Disorders of cofactor biosynthesis (e.g. coenzyme Q10) Disorders of mitochondrial transport and dynamics mtDNA depletion syndromes (e.g., *DGUOK, MPV17, POLG, SUCLG1*)
Lysosomal storage disorders	Niemann-Pick disease type C
Other	α_1 -Antitrypsin deficiency

Modified from Zinn AB: Inborn errors of metabolism. In Fanaroff & Martin's neonatal-perinatal medicine: diseases of the fetus and infant, ed 10, vol 2, Philadelphia, 2015, Elsevier (Table 99.5, p 1579).

Table 102.7

Select Metabolic Disorders Associated With Cardiomyopathy

CATEGORY OF DISORDERS	**DISORDERS**
Organic acidemias	Propionic acidemia Cobalamin C deficiency 3-methylglutaconic acidurias (e.g., Barth syndrome and DCMA syndrome)
Lysosomal storage disorders	Sphingolipidoses (e.g., Fabry disease) Oligosaccharidoses and mucolipidoses (e.g., I-cell disease) Mucopolysaccharidoses
Glycogen storage disorders (GSD)	GSD type II (Pompe disease) GSD type III (glycogen debrancher enzyme deficiency) *PRKAG2* -related disorders (includes lethal congenital glycogen storage disease of heart)
Congenital disorders of glycosylation	Multiple types
Fatty acid oxidation disorders	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency/trifunctional protein deficiency *ACAD9* -related disorder (mitochondrial acyl-CoA dehydrogenase deficiency) Multiple acyl-CoA dehydrogenase deficiency (includes glutaric aciduria type 2) Very-long-chain acyl-CoA dehydrogenase deficiency Systemic primary carnitine deficiency
Mitochondrial respiratory chain (RC) defects	*Mitochondrial DNA (mtDNA) or nuclear DNA (nDNA) defects* Specific single nucleotide pathogenic variants in mtDNA Large-scale mtDNA deletions Disorders of mitochondrial translation (e.g., tRNA^{Leu}) Disorders of protein synthesis of RC complexes (e.g., *MT-ATP6* , *MT-ATP8* , *NDUFS2, NDUFV2, SDHA, SCO2, COX10, COX15*) Disorders affecting the assembly or stabilization of RC complexes (e.g., *TMEM70*) Disorders of cofactor biosynthesis (e.g. coenzyme Q10) Disorders of mitochondrial transport and dynamics (e.g., *SLC25A3*) mtDNA depletion syndromes (e.g., *SUCLG1*)

Other	Danon disease

Modified from Zinn AB: Inborn errors of metabolism. In Fanaroff & Martin's neonatal-perinatal medicine: diseases of the fetus and infant, ed 10, vol 2, Philadelphia, 2015, Elsevier (Table 99.4, p 1576).

Table 102.8

Select Inborn Errors of Metabolism Associated With Dysmorphic Features

CATEGORY OF DISORDERS	DISORDERS
Congenital disorders of glycosylation	N-Glycosylation disorders (e.g., PMM2-CDG and ALG3-CDG) O-Glycosylation disorders (e.g., Walker-Warburg syndrome)
Disorders of cholesterol biosynthesis	Smith-Lemli-Opitz syndrome Desmosterolosis Lathosterolosis *EBP* -related disorder (includes Conradi-Hunermann syndrome)
Lysosomal storage disorders	Sphingolipidoses Oligosaccharidoses and mucolipidoses Mucopolysaccharidoses
Organic acidurias	Multiple acyl-CoA dehydrogenase deficiency (includes glutaric aciduria type 2) Mevalonic aciduria*
Peroxisomal disorders	Zellweger spectrum disorders Disorders of peroxisomal β-oxidation
Other	Pyruvate dehydrogenase complex deficiency

* Mevalonic aciduria has been classified as an organic acidemia based on the method used for its diagnosis, but it can also be classified as a peroxisomal single-enzyme disorder or as a defect in cholesterol biosynthesis because of its intracellular location and function, respectively.

Modified from Zinn AB: Inborn errors of metabolism. In Fanaroff & Martin's neonatal-perinatal medicine: diseases of the fetus and infant, ed 10, vol 2, Philadelphia, 2015, Elsevier (Table 99.8, p 1583).

Table 102.9

Select Inborn Errors of Metabolism Associated With Hydrops Fetalis

Lysosomal storage disorders
Mucopolysaccharidoses types I, IVA, and VII
Sphingolipidoses (e.g., Gaucher disease, Farber disease, Niemann-Pick disease A, GM_1 gangliosidosis, multiple sulfatase deficiency)
Lipid storage diseases (Wolman and Niemann-Pick disease C)
Oligosaccharidoses (e.g., sialidosis type I)
Mucolipidoses (e.g., I-cell disease)
Zellweger spectrum disorders

Glycogen storage disease type IV

Congenital disorders of glycosylation

Mitochondrial respiratory chain defects

Transaldolase deficiency

Modified and adapted from El-Hattab AW: Inborn errors of metabolism, Clin Perinatol 42:413-439, 2015 (Box 6, p 417).

Table 102.10

Pathognomonic Clinical Findings Associated With Inborn Errors of Metabolism (Select Examples)

FINDINGS	DISORDERS
Hepatomegaly	Disorders of fructose and galactose metabolism (e.g., classic galactosemia and hereditary fructose intolerance) Glycogen storage diseases Disorders of gluconeogenesis Disorders of fatty acid oxidation and transport Mitochondrial respiratory chain defects Tyrosinemia type 1 Urea cycle disorders Zellweger spectrum disorders Niemann-Pick disease type C Congenital disorders of glycosylation
Hepatosplenomegaly	Mucopolysaccharidoses Niemann-Pick disease types A, B, and C Sphingolipidoses (e.g., GM_1 gangliosidosis or Gaucher disease) Wolman disease Farber disease (acid ceramidase deficiency)
Macrocephaly	Glutaric acidemia type 1 Canavan disease
Microcephaly	Mitochondrial respiratory chain defects Disorders of intracellular cobalamin metabolism (e.g., *cbl* C deficiency)
Coarse facial features	Mucopolysaccharidoses Oligosaccharidoses and mucolipidoses (e.g., α-mannosidosis) Sphingolipidoses (e.g., GM_1 gangliosidosis) Galactosialidosis
Macroglossia	Glycogen storage disease type II (Pompe disease) Mucopolysaccharidoses Oligosaccharidoses and mucolipidoses Sphingolipidoses Galactosialidosis
Dystonia or extrapyramidal signs	Gaucher disease type 2 Glutaric acidemia type 1 Methylmalonic acidemia Propionic acidemia

	Krabbe disease Crigler–Najjar syndrome Disorders of neurotransmitter metabolism Pyruvate dehydrogenase complex deficiency
Macular “cherry-red spot”	GM$_1$ gangliosidosis Tay-Sachs disease (GM$_2$ gangliosidosis) Farber disease (acid ceramidase deficiency) Galactosialidosis Niemann-Pick disease type A Sialidosis Multiple sulfatase deficiency
“Bull eye” maculopathy	*cbl* C deficiency (combined methylmalonic acidemia and homocystinuria, type C)
Retinitis pigmentosa	Mitochondrial respiratory chain defects Peroxisomal disorders Abetalipoproteinemia
Optic nerve atrophy or hypoplasia	Pyruvate dehydrogenase complex deficiency Mitochondrial respiratory chain defects Peroxisomal disorders Propionic acidemia *MUT* -related methylmalonic acidemia and cobalamin metabolism disorders
Corneal clouding or opacities	Mucolipidoses Mucopolysaccharidoses Steroid sulfatase deficiency Tyrosinemia type II Cystinosis
Cataracts	Disorders of galactose metabolism (e.g., classic galactosemia) Congenital disorders of glycosylation Mitochondrial respiratory chain (RC) defects Peroxisomal disorders Lowe oculocerebrorenal syndrome
Dislocated lens	Cystathionine β-synthase deficiency Molybdenum cofactor deficiency and sulfite oxidase deficiency
Skeletal dysplasias and dysostosis multiplex	Oligosaccharidoses and mucolipidoses Mucopolysaccharidoses Sphingolipidoses Galactosialidosis Peroxisomal disorders Disorders of cholesterol biosynthesis Congenital disorders of glycosylation
Thick skin	Oligosaccharidoses and mucolipidoses Mucopolysaccharidoses Sphingolipidoses
Desquamating, eczematous, or vesiculobullous skin lesions	Acrodermatitis enteropathica Essential amino acid deficiencies in organic acidemias Hartnup disorder Multiple carboxylase deficiency (holocarboxylase synthetase deficiency and biotinidase deficiency) Porphyrias
Ichthyosis	Gaucher disease type 2 Steroid sulfatase deficiency Refsum disease *ELOVL4* -related disorder Serine deficiency disorders

Alopecia	Multiple carboxylase deficiency (holocarboxylase synthetase deficiency and biotinidase deficiency)
Steely or kinky hair	Menkes disease
Trichorrhexis nodosa	Argininosuccinic aciduria (ASL deficiency)
Persistent diarrhea	Glucose-galactose malabsorption Congenital lactase deficiency Congenital chloride diarrhea Sucrase-isomaltase deficiency Acrodermatitis enteropathica Abetalipoproteinemia Congenital folate malabsorption Wolman disease Lysinuric protein intolerance Classic galactosemia

Modified from Cederbaum S: Introduction to metabolic and biochemical genetic diseases. In Gleason CA, Juul SE, editors: Avery's diseases of the newborn, ed 10, Philadelphia, 2018, Elsevier (Table 21.1, p 227).

Table 102.11

Inborn Errors of Amino Acid Metabolism Associated With Peculiar Odor

INBORN ERROR OF METABOLISM	URINE ODOR
Isovaleric acidemia Glutaric acidemia (type II)	Sweaty feet, acrid
Maple syrup urine disease	Maple syrup, burnt sugar
Multiple carboxylase deficiency 3-Methylcrotonyl-CoA carboxylase deficiency 3-Hydroxy-3-methylglutaric aciduria	Cat urine
Phenylketonuria	Mousey or musty
Trimethylaminuria Dimethylglycine dehydrogenase deficiency	Rotten fish
Tyrosinemia type 1	Boiled cabbage, rancid butter
Hypermethioninemia	Boiled cabbage
Cystinuria Tyrosinemia type I	Sulfur
Hawkinsinuria	“Swimming pool”
Oasthouse urine disease	Hops-like

In an increasing number of patients, a metabolic condition may be recognized months or years after birth. This is more typical in patients carrying milder autosomal recessive pathogenic variants, in mitochondrial disorders, in females affected by X-linked recessive conditions, and specific metabolic conditions that usually present later in life. *Clinical manifestations*, such as intellectual disability, motor deficits, developmental regression, seizures, psychosis, cardiomyopathy, myopathy, organomegaly, and recurrent emesis, in patients beyond the neonatal period should suggest an inherited metabolic disease (Table

102.12). There may be an episodic or intermittent pattern, with episodes of acute clinical manifestations separated by periods of seemingly disease-free states. The episodes are usually triggered by stress or nonspecific catabolic stress such as an infection. The child may die during one of these acute attacks. An inborn error of metabolism should be considered in any child with 1 or more of the following manifestations: unexplained developmental delay; intellectual disability; developmental regression; motor deficits or adventitious movements (e.g., dystonia, choreoathetosis, ataxia); seizures; catatonia; unusual odor (particularly during an acute illness); intermittent episodes of unexplained vomiting, acidosis, mental deterioration, psychosis, or coma; hepatomegaly; renal stones; renal dysfunction, especially Fanconi syndrome or renal tubular acidosis; muscle weakness; and cardiomyopathy (Table 102.12).

Table 102.12

Clinical Findings That Should Prompt a Metabolic Workup

Family history	Sibling(s) who died from unexplained causes or exhibit overlapping symptoms Ethnic groups with high prevalence of metabolic disorders Consanguinity
Perinatal history	Intrauterine growth retardation, sepsis-like presentation in the neonatal period, nonimmune fetal hydrops
Growth	Postnatal failure to thrive, microcephaly, macrocephaly, short stature
Central and peripheral nervous systems	Progressive encephalopathy, lethargy, coma, intractable seizures, developmental delay, developmental regression, intellectual disability, autism spectrum disorder, hypotonia, spasticity, dystonia, strokes, ataxia, psychosis, intracranial calcifications, white matter disease, peripheral neuropathy
Respiratory system	Hyperventilation, apnea
Cardiovascular system	Cardiac failure with or without cardiomyopathy, arrhythmia
Musculoskeletal system	Rhabdomyolysis, myopathy Osteopenia, early-onset osteoporosis, skeletal dysplasia, epiphyseal abnormalities, bone crises
Eye	Retinitis pigmentosa, macular dystrophy, cataracts, corneal opacities, nystagmus, cherry-red spot
Hearing	Sensorineural hearing loss
Gastrointestinal system	Hepatomegaly, splenomegaly, liver failure, Reye syndrome, cholestasis, cirrhosis, chronic diarrhea, vomiting, acute pancreatitis
Kidney	Renal dysfunction, renal stones
Hematological system	Anemia, leukopenia, thrombocytopenia, pancytopenia, hemolytic-uremic syndrome
Skin	Hair abnormality, alopecia, lipodystrophy, recalcitrant eczema

Diagnosis usually requires a variety of specific *laboratory studies.* Plasma amino acid analysis, plasma acylcarnitine profile, total and free carnitine profile, and urine organic acid assay, while not exhaustive in their diagnostic scope, are useful as initial screening tests to evaluate for a suspected inborn error of metabolism. Measurements of plasma ammonia, lactate, bicarbonate, and pH are readily available in hospitals and very helpful initially in differentiating major causes of genetic metabolic disorders (Table 102.13 ; see Fig. 102.1). Elevation of blood ammonia is usually caused by defects of urea cycle enzymes, organic acidemias, and disorders of fatty acid oxidation. Infants with elevated blood ammonia levels from urea cycle defects tend to have normal serum pH and bicarbonate values; without measurement of blood ammonia, they may remain undiagnosed and succumb to their disease. In organic acidemias, elevated plasma ammonia is accompanied by severe acidosis caused by accumulation of organic acids, ketone bodies, and lactate in body fluids.

Table 102.13

Laboratory Findings That Should Prompt a Metabolic Workup

Hyperammonemia
Metabolic acidosis
Lactic acidosis
Ketosis
Hypoglycemia
Liver dysfunction
Pancytopenia

When blood ammonia, pH, and bicarbonate values are normal, other aminoacidopathies (e.g. hyperglycinemia) or galactosemia should be considered. Galactosemic infants may also manifest cataracts, hepatomegaly, ascites, and jaundice.

Treatment

The majority of patients with genetic disorders of metabolism respond to one or more of the following treatments:

1. Special diets play an important role in the treatment of affected children.

Dietary changes should be tailored to the pathophysiology of the condition and vary greatly among disorders.

2. Hemodialysis for expeditious removal of accumulated noxious compounds. This is a very effective modality for treatment of the acute phase of the condition.
3. Catabolic states in patients at risk for metabolic crisis can be treated with fluids containing dextrose and electrolytes.
4. Administration of the deficient metabolite.
5. Administration of the cofactor or coenzyme to maximize the residual enzyme activity.
6. Activation of alternate pathways to reduce the noxious compounds accumulated because of the genetic mutation.
7. Administration of the deficient enzyme.
8. Bone marrow transplantation.
9. Liver and kidney transplantation.

The organ transplantation modalities may offer the best treatment modality to stabilize a metabolic patient and improve quality of life. To date, replacement of the mutant gene with a normal copy using gene therapy has been successful in only a few diseases.

Treatment of genetic disorders of metabolism is complex and requires medical and technical expertise. The therapeutic regimen often needs to be tailored to the individual patient because of large phenotypic variations in the severity of the disease, even within a single family. Providing education and support for the family is the key to successful long-term therapy. Even in patients with poor prognoses, every effort should be made to establish correct diagnoses premortem. Effective treatment is best achieved by a team of specialists—metabolic genetics specialist, nutritionist, neurologist, and psychologist—in a major medical center.

Phenylalanine is an essential amino acid. Dietary phenylalanine not utilized for protein synthesis is normally degraded by way of the tyrosine pathway (Fig. 103.1). Deficiency of the enzyme **phenylalanine hydroxylase (PAH)** or of its cofactor **tetrahydrobiopterin (BH_4)** causes accumulation of phenylalanine in body fluids and in the brain.

FIG. 103.1 Pathways of phenylalanine and tyrosine metabolism. Enzyme defects causing genetic conditions are depicted as *horizontal bars* crossing the reaction arrow(s). Pathways for synthesis of cofactor BH_4 are shown in *purple.* BH_4 * refers to defects of BH_4 metabolism that affect the phenylalanine, tyrosine, and tryptophan hydroxylases (see Figs. 103.2 and 103.5). PKU, Phenylketonuria; NE, nonenzymatic. Enzymes: *(1)* Phenylalanine hydroxylase, *(2)* pterin-carbinolamine dehydratase, *(3)* dihydrobiopterin reductase, *(4)* guanosine triphosphate (GTP) cyclohydrolase, *(5)* 6-pyruvoyltetrahydropterin synthase, *(6)* sepiapterin reductase, *(7)* carbonyl reductase, *(8)* aldolase reductase, *(9)* dihydrofolate reductase, *(10)* tyrosine aminotransferase, *(11)* 4-hydroxyphenylpyruvate dioxygenase, *(12)* homogentisic acid dioxygenase, *(13)* maleylacetoacetate isomerase, *(14)* fumarylacetoacetate hydrolase.

Elevations of phenylalanine in the plasma depend on the degree of enzyme deficiency. In patients with **severe PAH deficiency** (previously referred to as *classic phenylketonuria*), plasma phenylalanine levels on unrestricted diet usually exceed 20 mg/dL (>1,200 µmol/L). Patients with milder PAH pathogenic variants have plasma phenylalanine levels between 10 mg/dL (600 µmol/L) and 20 mg/dL (1,200 µmol/L). Levels between 2 and 10 mg/dL (120-600 µmol/L) on unrestricted diet are observed in patients with **mild hyperphenylalaninemia** . In affected infants with plasma concentrations >20 mg/dL, excess phenylalanine is metabolized to phenylketones (phenylpyruvate and phenylacetate; see Fig. 103.1) that are excreted in the urine, giving rise to the term *phenylketonuria* (PKU).

These metabolites have no known role in pathogenesis of central nervous system (CNS) damage in PKU patients; their presence in the body fluids simply signifies the severity of the condition. The **brain** is the main organ damaged by PKU, but the exact mechanism of injury remains elusive. Both toxic levels of phenylalanine and insufficient tyrosine may play a role. Phenylalanine hydroxylase converts phenylalanine to **tyrosine** , which is necessary for the production of neurotransmitters such as epinephrine, norepinephrine, and dopamine (Fig. 103.2). If the degree of enzymatic block is severe, tyrosine becomes an essential amino acid and may be deficient if intake is not adequate. On the other hand, observations that lower concentration of phenylalanine in plasma and brain tissue are associated with improved neurobehavioral outcomes support the view that toxic levels of phenylalanine are key to the mechanisms of the disease. High blood levels of phenylalanine can saturate the transport system across the blood-brain barrier and cause inhibition of the cerebral uptake of other large neutral amino acids such as branched-chain amino acids, tyrosine, and tryptophan, impairing brain protein synthesis.

Severe Phenylalanine Hydroxylase Deficiency (Classic Phenylketonuria)

Elevations of plasma phenylalanine >20 mg/dL (>1,200 µmol/L), if untreated, invariably result in the development of signs and symptoms of classic PKU, except in uncommon and unpredictable cases.

Clinical Manifestations

The affected infant appears normal at birth. Profound intellectual disability develops gradually if the infant remains untreated. Cognitive delay may not be evident for the 1st few months. In untreated patients, 50–70% will have an IQ below 35, and 88–90% will have an IQ below 65. Only 2–5% of untreated patients may have normal intelligence. Vomiting, sometimes severe enough to be misdiagnosed as pyloric stenosis, may be an early symptom. Older untreated children become hyperactive with autistic behaviors, including purposeless hand movements, rhythmic rocking, and athetosis.

Untreated and undertreated infants are lighter in their complexion than unaffected siblings. Some may have a seborrheic or eczematoid rash, which is usually mild and disappears as the child grows older. These children have an odor of phenylacetic acid, which has been described as musty or “mousey.” Neurologic signs include seizures (approximately 25%), spasticity, hyperreflexia, and tremors; >50% have electroencephalographic (EEG) abnormalities. Microcephaly, prominent maxillae with widely spaced teeth, enamel hypoplasia, and growth retardation are other common findings in untreated children. Low bone mineral density and osteopenia have been reported in affected individuals of all ages. Although inadequate intake of natural proteins seems to be the major culprit, the exact pathogenesis of this sequela remains unclear. Long-term care of patients with PKU is best achieved by a team of experienced professionals (metabolic specialist, nutritionist, and psychologist) in a regional treatment center. The clinical manifestations of classic PKU are rarely seen in countries where neonatal screening programs for the detection of PKU are in effect.

Non-PKU Hyperphenylalaninemia

In any screening program for PKU, a group of infants will be identified in whom initial plasma concentrations of phenylalanine are above normal (i.e., >2 mg/dL, or 120 µmol/L) but <20 mg/dL (1,200 µmol/L). These infants typically do not excrete phenylketones. Patients with non-PKU hyperphenylalaninemia may still require dietary therapy, depending on their untreated plasma phenylalanine level. Attempts have been made to classify these patients in different subgroups depending on the degree of hyperphenylalaninemia, but such a practice has little clinical or therapeutic advantage. The possibility of deficiency of BH_4 should be investigated in all infants with the milder forms of hyperphenylalaninemia.

Diagnosis

Because of the gradual and nonspecific nature of early clinical symptoms such as vomiting, developmental delay, or eczematoid rash, hyperphenylalaninemia is usually diagnosed through newborn screening in all developed countries. In infants with positive screening results, diagnosis should be confirmed by quantitative measurement of plasma phenylalanine concentration. Identification and measurement of phenylketones in the urine has no place in any screening program. In countries and places where such programs are not in effect, identification of phenylketones in the urine by ferric chloride may offer a simple test for diagnosis of infants with developmental and neurologic abnormalities. Once the diagnosis of hyperphenylalaninemia is established, additional studies for BH_4 metabolism should be performed to rule out BH_4 deficiency as the cause of hyperphenylalaninemia.

Neonatal Screening for Hyperphenylalaninemia

Effective and relatively inexpensive methods for mass screening of newborn infants are used in the United States and many other countries. A few drops of blood, which are placed on a filter paper and mailed to a central laboratory, are used for assay. The screening method of choice uses **tandem mass spectrometry** , which identifies all forms of hyperphenylalaninemia with a low false-positive rate and excellent accuracy and precision. The addition of the phenylalanine:tyrosine molar ratio has further reduced the number of false-positive results. Diagnosis must be confirmed by measurement of plasma phenylalanine concentration. Blood phenylalanine in affected infants with PKU may rise to diagnostic levels as early as 4 hr after birth, even in the absence of protein feeding. It is recommended that the blood for screening be obtained in the 1st 24-48 hr of life after feeding protein to reduce the possibility of false-negative results, especially in the milder forms of the condition.

Treatment

The mainstay of treatment of PKU is a *low-phenylalanine diet* . The general consensus is to start diet treatment immediately in patients with blood phenylalanine levels >10 mg/dL (600 µmol/L). It is generally accepted that infants with persistent (more than a few days) plasma levels of phenylalanine ≥6 mg/dL (360 µmol/L) should also be treated with a phenylalanine-restricted diet similar to that in classic PKU. The goal of therapy is to reduce phenylalanine levels in the plasma and brain. Formulas free of, or low in, phenylalanine are commercially available. The diet should be started as soon as the diagnosis is established. Because phenylalanine is not synthesized endogenously, the diet should provide phenylalanine to prevent phenylalanine deficiency. Dietary phenylalanine tolerance is determined based on age and severity of the PAH deficiency. **Phenylalanine deficiency** is manifested by lethargy, failure to thrive, anorexia, anemia, rashes, diarrhea, and even death. Further, tyrosine becomes an essential amino acid in this disorder, and its adequate intake must be ensured. Special food items low in phenylalanine are commercially available for dietary treatment of affected children and adults.

There is no firm consensus concerning optimal levels of blood phenylalanine in affected patients either across different countries or among treatment centers in the United States. The current recommendation is to maintain blood phenylalanine levels between 2 and 6 mg/dL (120-360 µmol/L) throughout life. Discontinuation of therapy, even in adulthood, may cause deterioration of IQ and cognitive performance. Lifelong adherence to a low-phenylalanine diet is extremely difficult. Patients who maintain good control as children but discontinue the phenylalanine-restricted diet as teenagers or adults may experience significant difficulties with executive function, concentration, emotional liability, and depression. Executive dysfunction may also occur in early-treated children despite diet treatment.

Given the difficulty of maintaining a strict low-phenylalanine diet, there are continuing attempts to find other modalities for treatment of these patients. Administration of **large neutral amino acids** (LNAAs) is another approach to dietary therapy. LNAAs (tyrosine, tryptophan, leucine, isoleucine, valine, methionine, histidine, and phenylalanine) share the same transporter protein (LNAA type 1 or LAT-1) for transit through the intestinal cell membrane and blood-brain barrier (BBB). Binding of LNAAs to the transporter protein is a competitive process. The rationale for use of LNAA is that these molecules compete with phenylalanine for transport across the BBB; therefore, large concentrations of other LNAAs in the intestinal lumen and in the blood reduce the uptake of phenylalanine into bloodstream and the brain. Large, controlled clinical trials are necessary to establish the efficacy of this treatment.

Oral administration of BH_4 , the cofactor for PAH, may result in reduction of plasma levels of phenylalanine in some patients with PAH deficiency. Plasma levels of phenylalanine in these patients may decrease enough to allow for considerable modification of their dietary restriction. In very rare cases the diet may be discontinued because the phenylalanine levels remain under 6 mg/dL (360 µmol/L). The response to BH_4 cannot be predicted consistently based on the genotype alone, especially in compound heterozygous patients. **Sapropterin dihydrochloride** , a synthetic form of BH_4 , which acts as a cofactor in patients with residual PAH activity, is approved by the U.S. Food and Drug Administration (FDA) to reduce phenylalanine levels in PKU. A sustained decrease of plasma phenylalanine by at least 30% is consistent with sapropterin responsiveness. Injectable PEGylated recombinant phenylalanine ammonia lyase is in development.

Pregnancy in Women With PAH Deficiency (Maternal Phenylketonuria)

Pregnant women with PAH deficiency who are not on a phenylalanine-restricted diet have a very high risk of having offspring with intellectual disability, microcephaly, growth retardation, congenital malformations, and congenital heart disease. These complications are directly correlated with elevated maternal blood phenylalanine levels during pregnancy. Prospective mothers who have been treated for PAH deficiency should be maintained on a phenylalanine-restricted diet before and during pregnancy. The best observed outcomes occur when strict control of maternal blood phenylalanine concentration is instituted before pregnancy. Plasma phenylalanine levels >6 mg/dL (360 µmol/L) after conception are associated with increased incidence of intrauterine growth restriction and congenital malformations, as well as lower IQ. However, there is strong evidence that phenylalanine control instituted after conception results in improved outcomes. The currently recommended phenylalanine concentration is

2-6 mg/dL (120-360 µmol/L) throughout the pregnancy, although some expert groups advocate plasma phenylalanine levels <4 mg/dL (<240 µmol/L). All women with PAH deficiency who are of childbearing age should be counseled properly regarding the risk of congenital anomalies in their offspring.

Hyperphenylalaninemia Caused by Deficiency of the Cofactor Tetrahydrobiopterin

In 1-3% of infants with hyperphenylalaninemia, the defect resides in one of the enzymes necessary for production or recycling of the cofactor BH_4 (see Fig. 103.1). If these infants are misdiagnosed as having PKU, they may deteriorate neurologically despite adequate control of plasma phenylalanine. BH_4 is synthesized from guanosine triphosphate (GTP) through several enzymatic reactions (see Fig. 103.1). In addition to acting as a cofactor for PAH, BH_4 is also a cofactor for tyrosine hydroxylase and tryptophan hydroxylase, which are involved in the biosynthesis of dopamine (see Fig. 103.2) and serotonin (see Fig. 103.5), respectively. Therefore, patients with hyperphenylalaninemia resulting from BH_4 deficiency also manifest neurologic findings related to deficiencies of these neurotransmitters. Four enzyme deficiencies leading to defective BH_4 formation cause hyperphenylalaninemia with concomitant deficiencies of dopamine and serotonin: autosomal recessive GTP cyclohydrolase I deficiency, 6-pyruvoyl-tetrahydropterin synthase deficiency, dihydropteridine reductase deficiency, and pterin-4-α-carbinolamine dehydratase deficiency. More than half the reported patients have had a deficiency of 6-pyruvoyl-tetrahydropterin synthase. Autosomal dominant forms of GTP cyclohydrolase I deficiency and sepiapterin reductase deficiency result in deficiencies of neurotransmitters without hyperphenylalaninemia (see Chapter 103.11).

Clinical Manifestations

Infants with cofactor BH_4 deficiency are identified during screening programs for PKU because of evidence of hyperphenylalaninemia. Plasma phenylalanine levels may be as high as those in classic PKU or may be in the milder range.

However, the clinical manifestations of the neurotransmitter disorders differ greatly from those of PKU. Neurologic symptoms of the neurotransmitter disorders often manifest in the 1st few months of life and include extrapyramidal signs (choreoathetotic or dystonic limb movements, axial and truncal hypotonia, hypokinesia), feeding difficulties, and autonomic abnormalities. Intellectual disability, seizures, hypersalivation, and swallowing difficulties are also seen. The symptoms are usually progressive and often have a marked diurnal fluctuation. Prognosis and outcome strongly depend on the age at diagnosis and at introduction of treatment, but also on the specific nature of the pathogenic variant and resulting enzyme defect.

Diagnosis

Despite the low incidence of BH_4 synthesis defects, all newborns with hyperphenylalaninemia detected through newborn screening *must* be screened for BH_4 synthesis defects. BH_4 deficiency and the responsible enzyme defect may be diagnosed by several studies.

Measurement of Neopterin and Biopterin.

Neopterin (oxidative product of dihydroneopterin triphosphate) and biopterin (oxidative product of dihydrobiopterin and BH_4) are measured in body fluids, especially urine (see Fig. 103.1). In patients with GTP cyclohydrolase I deficiency, urinary excretion of both neopterin and biopterin is very low. In patients with 6-pyruvoyl-tetrahydropterin synthase deficiency, there is a marked elevation of neopterin excretion and a concomitant decrease in biopterin excretion. In patients with dihydropteridine reductase deficiency, the excretion of neopterin and biopterin is elevated. Excretion of biopterin increases in this enzyme deficiency because the quinonoid dihydrobiopterin cannot be recycled back to BH_4 . Patients with pterin-4-α-carbinolamine dehydratase deficiency excrete 7-biopterin (an unusual isomer of biopterin) in their urine.

Cerebrospinal Fluid Studies.

Examination of cerebrospinal fluid (CSF) may reveal decreased levels of dopamine and serotonin metabolites (see Chapter 103.11).

BH_4 Loading Test.

An oral dose of BH_4 (20 mg/kg) normalizes plasma phenylalanine and phenylalanine:tyrosine ratio in patients with BH_4 deficiency within 4-12 hr. The blood phenylalanine should be elevated (>400 µmol/L) to enable interpretation of the results. This may be achieved by discontinuing diet therapy for 2 days before the test or by administering a loading dose of phenylalanine (100 mg/kg) 3 hr before the test. In BH_4 -responsive PKU caused by PAH deficiency, blood phenylalanine levels may decrease during the BH_4 loading test, but increase later even with BH_4 supplementation. Patients who demonstrate phenylalanine levels within normal range over at least 1 wk without a phenylalanine-restricted diet can continue BH_4 supplementation as the sole treatment for the hyperphenylalaninemia. However, it is imperative that plasma phenylalanine levels be monitored prospectively to ensure that phenylalanine levels remain within the normal range.

Molecular Testing.

Sequencing and deletion/duplication analysis are clinically available and play an increasingly more important role in confirming the biochemical diagnosis.

Enzyme Assay.

The activity of dihydropteridine reductase can be measured in the dry blood spots on the filter paper used for screening purposes. 6-Pyruvoyl-tetrahydropterin synthase activity can be measured in the liver, fibroblasts, and erythrocytes. Pterin-4-α-carbinolamine dehydratase activity can be measured in the liver and fibroblasts. GTP cyclohydrolase I activity can be measured in the liver and in cytokine (interferon-γ)–stimulated mononuclear cells or fibroblasts (the enzyme activity is normally very low in unstimulated cells).

Treatment

The goals of therapy are to correct hyperphenylalaninemia and to restore neurotransmitter deficiencies in the CNS. The control of hyperphenylalaninemia is important in patients with cofactor deficiency, because high levels of phenylalanine cause intellectual disability and interfere with the transport of neurotransmitter precursors (tyrosine and tryptophan) into the brain. Plasma phenylalanine should be maintained as close to normal as possible (<6 mg/dL or

<360 µmol/L). This can be achieved by oral supplementation of BH_4 (5-20 mg/kg/day). Sapropterin dihydrochloride, the synthetic form of BH_4, is commercially available but expensive.

Lifelong supplementation with neurotransmitter precursors such as L -dopa and 5-hydroxytryptophan, along with carbidopa to inhibit degradation of L -dopa before it enters the CNS, is necessary in most of these patients even when treatment with BH_4 normalizes plasma levels of phenylalanine. BH_4 does not readily enter the brain to restore neurotransmitter production. To minimize untoward side effects (especially L -dopa–induced dyskinesia), the treatment should be started with low doses of L -dopa/carbidopa and 5-hydroxytryptophan and should be gradually adjusted based on response to therapy and clinical improvement for each individual patient. Supplementation with folinic acid is also recommended in patients with dihydropteridine reductase deficiency. Unfortunately, attempting to normalize neurotransmitter levels using neurotransmitter precursors usually does not fully resolve the neurologic symptoms, because of the inability to attain normal levels of BH_4 in the brain. Patients often demonstrate intellectual disability, fluctuating abnormalities of tone, eye movement abnormalities, poor balance and coordination, decreased ability to ambulate, and seizures despite supplementation with neurotransmitter precursors.

Hyperprolactinemia occurs in patients with BH_4 deficiency and may be the result of hypothalamic dopamine deficiency. Measurement of serum prolactin levels may be a convenient method for monitoring adequacy of neurotransmitter replacement in affected patients.

Some drugs, such as trimethoprim/sulfamethoxazole, methotrexate, and other antileukemic agents, are known to inhibit dihydropteridine reductase enzyme activity and should be used with great caution in patients with BH_4 deficiency.

Genetics and Prevalence

All defects causing hyperphenylalaninemia are inherited as autosomal recessive traits. The prevalence of PKU in the United States is estimated at 1 in 14,000 to 1 in 20,000 live births. The prevalence of non-PKU hyperphenylalaninemia is estimated at 1 in 50,000 live births. The condition is more common in whites and Native Americans and less prevalent in blacks, Hispanics, and Asians.

The gene for PAH is located on chromosome 12q23.2, and many disease-causing mutations have been identified in different families. Most patients are compound heterozygotes for 2 different mutant alleles. The gene for 6-pyruvoyl-tetrahydropterin synthase *(PTS)* , the most common cause of BH_4 deficiency, resides on chromosome 11q23.1, the gene for dihydropteridine reductase *(QDPR)* is located on chromosome 4p15.32, and those of pterin-4-α-carbinolamine dehydratase *(PCBD1)* and GTP cyclohydrolase I *(GCH1)* are on 10q22.1 and 14q22.2, respectively. Prenatal diagnosis is possible if causative mutations are known.

Tyrosine is derived from ingested proteins or is synthesized endogenously from phenylalanine. It is used for protein synthesis and is a precursor of dopamine, norepinephrine, epinephrine, melanin, and thyroxine. Excess tyrosine is metabolized to carbon dioxide and water (see Fig. 103.1). Hereditary causes of hypertyrosinemia include deficiencies of the enzymes fumarylacetoacetate hydrolase (**FAH**), tyrosine aminotransferase, and 4-hydroxyphenylpyruvate dioxygenase (**4-HPPD**). **Acquired hypertyrosinemia** may occur in severe hepatocellular dysfunction (liver failure), scurvy (vitamin C is the cofactor for 4-HPPD), and hyperthyroidism. Hypertyrosinemia is common in blood samples obtained soon after eating and in premature infants.

Tyrosinemia Type I (Fumarylacetoacetate Hydrolase Deficiency, Hepatorenal Tyrosinemia)

Tyrosinemia type I is a severe multisystemic disease caused by FAH deficiency. Liver, kidney, and nerve damage is likely caused by metabolites of tyrosine degradation, especially fumarylacetoacetate and succinylacetone.

Clinical Manifestations and Natural History

Without treatment, affected infants appear normal at birth and develop symptoms in the 1st yr of life. Most patients present between 2 and 6 mo of age but rarely may become symptomatic in the 1st mo or appear healthy beyond the 1st yr of life. Earlier presentation confers poorer prognosis. The 1-yr mortality of untreated children, which is approximately 60% in infants developing symptoms before 2 mo of age, decreases to 4% in infants who become symptomatic after 6 mo.

An acute **hepatic crisis** typically heralds the onset of the disease and is usually precipitated by an intercurrent illness that produces a catabolic state. Fever, irritability, vomiting, hemorrhage, hepatomegaly, jaundice, elevated levels of serum transaminases, hypoglycemia, and neuropathy are common. An odor resembling boiled cabbage may be present, resulting from increased methionine metabolites. Hepatic crises may progress to liver failure and death. Between the crises, varying degrees of failure to thrive, hepatomegaly, and coagulation abnormalities often persist. Cirrhosis and eventually hepatocellular carcinoma occur with increasing age.

Episodes of acute **peripheral neuropathy** resembling acute porphyria occur in approximately 40% of affected children. These crises, often triggered by a minor infection, are characterized by severe pain, often in the legs, associated with extensor hypertonia of the neck and trunk, vomiting, paralytic ileus, and occasionally self-induced injuries of the tongue or buccal mucosa. Marked weakness occurs in about 30% of episodes, which may lead to respiratory failure requiring mechanical ventilation. Crises typically last 1-7 days, but recuperation from paralytic crises can require weeks to months.

Renal involvement is manifested as a Fanconi-like syndrome with hyperphosphaturia, hypophosphatemia, normal–anion gap metabolic acidosis, and vitamin D–resistant rickets. Nephromegaly and nephrocalcinosis may be present on ultrasound examination. Glomerular failure may occur in adolescents and older patients.

Hypertrophic cardiomyopathy and hyperinsulinism are seen in some infants.

Laboratory Findings

Elevated levels of succinylacetone in serum and urine are diagnostic for tyrosinemia type I (see Fig. 103.1). Succinylacetone levels may fall below the diagnostic threshold in patients treated with nitisinone. In untreated patients, the blood level of α-fetoprotein is increased, often greatly, and liver-synthesized coagulation factors are decreased in most patients. Increased levels of α-fetoprotein are present in the cord blood of affected infants, indicating intrauterine liver damage. Serum transaminase levels are often increased, with marked increases possible during acute hepatic episodes. Serum concentration of bilirubin is usually normal but can be increased with liver failure. Plasma tyrosine levels are usually elevated at diagnosis, but this is a nonspecific finding and depends on dietary intake. Plasma levels of other amino acids, particularly methionine, may also be elevated in patients with liver damage. Hyperphosphaturia, hypophosphatemia, and generalized aminoaciduria may occur. The urinary level of 5-aminolevulinic acid (also known as delta aminolevulinic acid) is elevated because of inhibition of 5-aminolevulinate dehydratase by succinylacetone (see Fig. 110.1).

Diagnosis is usually established by demonstration of elevated levels of succinylacetone in urine or blood. Neonatal screening for hypertyrosinemia using tyrosine alone detects only a fraction of patients with tyrosinemia type I. Succinylacetone, which is assayed by many neonatal screening programs, has higher sensitivity and specificity than tyrosine and is the preferred metabolite for screening. Tyrosinemia type I should be differentiated from other causes of hepatitis and hepatic failure in infants, including galactosemia, hereditary fructose intolerance, neonatal iron storage disease, giant cell hepatitis, and citrullinemia type II (see Chapter 103.12).

Treatment and Outcome

A diet low in phenylalanine and tyrosine can slow but does not halt the progression of the condition. The treatment of choice is **nitisinone** (NTBC), which inhibits 4-HPPD and reduces the flux of tyrosine metabolites to FAH, thus decreasing the production of the offending compounds, fumarylacetoacetate and succinylacetone (see Fig. 103.1). The dose of nitisinone is titrated to the lowest, most effective dose (usually targeting the blood range of 20-40 µmol/L) to suppress production of succinylacetone while maintaining plasma tyrosine level <400 µmol/L (7.2 mg/dL). This treatment prevents acute hepatic and neurologic crises. Although nitisinone greatly slows disease progression, some pretreatment liver damage is not reversible. Therefore, patients must be followed for development of *cirrhosis* or *hepatocellular carcinoma* . On imaging, the presence of even a single liver nodule usually indicates underlying cirrhosis. Most liver nodules in tyrosinemic patients are benign, but current imaging techniques do not accurately distinguish all malignant nodules. For patients with severe liver failure not responding to nitisinone, liver transplantation is an effective therapy, which can also alleviate the risk of hepatocellular carcinoma. The impact of nitisinone treatment on the need for liver transplantation is still under study, but the greatest effect is in patients treated early, such as children detected by neonatal screening, prior to developing clinical symptoms. In early-treated patients, nitisinone has greatly reduced the need for liver transplantation. Because nitisinone treatment increases plasma tyrosine, a low-tyrosine, low-phenylalanine diet is recommended. Rarely, nitisinone-treated patients develop corneal crystals, presumably of tyrosine, which are reversible by strict dietary compliance. This finding, combined with observations of developmental delay in some patients with tyrosinemia type II who chronically have elevated tyrosine levels, suggest that a diet low in phenylalanine and tyrosine should be continued in patients treated with nitisinone. The dietary treatment of patients with tyrosine and phenylalanine restriction necessitates surveillance of growth and development by ensuring adequate intakes of amino acids and other nutrients.

Genetics and Prevalence

Tyrosinemia type I is inherited as an autosomal recessive trait. The *FAH* gene maps to chromosome 15q25.1. DNA analysis is useful for molecular prenatal diagnosis if the familial pathogenic variants are known and for carrier testing in groups at risk for specific mutations, such as French-Canadians from the Saguenay-Lac Saint-Jean region of Quebec. The prevalence of the condition is estimated to be 1 in 1,846 live births in the Saguenay-Lac Saint-Jean region and approximately 1 in 100,000 live births worldwide. Prenatal screening can be performed by measurement of succinylacetone in amniotic fluid. Prenatal diagnosis is possible using DNA analysis of amniocytes or of chorionic villi, if the familial pathogenic variants are known.

Tyrosinemia Type II (Tyrosine Aminotransferase Deficiency, Richner-Hanhart Syndrome, Oculocutaneous Tyrosinemia)

Tyrosinemia type II is a rare autosomal recessive disorder caused by deficiency of cytosolic tyrosine aminotransferase and results in palmar and plantar hyperkeratosis, herpetiform corneal ulcers, and intellectual disability (see Fig. 103.1). *Ocular manifestations* , which may occur as early as 6 mo of age, include excessive tearing, redness, pain, and photophobia. Corneal lesions are presumed to be caused by tyrosine deposition. In contrast to herpetic ulcers, corneal lesions in tyrosinemia type II stain poorly with fluorescein and often are bilateral. *Skin lesions* , which may develop later in life, include painful, nonpruritic hyperkeratotic plaques on the soles, palms, and fingertips. Intellectual disability, which occurs in approximately 50% of patients, is usually mild to moderate. The contribution of consanguinity in this rare disorder is incompletely understood.

The principal **laboratory finding** in untreated patients is marked hypertyrosinemia, >500 µmol/L and may reach 1,100-2,750 µmol/L. Surprisingly, 4-hydroxyphenylpyruvic acid and its metabolites are also elevated in urine despite being downstream from the metabolic block (see Fig. 103.1). This is hypothesized to occur via the action of other transaminases in the presence of high tyrosine concentrations, producing 4-hydroxyphenylpyruvic acid in mitochondria, where it cannot be further degraded. In contrast to tyrosinemia type I, liver and kidney function are normal, as are serum concentrations of other amino acids and succinylacetone. Tyrosinemia type II is caused by tyrosine aminotransferase *(TAT)* gene pathogenic variants, causing deficiency of cytosolic TAT activity in liver. *TAT* maps to chromosome 16q22.

Diagnosis of type II tyrosinemia is established by assay of plasma tyrosine concentration in patients with suggestive findings. Molecular diagnosis is possible. Assay of liver TAT requires a liver biopsy and is rarely indicated.

Treatment with a diet low in tyrosine and phenylalanine aiming to achieve plasma tyrosine levels <500 µmol/L improves skin and eye manifestations. The claim that intellectual disability may be prevented by early diet therapy is reasonable and is consistent with some case reports.

Tyrosinemia Type III (Primary Deficiency of 4-Hydroxyphenylpyruvate Dioxygenase)

Only a few patients with tyrosinemia type III have been reported. Most were detected by amino acid chromatography performed for various neurologic findings; therefore ascertainment bias likely confounds our current understanding of this disorder. Apparently, asymptomatic infants with 4-HPPD deficiency have been identified by neonatal screening for hypertyrosinemia. Age at presentation has been from 1-17 mo. In symptomatic patients, developmental delay, seizures, intermittent ataxia, and self-injurious behavior have been reported. Liver and renal abnormalities are absent.

The role of 4-HPPD deficiency in the disease mechanisms needs further study. The **diagnosis** is suspected in children with sustained moderate increases in plasma levels of tyrosine (typically 350-700 µmol/L on a normal diet) and the presence of 4-hydroxyphenylpyruvic acid and its metabolites 4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids in urine. Diagnosis may be refined by demonstrating the presence of pathogenic variants in the *HPD* gene encoding 4-HPPD, or rarely by demonstrating a low activity of 4-HPPD enzyme; the latter requires a liver biopsy and is not usually indicated.

Given the possible association with neurologic abnormalities, dietary reduction of plasma tyrosine levels is prudent. It is also logical to attempt a trial of vitamin C, the cofactor for 4-HPPD. The condition is inherited as an autosomal recessive trait.

Hawkinsinuria

A missense variant c.722A>G (p.Asn241Ser) in *HPD* encoding 4-HPPD results in the uncoupling of normal oxidization of 4-hydroxyphenylpyruvate to homogentisic acid and premature release of quinolacetic acid. The abnormal enzyme, incapable of normally oxidizing 4-hydroxyphenylpyruvate to homogentisic acid, forms an intermediate that reacts with glutathione to form the unusual organic acid **hawkinsin** ([2-L -cystein-*S* -yl-1,4-dihydroxycyclohex-5-en-1-yl]acetic acid), named after the first affected family (see Fig. 103.1). As a result, secondary glutathione deficiency may ensue. Hawkinsinuria is inherited as an autosomal dominant trait. In one patient, compound heterozygosity for hawkinsuria and tyrosinemia type III alleles produced only biochemical features of hawkinsuria.

The clinical course of this rare disorder is incompletely understood. Individuals with hawkinsinuria may be symptomatic only during infancy. The symptoms usually appear in the 1st few months of life, typically after weaning from breastfeeding and with the introduction of a high-protein diet. Severe metabolic acidosis, ketosis, failure to thrive, anemia, mild hepatomegaly, renal tubular acidosis, and an unusual odor are reported manifestations of this disorder. Neurocognitive development is usually normal.

Symptomatic infants and asymptomatic affected children and adults excrete hawkinsin, 4-hydroxyphenylpyruvic acid, and its metabolites (4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids), 4-hydroxycyclohexylacetic acid and 5-oxoproline (from secondary glutathione deficiency) in their urine. The plasma tyrosine level, which is moderately elevated in the symptomatic infants, may become normal in the asymptomatic affected individuals.

Treatment consists of a low-protein diet during infancy. Breastfeeding is encouraged. Avoidance of protein overrestriction is important because some patients may present with failure to thrive. Successful long-term use of *N* -acetyl-L -cysteine to treat secondary glutathione deficiency has been reported. A trial with vitamin C is recommended. The abnormal enzyme is susceptible to inhibition by nitisinone. Clinical studies showing the efficacy of this agent in symptomatic infants are lacking at this time, and the indications for its use are not known.

Transient Tyrosinemia of the Newborn

In a small number of newborn infants, plasma tyrosine may be as high as 3,300 µmol/L during the 1st 2 wk of life. Most affected infants are premature and are receiving a high-protein diet. Transient tyrosinemia is thought to result from delayed maturation of 4-HPPD (see Fig. 103.1). Lethargy, poor feeding, and decreased motor activity are noted in some patients. Most are asymptomatic and are identified by a high blood phenylalanine or tyrosine level on routine screening. Laboratory findings include marked elevation of plasma tyrosine with a moderate increase in plasma phenylalanine. The finding of hypertyrosinemia differentiates this condition from PKU. 4-Hydroxyphenylpyruvic acid and its metabolites are present in the urine. Hypertyrosinemia usually resolves spontaneously in the 1st 2 mo of life. It can be corrected by reducing dietary protein to below 2 g/kg/24 hr and by administering vitamin C. Mild intellectual deficits have been reported in some infants who had this condition, but the causal relationship to hypertyrosinemia is not conclusively established.

Alkaptonuria

Alkaptonuria is a rare (approximately 1 in 250,000 live births) autosomal recessive disorder caused by a deficiency of homogentisate 1,2-dioxigenase.Large amounts of homogentisic acid are formed (see Fig. 103.1), which are excreted in urine or deposited in tissues.

The main **clinical manifestations** of alkaptonuria consist of ochronosis and arthritis in adulthood. The only sign in children is blackening of the urine on standing, caused by oxidation and polymerization of homogentisic acid. A history of gray- or black-stained diapers should suggest the diagnosis. This sign may never be noted; thus diagnosis is often delayed until adulthood. *Ochronosis,* which is seen clinically as dark spots on the sclera or ear cartilage, results from the accumulation of the black polymer of homogentisic acid. *Arthritis* is another result of this deposition and can be disabling with advancing age. It involves the spine and large joints (shoulders, hips, and knees) and is usually more severe in males. As with rheumatoid arthritis, the alkaptonuric arthritis has acute exacerbations, but the radiologic findings are typical of osteoarthritis, with characteristic narrowing of the joint spaces and calcification of the intervertebral disks. High incidence of heart disease (mitral and aortic valvulitis, calcification of heart valves, myocardial infarction) has been reported.

The **diagnosis** is confirmed by finding massive excretion of homogentisic acid on urine organic acid testing. Tyrosine levels are normal. The enzyme is expressed only in the liver and kidneys.

Treatment of the arthritis is symptomatic. Nitisinone efficiently reduces homogentisic acid production in alkaptonuria. If presymptomatic individuals are detected, treatment with nitisinone, combined with a phenylalanine- and tyrosine-restricted diet, seems reasonable, although no experience is available regarding long-term efficacy.

The gene for homogentisate 1,2-dioxygenase *(HGD)* maps to chromosome 3q13.3. Alkaptonuria is most common in the Dominican Republic and Slovakia.

Tyrosine Hydroxylase Deficiency

See Chapter 103.11 .

Albinism

See also Chapters 640 and 672 .

Albinism is caused by deficiency of **melanin** , the main pigment of the skin and eye (Table 103.1). Melanin is synthesized by melanocytes from tyrosine in a membrane-bound intracellular organelle, the melanosome. Melanocytes originate from the embryonic neural crest and migrate to the skin, eyes (choroid and iris), hair follicles, and inner ear. The melanin in the eye is confined to the iris stromal and retinal pigment epithelia, whereas in skin and hair follicles, it is secreted into the epidermis and hair shaft. Albinism can be caused by deficiencies of melanin synthesis, by some hereditary defects of melanosomes, or by disorders of melanocyte migration. Neither the biosynthetic pathway of melanin nor many facets of melanocyte cell biology are completely elucidated (see Fig. 103.2). The end products are 2 pigments: *pheomelanin,* which is a yellow-red pigment, and *eumelanin,* a brown-black pigment.

Table 103.1

Classification of Major Causes of Albinism

TYPE	GENE	CHROMOSOME
OCULOCUTANEOUS ALBINISM (OCA)		
OCA1 (tyrosinase deficient)	*TYR*	11q14-q21

OCA1A (severe deficiency)	*TYR*	11q14-q21
OCA1B (mild deficiency)[*]	*TYR*	11q14-q21
OCA2 (tyrosinase positive) [†]	*OCA2*	15q12-q13
OCA3 (Rufous, red OCA)	*TYRP1* [‡]	9p23
OCA4	*SLC45A2*	5p13.3
Hermansky-Pudlak syndrome	*HPS1-9*	Different chromosomes
Chédiak-Higashi syndrome	*LYST*	1q42.1
OCULAR ALBINISM (OA)		
OA1 (Nettleship-Falls type)	*OA*	Xp22.3
LOCALIZED ALBINISM		
Piebaldism	*KIT*	4q12
Waardenburg syndrome (WS1-WS4)	See text	See text

[*] This includes Amish, minimal pigment, yellow albinism, and platinum and temperature-sensitive variants.

[†] Includes brown OCA.

[‡] Tyrosinase-related protein 1.

Clinically, primary albinism can be *generalized* or *localized.* Primary generalized albinism can be *ocular* or *oculocutaneous.* Some syndromes feature albinism in association with platelet, immunologic, or neurologic dysfunction. In generalized oculocutaneous albinism, hypopigmentation can be either complete or partial. Individuals with complete albinism do not develop either generalized (tanning) or localized (pigmented nevi) skin pigmentation.

The **diagnosis** of albinism is usually evident, but for some white children whose families are particularly light-skinned, normal variation may be a diagnostic consideration. Unlike patients with albinism, normal fair-skinned children progressively develop pigmentation with age, do not exhibit the eye manifestations of albinism, and have pigmentary development similar to other family members. The clinical diagnosis of oculocutaneous albinism, as opposed to other types of cutaneous hypopigmentation, requires the presence of characteristic eye findings.

The **ocular manifestations** of albinism include hypopigmentation of iris and retina with foveal hypoplasia, along with reduced visual acuity, refractive errors, nystagmus, alternating strabismus, and iris transillumination (diffuse reddish hue of iris produced during ophthalmoscopic or slit-lamp examination of eye). There is also an abnormality in routing of the optic fibers at the chiasm. Unlike in pigmented individuals, in patients with albinism the majority of the nerve fibers from the temporal side of the retina cross to the contralateral hemisphere of the brain. This results in lack of binocular (stereoscopic) vision and depth perception and in repeated switching of vision from eye to eye, causing alternating strabismus. This abnormality also causes a characteristic pattern of visual evoked potentials. These findings are highly specific for albinism and can be used to enable the clinical diagnosis. Regular ophthalmologic follow-up is recommended for patients with oculocutaneous albinism. Correction of refractive errors can maximize visual function. Usually, the alternating strabismus does not result in amblyopia and does not require surgery.

Patients with albinism should be counseled to avoid ultraviolet (UV) radiation by wearing protective long-sleeved clothing and by using sunscreens with a sun protection factor (SPF) rating >30. Melanin is also present in the cochlea. Albino individuals may be more susceptible to ototoxic agents such as gentamicin.

Oculocutaneous albinism is inherited as autosomal recessive trait. Many clinical forms of albinism have been identified. Some of the seemingly distinct clinical forms are caused by different pathogenic variants of the same gene. Several genes located on different chromosomes are involved in melanogenesis (see Table 103.1). Attempts to differentiate types of albinism based on the mode of inheritance, tyrosinase activity, or extent of hypopigmentation have failed to yield a comprehensive classification. The classification outlined next is based on the distribution of albinism in the body and the affected genes.

Genetic analysis is clinically available for most albinism genes (see Table 103.1). Molecular diagnosis is of little use therapeutically in isolated albinism but can be helpful for precise genetic counseling of families.

Oculocutaneous (Generalized) Albinism

Lack of pigment is generalized, affecting skin, hair, and eyes. At least 4 genetically distinct forms of oculocutaneous albinism (**OCA**) have been identified: OCA_1 , OCA_2 , OCA_3 , and OCA_4 . The lack of pigment is complete in patients with OCA_1 A; the other types may not be clinically distinguishable from one another. All affected individuals have ocular manifestations of albinism. All forms are inherited as autosomal recessive traits.

OCA_1 (Tyrosinase-Deficient Albinism)

The defect in patients with OCA_1 resides in the tyrosinase gene, *TYR* , located on chromosome 11q14.3. Many mutant alleles have been identified. Most affected individuals are compound heterozygotes. A clinical clue to the diagnosis of OCA_1 is complete lack of pigment at birth. The condition can be subdivided to OCA_1 A and OCA_1 B, based on enzyme activity and difference in clinical manifestations as a function of age.

OCA_1 A (Tyrosinase-Negative OCA)

In patients with OCA_1 A, the most severe form of OCA, both *TYR* alleles have pathogenic variants that completely inactivate tyrosinase. Clinically, lack of pigment in the skin (milky white), hair (white hair), and eyes (red-gray irides) is evident at birth and remains unchanged throughout life. They do not tan and do not develop pigmented nevi or freckles.

OCA_1 B

Patients with OCA_1 B have *TYR* gene pathogenic variants that preserve some residual activity. Clinically, they completely lack pigment at birth, but with age become light blond with light-blue or hazel eyes. They develop pigmented nevi and freckles, and they may tan. OCA_1 B patients, depending on the degree of pigmentation, were once subdivided into different groups and thought to be genetically distinct.

OCA_2 (Tyrosinase-Positive OCA)

OCA_2 is the *most common form of generalized OCA*, particularly in patients of African ancestry. Clinically, the phenotype is highly variable; most patients demonstrate some pigmentation of the skin and eyes at birth and continue to accumulate pigment throughout life. The hair is yellow at birth and may darken with age. They have pigmented nevi and freckles, and some may tan. They may be clinically indistinguishable from OCA_1 B patients. Individuals with $OCA_{2,}$ however, have normal tyrosinase activity in hair bulbs. The defect is in the *OCA2* gene, which is an orthologue of the *p* (pink-eyed dilution) gene in the mouse. This gene produces the P protein, a melanosome membrane protein. Patients with **Prader-Willi** and **Angelman** syndromes caused by microdeletion of chromosome 15q12 that includes the *OCA2* gene have mild pigmentary deficiency (see Chapter 98.8).

OCA_3 (Rufous Albinism)

This form has been identified predominantly in Africans, African-Americans, and natives of New Guinea. Patients with OCA_3 can make pheomelanin but not eumelanin. Patients have reddish hair and reddish brown skin as adults. The skin color is peculiar to this form. In young persons the coloration may resemble that of OCA_2 . The pathogenic variant is in the tyrosinase-related protein 1 *(TYRP1)* gene (located on chromosome 9p23), the function of which is not well-understood.

OCA_4

Similar manifestations to OCA_2 (both in the skin and the eyes) have been observed in OCA_4 patients (mostly from Japan) with pathogenic variants in the *SLC45A2* (previously called *MATP*) gene (located on chromosome 5p13.2).

Ocular Albinism

Patients with ocular albinism (**OA**) present in the 1st months of life with nystagmus, hypopigmentation of iris and fundus, foveal hypoplasia, and decreased visual acuity. Electron microscopy demonstrates characteristic macromelanosomes in skin biopsies or hair root specimens. Most patients affected by ocular albinism have ocular albinism type 1 (**OA_1**), an X-linked disorder caused by pathogenic variants in the *GPR143* gene. A rare form of OA with late-onset sensorineural deafness and apparent autosomal dominant inheritance has also been reported.

Ocular Albinism Type 1 (Nettleship-Falls Ocular Albinism)

OA_1 is an X-linked disorder characterized by congenital nystagmus, reduced pigmentation of ocular structures, and visual impairment in affected males. Heterozygous females may present with segments of abnormal retinal pigmentations. Infrequently, depending on the pattern of X chromosome inactivation, heterozygous females may also present with severe manifestations, including nystagmus, iris and foveal hypopigmentation, foveal hypoplasia, and reduced visual acuity. In families with darker skin complexion, mild skin hypopigmentation can be seen. The diagnosis of OA_1 is suspected in males with features of albinism in the eye, normal to mildly reduced skin pigmentation, and a family history suggestive of an X-linked transmission. It is a nonprogressive disorder, and the eye findings often improve with age. In patients who are the first of their families to be affected, genetic analysis of the *GPR143* gene

(Xp22.2) helps confirm the diagnosis.

Syndromic Forms of Generalized Albinism

Hermansky-Pudlak Syndrome

This group of autosomal recessive disorders is caused by pathogenic variants of 1 of 9 different genes located on different chromosomes, *HPS1* to *HPS9* . Hermansky-Pudlak syndrome (**HPS**) is suspected in patients with albinism and a bleeding diathesis with inflammatory bowel disease (IBD) or pulmonary fibrosis. Disease subtype can be established with molecular studies (see Chapter 511).

The *HPS* genes are necessary for normal structure and function of lysosome-derived organelles, including melanosomes and platelet dense bodies. Patients have a tyrosinase-positive OCA of variable severity associated with platelet dysfunction (caused by the absence of platelet dense bodies). A ceroid-like material accumulates in tissues. HPS is panethnic. However, taking into account patients' ancestry can help develop a cost-effective testing strategy. HPS is prevalent in two regions of Puerto Rico (**type 1** in the northwest and **type 3** in the central regions as a result of different founder effects). The cutaneous and ocular symptoms of albinism are present. Patients can develop epistaxis, postsurgical bleeding, or abundant menses. Bleeding time is prolonged, but platelet count is normal. Major complications include progressive pulmonary fibrosis in young adults and Crohn-like IBD in adolescents and young adults. Kidney failure and cardiomyopathy have been reported. Neutropenia has been described in HPS **type 2** . Treatment is symptomatic.

Chédiak-Higashi Syndrome

Patients with this rare autosomal recessive condition have OCA of variable severity and susceptibility to infection (see Chapter 156). Bacterial infections of skin and upper respiratory tract are common. Giant peroxidase-positive lysosomal granules can be seen in granulocytes in a blood smear. Patients have a reduced number of melanosomes, which are abnormally large (macromelanosomes). The bleeding tendency is typically mild. If treatment is not successful, children can reach a stage of the disease known as the **accelerated phase** , which is a major, life-threatening complication of Chédiak-Higashi syndrome. It is caused by macrophage activation resulting in hemophagocytic lymphohistiocytosis, and systemic manifestations include fever, lymphadenopathy, hepatosplenomegaly, cytopenia, and elevated plasma ferritin level. Patients surviving childhood may develop cerebellar atrophy, peripheral neuropathy, and cognitive delay. Pathogenic variants in the *LYST* gene on chromosome 1q42.3 are the only known cause of this syndrome. Hematopoietic stem cell transplantation offers an effective approach to control immunodeficiency and hematologic abnormalities as well as prevent development of the accelerated phase.

Other Disorders Featuring Generalized Albinism

Hypopigmentation is a feature of other syndromes, some with abnormalities of lysosomal biogenesis or melanosome biology. **Griscelli syndrome** patients have silver-gray hair, pigmentary dilution of skin, and melanosomal clumping in hair shafts and the center of melanocytes, with intellectual disability or macrophage activation with hemophagocytosis in different subtypes. **Vici syndrome** patients have combined immunodeficiency, intellectual disability, agenesis of the corpus callosum, cataracts, and cleft lip/palate. Patients with **MAPBP-interacting protein deficiency** have short stature, recurrent infections, neutropenia.

Localized Albinism

Localized albinism refers to localized patches of hypopigmentation of skin and hair, which may be evident at birth or develop with time. These conditions are caused by abnormal migration of melanocytes during embryonic development.

Piebaldism

Piebaldism is an autosomal dominant inherited condition in which the individual is usually born with a white forelock. The underlying skin is depigmented and devoid of melanocytes. In addition, there are usually white macules on the face, trunk, and extremities. Pathogenic variants in the *KIT* and *SNAI2* genes have been shown in affected patients.

Waardenburg Syndrome

In Waardenburg syndrome, a white forelock is often associated with lateral displacement of inner canthi of the eyes, broad nasal bridge, heterochromia of irides, and sensorineural deafness. This condition is inherited as an autosomal dominant trait; 4 major types have been identified. Patients with Waardenburg syndrome type 1 (**WS1** , the *most common form*) have all the previous clinical findings, including lateral displacement of inner canthi. The condition is caused by pathogenic variants (>90%) in the *PAX3* gene. Patients with Waardenburg syndrome type 2 (**WS2**) have the clinical findings of WS1 except for the lateral displacement of inner canthi. Genetically, this is a heterogeneous condition caused by pathogenic variants in several genes, including *MITF* , *SOX10* , and *SNAI2* . Patients with Waardenburg syndrome type 3 (**WS3**) have all the findings seen in individuals with WS1 plus hypoplasia and contractures of the upper limbs. It is caused by heterozygous or homozygous pathogenic variants of *PAX3* gene. Waardenburg syndrome type 4 (**WS4**), associated with **Hirschsprung disease** , is genetically heterogeneous; pathogenic variants in different genes (*EDN3*, *EDNRB*, or *SOX10*) have been identified in different patients.

Other causes of **localized hypopigmentation** include vitiligo and hypomelanosis of Ito (see Chapter 672).

Homocystinuria (Homocystinemia)

Normally, most *homocysteine*, an intermediate compound of methionine degradation, is remethylated to methionine. This methionine-sparing reaction is catalyzed by the enzyme methionine synthase, which requires a metabolite of folic acid (5-methyltetrahydrofolate) as a methyl donor and a metabolite of vitamin B_{12} (methylcobalamin) as a cofactor (see Fig. 103.3). In healthy individuals, most plasma homocysteine is either protein-bound or exists as disulfides. Three major forms of homocystinemia and homocystinuria have been identified.

Homocystinuria Caused by Cystathionine β-Synthase Deficiency (Classic Homocystinuria)

This is the most common inborn error of methionine metabolism. Approximately 40% of affected patients respond to high doses of vitamin B_6 and usually have milder clinical manifestations than those who are unresponsive to vitamin B_6 therapy. These patients possess some residual enzyme activity.

Infants with classic homocystinuria appear normal at birth. **Clinical manifestations** during infancy are nonspecific and may include failure to thrive and developmental delay. Without newborn screening, the diagnosis can be delayed and is usually made after 3 yr of age, when subluxation of the ocular lens (*ectopia lentis*) occurs. This causes severe myopia and iridodonesis (quivering of the iris). Astigmatism, glaucoma, staphyloma, cataracts, retinal detachment, and optic atrophy may develop later in life. Progressive intellectual disability is common. Normal intelligence has been reported. In an international survey of >600 patients, IQ scores ranged from 10-135. Higher IQ scores are seen in vitamin B_6 –responsive patients. Psychiatric and behavioral disorders have been observed in more than 50% of affected patients. Seizures are seen in approximately 20% of untreated patients. Affected individuals with homocystinuria manifest skeletal abnormalities resembling those of Marfan syndrome (see Chapter 722): tall with elongated limbs and arachnodactyly. Scoliosis, pectus excavatum or pectus carinatum, genu valgum, pes cavus, high-arched palate, and crowding of the teeth are typically seen. These children usually have fair complexions, blue eyes, and a peculiar malar flush. Generalized osteoporosis, especially of the spine, is the main x-ray finding. Thromboembolic episodes involving both large and small vessels, especially those of the brain, are common and may occur at any age. Optic atrophy, paralysis, cor pulmonale, and severe hypertension (from renal infarcts) are among the serious consequences of thromboembolism, which is likely caused by elevated homocysteine levels leading to abnormal angiogenesis and inhibition of fibrinolytic activity. The risk of thromboembolism increases after surgical procedures. Spontaneous pneumothorax and acute pancreatitis are rare complications.

Elevations of both methionine and homocystine (or homocysteine) in body fluids are the diagnostic **laboratory findings** . Freshly voided urine should be tested for homocystine because this compound is unstable and may disappear after prolonged storage. Cysteine is low or absent in plasma. Total plasma homocysteine is the preferred analyte for management of classic homocystinuria. Free plasma homocysteine may normalize or remain normal when total plasma homocysteine is lowered. The diagnosis may be established by molecular analysis of cystathionine β-synthase *(CBS)* or by assay of the enzyme in cultured fibroblasts, phytohemagglutinin-stimulated lymphocytes, or liver biopsy specimens.

Treatment with high doses of vitamin B_6 (100-500 mg/24 hr) causes dramatic improvement in patients who are responsive to this therapy. The degree of response to vitamin B_6 treatment may vary across families. Some patients may not respond because of folate depletion; a patient should not be considered unresponsive to vitamin B_6 until folic acid (1-5 mg/24 hr) has been added to the treatment regimen. For patients who are unresponsive to vitamin B_6 , restriction of methionine intake in conjunction with cysteine supplementation is also recommended. The need for dietary restriction and its extent remains controversial in patients with vitamin B_6 –responsive form. In some patients with this form, addition of betaine may obviate the need for any dietary restriction. *Betaine* (trimethylglycine, 6 g/24 hr for adults or 200-250 mg/kg/day for children) lowers homocysteine levels in body fluids by remethylating homocysteine to methionine (see Fig. 103.3), which may result in elevation of plasma methionine levels. This treatment has produced clinical improvement (preventing vascular events) in patients who are unresponsive to vitamin B_6 therapy. Cerebral edema has occurred in a patient with vitamin B_6 –nonresponsive homocystinuria and dietary noncompliance during betaine therapy.

More than 100 pregnancies in women with classic homocystinuria have been reported with favorable outcomes for both mothers and infants. The majority of infants were full-term and normal. Postpartum thromboembolic events occurred in a few mothers.

The screening of newborn infants for classic homocystinuria has been performed worldwide, with an estimated prevalence of 1 in 200,000 to 1 in 350,000 live births, although it can be more common in some parts of the world (e.g., 1 : 1,800 in Qatar). Early treatment of patients identified by screening has produced favorable results. The mean IQ of patients with vitamin B_6 –unresponsive form treated in early infancy was in the normal range. Dislocation of the lens seemed to be prevented in some patients.

Classic homocystinuria is inherited as an autosomal recessive trait. The gene for cystathionine β-synthase *(CBS)* is located on chromosome 21q22.3. Prenatal diagnosis is feasible by DNA analysis or by performing an enzyme assay of cultured amniotic cells. Most affected patients are compound heterozygotes for 2 different alleles. Heterozygous carriers are asymptomatic.

Homocystinuria Caused by Defects in Methylcobalamin Formation

Methylcobalamin is the cofactor for the enzyme methionine synthase, which catalyzes remethylation of homocysteine to methionine. At least 7 distinct defects in the intracellular metabolism of cobalamin may interfere with the formation of methylcobalamin. (To better understand the metabolism of cobalamin, see Methylmalonic Acidemia in Chapter 103.6 and Figs. 103.3 and 103.4 .) The 7 defects are designated as *cbl* C, *cbl* D (including *cbl* D variant 1), *cbl* E (methionine synthase reductase), *cbl* G (methionine synthase), *cbl* F, *cbl* J, and *cbl* X. Patients with *cbl* C, *cbl* D, *cbl* F, *cbl* J, and *cbl* X defects have **methylmalonic acidemia** in addition to homocystinuria, because the formation of both adenosylcobalamin and methylcobalamin is impaired.

See text for the name of the enzymes.**

Patients with *cbl* E, *cbl* G, and *cbl* D variant 1 defects are unable to form methylcobalamin and develop homocystinuria without methylmalonic acidemia (Fig. 103.4). The clinical manifestations are similar in patients with these 3 defects. Nonspecific symptoms such as vomiting, poor feeding, failure to thrive, lethargy, hypotonia, seizures, and developmental delay may occur in the 1st few months of life. Late-onset forms of these disorders may present with neurocognitive defects, psychosis, and peripheral neuropathy. **Laboratory findings** include megaloblastic anemia, hyperhomocysteinemia, homocystinuria, and hypomethioninemia. The absence of hypermethioninemia differentiates these conditions from cystathionine β-synthase deficiency (see earlier). Renal artery thrombosis, hemolytic uremic syndrome, pulmonary hypertension, and optic nerve atrophy have been reported in some patients with these defects.

Diagnosis is established by DNA testing or by complementation studies performed in cultured fibroblasts. Prenatal diagnosis has been accomplished by studies in amniotic cell cultures. *cbl* E, *cbl* G, and *cbl* D variant 1 deficiencies are inherited as autosomal recessive traits. The gene for *cbl* E is *MTRR* , encoding methionine synthase reductase (located on chromosome 5p15.31). The gene for *cbl* G is *MTR* , encoding methionine synthase (located on chromosome 1q43). The *cbl* D variant 1 deficiency is caused by pathogenic variants affecting the C-terminal of the *MMADHC* gene (located on chromosome 2q23.2).

Treatment with vitamin B_{12} in the form of high-dose hydroxycobalamin helps improve the clinical and biochemical findings. Results vary among both diseases and sibships.

Homocystinuria Caused by Deficiency of Methylenetetrahydrofolate Reductase (MTHFR Deficiency)

This enzyme reduces 5,10-methylenetetrahydrofolate to form 5-methyltetrahydrofolate, which provides the methyl group needed for remethylation of homocysteine to methionine (see Fig. 103.3). The severity of the enzyme defect and the clinical manifestations vary considerably in different families. **Clinical findings** vary from apnea, seizure, microcephaly, coma, and death to developmental delay, ataxia, motor abnormalities, peripheral neuropathy, and psychiatric manifestations. Thromboembolism has also been observed. Exposure to the anesthetic nitrous oxide (which inhibits methionine synthase) in patients with MTHFR deficiency may result in neurologic deterioration and death.

Laboratory findings include moderate homocystinemia and homocystinuria. The methionine concentration is low or low-normal. This finding helps differentiate this condition from classic homocystinuria caused by cystathionine β-synthase deficiency. The diagnosis may be confirmed by molecular analysis of *MTHFR* or by the enzyme assay in cultured fibroblasts or leukocytes.

MTHFR deficiency should be differentiated from **mild hyperhomocysteinemia** due to two common polymorphisms in the *MTHFR* gene. Two "thermolabile" polymorphisms have been extensively studied, c.665C>T (p.Ala222Val, previously referred to as c.677C>T) and c.1286A>C (p.Glu429Ala, formerly referred to as c.1298A>C). These polymorphisms may minimally affect levels of plasma total homocysteine in some patients and are often confounded by dietary folate deficiency. Both polymorphisms have been studied as possible risk factors for a wide variety of medical conditions, including birth defects, autism, vascular disease, stroke, pregnancy loss, cancer, and response to chemotherapy. Population-based studies revealed a surprisingly high prevalence of homozygosity for these polymorphisms in the general population: up to 10–15% of the North American Caucasians and >25% in some Hispanics. It is hypothesized that fortification of flour with folate may have decreased the strength of associations observed in the past. To date, the best data support a role for the c.665C>T polymorphism (formerly c. 677C>T) as a risk factor for neural tube defects. Although a clinical test for this polymorphism is widely available, recent meta-analyses have not supported the association between the *MTHFR* polymorphism and risk for venous thromboembolism or between mild hyperhomocysteinemia and an increased risk for coronary heart disease.

The condition is inherited as an autosomal recessive trait. The **diagnosis** can be confirmed by *MTHFR* gene analysis. Prenatal diagnosis can be achieved by molecular analysis of *MTHFR* of the known familial pathogenic variants or by measuring MTHFR enzyme activity in cultured chorionic villus cells or amniocytes.

Treatment of MTHFR deficiency with a combination of folic acid, vitamin B_6 , vitamin B_{12} , methionine supplementation, and betaine has been tried. Of these, early treatment with betaine appears to have the most beneficial effect.

Hypermethioninemia

Primary (Genetic) Hypermethioninemia

Elevation of plasma level of methionine occurs in several genetic conditions.

Classic Homocystinuria.

See earlier discussion.

Hepatic Methionine Adenosyltransferase (MAT I/MAT III) Deficiency (Mudd Disease).

This enzyme, which has 2 isoforms, MAT I (tetrameric) and MAT III (dimeric), is encoded by a single gene (*MAT1A* on chromosome 10q22.3) and is involved in the 1st step of methionine catabolism (see Fig. 103.3). Another structurally similar enzyme, MAT II, is encoded by a different gene (*MAT2A* on chromosome 2p11.2) and is expressed predominantly in nonhepatic tissues (kidney, brain, lymphocytes). Deficiency of MAT I/MAT III causes hypermethioninemia. In severe deficiency, total plasma homocysteine can also be elevated. The majority of these patients have been diagnosed in the neonatal period through screening for homocystinuria. Most affected individuals have residual enzyme activity and remain asymptomatic throughout life despite persistent hypermethioninemia. Some complain of an unusual odor to their breath, likely caused by accumulation of dimethylsulfide. A few patients with complete enzyme deficiency have had neurologic abnormalities related to demyelination (intellectual disability, dystonia, dyspraxia).

Laboratory studies reveal markedly elevated levels of plasma methionine with a normal or low level of *S* -adenosylmethionine and normal concentrations of *S* -adenosylhomocysteine and homocysteine. These findings help differentiate MAT I/MAT III deficiency from other causes of hypermethioninemia.

No uniformly accepted therapeutic regimen has yet emerged. Although no specific treatment is used in most patients, long-term follow-up to monitor for neurologic and liver abnormalities should be considered. Diets low in methionine result in lowering of plasma methionine, but the advisability of such diets has been questioned since lowering the plasma methionine level causes further lowering of *S* -adenosylmethionine in the body. Supplementation with *S* -adenosylmethionine in conjunction with a low-methionine diet seems prudent, but no large clinical experience is yet available. Normal pregnancies producing normal offspring have been reported in mothers with MAT I/MAT III *(MAT1A)* deficiency. The condition is inherited as an autosomal recessive trait, although pathogenic variant p.R264H in *MAT1A* appears to disrupt protein dimerization and may result in mild hypermethioninemia even in heterozygous patients.

Glycine *N* -Methyltransferase Deficiency.

Glycine *N* -methyltransferase mediates catabolism of *S* -adenosylmethionine to *S* -adenosylhomocysteine (see Fig. 103.3). A few patients with deficiency of this enzyme have been reported to date. Clinically, patients were asymptomatic except for mild hepatomegaly and elevated serum levels of transaminases. Other laboratory findings included hypermethioninemia and very high levels of serum *S* -adenosylmethionine. No specific treatment has yet been identified. The condition is inherited as an autosomal recessive trait; the gene *GNMT* is on chromosome 6p21.1.

S -Adenosylhomocysteine Hydrolase (SAHH) Deficiency.

Deficiency of SAHH (see Fig. 103.3) has been described infrequently. Intellectual disability, severe hypotonia, and progressive liver dysfunction were common clinical findings. Laboratory studies included elevated levels of serum creatine kinase, hypoalbuminemia (associated with fetal hydrops in one family), hypoprothrombinemia and greatly elevated levels of serum *S* -adenosylhomocysteine with moderate elevations of plasma methionine and *S* -adenosylmethionine. Marked elevation in *S* -adenosylhomocysteine has been thought to cause inhibition of methyltransferases, including those involved in the synthesis of creatine (see Fig. 103.10) and choline, resulting in their deficiencies. MRI of the brain can reveal delayed myelination of the white matter. The diagnosis can be achieved by the *AHCY* gene analysis (chromosome 20q11.22) or by biochemical assay of red blood cells, cultured skin fibroblasts, or liver biopsy. Treatment with a low-methionine diet has been used, but its long-term effectiveness has not been established.

Tyrosinemia Type I.

See Chapter 103.2 .

Citrin Deficiency.

See Chapter 103.12 .

Acquired (Nongenetic) Hypermethioninemia

Hypermethioninemia occurs in premature and some full-term infants receiving high-protein diets, in whom it may represent delayed maturation of the enzyme

MAT. Lowering the protein intake usually resolves the abnormality. It is also commonly found in patients with various forms of liver disease.

Primary Cystathioninemia (Cystathioninuria)

Cystathionase (cystathionine γ-lyase) deficiency results in massive cystathioninuria and mild to moderate cystathioninemia. Deficiency of this enzyme is inherited as an autosomal recessive trait, with an estimated prevalence of 1 in 14,000 live births. A wide variety of clinical manifestations have been reported. Lack of a consistent clinical picture and the presence of cystathioninuria in a number of individuals free of clinical findings suggest that cystathionase deficiency may be of no clinical significance. Many reported cases are responsive to oral administration of large doses of vitamin B_6 (≥100 mg/24 hr). When cystathioninuria is discovered in a patient, vitamin B_6 treatment can be tried, but its beneficial effect has not been established. The gene encoding for cystathionase *(CTH)* is located on chromosome 1p31.1. The disorder is inherited as an autosomal recessive trait.

Primary cystathioninuria needs to be differentiated from secondary cystathioninuria, which can occur in patients with vitamin B_6 or B_{12} deficiency, liver disease (particularly damage caused by galactosemia), thyrotoxicosis, hepatoblastoma, neuroblastoma, ganglioblastoma, or defects in remethylation of homocysteine.

Cysteine is a sulfur-containing amino acid that is synthesized from methionine (see Fig. 103.3). Oxidation of cysteine forms *cystine,* a poorly soluble dimer. The most common genetic disorders of cysteine and cystine metabolism are cystinuria (see Chapter 562) and cystinosis (see Chapter 547.3).

Sulfite Oxidase Deficiency and Molybdenum Cofactor Deficiency

In the last step in cysteine metabolism, sulfite is oxidized to sulfate by sulfite oxidase, and the sulfate is excreted in the urine (see Fig. 103.3). Sulfite oxidase is encoded by *SUOX* (located on chromosome 12q13.2). This enzyme requires a molybdenum-pterin complex termed *molybdenum cofactor.* This cofactor is also necessary for the function of 2 other enzymes in humans: xanthine dehydrogenase (which oxidizes xanthine and hypoxanthine to uric acid) and aldehyde oxidase (involved in oxidizing a number of natural compounds and drugs). Three enzymes, encoded by 3 different genes (*MOCS1* , *MOCS2,* and

GPHN, mapped to chromosomes 6p21.2, 5q11.2, and 14q23.3, respectively), are involved in the synthesis of the cofactor. Deficiency of any of the 3 enzymes causes cofactor deficiency with similar phenotypes. Most patients, who were originally diagnosed as having **sulfite oxidase deficiency** , have been shown to have **molybdenum cofactor deficiency** . Sulfite oxidase deficiency and molybdenum cofactor deficiency are inherited as autosomal recessive traits.

The enzyme and cofactor deficiencies produce overlapping **clinical manifestations** . Refusal to feed, vomiting, an exaggerated startle reaction, severe intractable seizures (tonic, clonic, myoclonic), cortical atrophy with subcortical multicystic lesions, and severe developmental delay may develop within a few weeks after birth. The biochemical diagnosis should be considered in infants presenting with neonatal seizures and neonates with symptoms reminiscent of hypoxic-ischemic encephalopathy. Bilateral dislocation of ocular lenses is a common finding in patients who survive the neonatal period. The intractable seizures seen in this condition are in part a consequence of secondary vitamin B_6 dependency. The accumulation of sulfites in body fluids in this condition causes the inhibition of *antiquitin* enzyme, which is necessary for conversion of α-amino adipic semialdehyde to α-aminoadipic acid; the resultant accumulation of α-aminoadipic semialdehyde and its cyclic form, P6C, causes the inactivation of pyridoxal-5-phosphate (active form of vitamin B_6) and thus the vitamin B_6 –dependent epilepsy (see also Chapter 103.14).

Affected children excrete large amounts of sulfite, thiosulfate, *S* -sulfocysteine, xanthine, and hypoxanthine in the urine. Urinary and serum levels of uric acid and urinary concentration of sulfate are diminished. Fresh urine should be used for screening purposes and for quantitative measurements of sulfite, because oxidation of sulfite to sulfate at room temperature may produce false-negative results. Increased concentrations of α-aminoadipic semialdehyde and P6C are present in the cerebrospinal fluid, plasma, and urine.

Diagnosis is confirmed by measurement of sulfite oxidase and molybdenum cofactor in fibroblasts and liver biopsies, respectively or by DNA studies. Prenatal diagnosis is possible by performing an assay of sulfite oxidase activity in cultured amniotic cells, in samples of chorionic villi or by DNA studies. The prevalence of these deficiencies in the general population is not known, but likely is very low.

No effective treatment is available. Large doses of vitamin B_6 (5-100 mg/kg) result in alleviation of seizures but do not seem to alter the devastating neurologic outcome. Most children die in the 1st 2 yr of life. Patients with molybdenum cofactor deficiency caused by pathogenic variants in *MOCS1* have benefited from supplementation using intravenous **cyclic pyranopterin monophosphate** (cPMP), which is undergoing a multicenter clinical trial.

Hartnup Disorder

In the autosomal recessive Hartnup disorder, named after the 1st affected family, a defect occurs in the transport of monoamino-monocarboxylic amino acids (neutral amino acids), including tryptophan, by the intestinal mucosa and renal tubules. The transporter protein for these amino acids (**B^0 AT1**) is encoded by the *SLC6A19* gene (located on chromosome 5p15.33). Most children with Hartnup defect remain asymptomatic. Patients show significant variability in presentation, likely related to the nutritional factors, environment, and genetic heterogeneity (e.g., 2 proteins, TMEM27 and ACE2, that interact with B^0 AT1). Decreased intestinal absorption of tryptophan in conjunction with its increased renal loss can lead to reduced availability of tryptophan for niacin synthesis. **Tryptophan deficiency** can be accentuated by malabsorption such as celiac disease. The major clinical manifestation in the rare symptomatic patient is **cutaneous photosensitivity** . The skin becomes rough and red after moderate exposure to the sun, and with greater exposure, a *pellagra-like rash* may develop. The rash may be pruritic, and a chronic eczema may develop. The skin changes have been reported in affected infants as young as 10 days of age. Some patients may have intermittent ataxia manifested as an unsteady, wide-based gait. The ataxia may last a few days and can respond to niacin supplementation.

Cognitive development is usually normal. Episodic psychiatric manifestations such as irritability, emotional instability, depression, and suicidal tendencies, have been observed; these changes are usually associated with bouts of ataxia. Short stature and atrophic glossitis are seen in some patients.

Most children diagnosed with Hartnup disorder by neonatal screening have remained asymptomatic. This indicates that other factors are also involved in pathogenesis of the clinical condition.

The main laboratory finding is **aminoaciduria** , which is restricted to neutral amino acids (alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine). Urinary excretion of proline, hydroxyproline, and arginine remains normal. This finding helps differentiate Hartnup disorder from other causes of generalized aminoaciduria, such as Fanconi syndrome. Plasma concentrations of neutral amino acids are normal or mildly decreased. This seemingly unexpected finding reflects compensatory mechanisms required to maintain normal transport and utilization of amino acids. The indole derivatives (especially indican) may be found in large amounts in some patients, resulting from bacterial breakdown of unabsorbed tryptophan in the intestines.

Diagnosis of Hartnup disorder is established by the intermittent nature of symptoms and characteristic findings on the urine amino acid analysis. If necessary, the diagnosis can be confirmed molecularly by *SLC6A19* gene analysis.

Treatment with nicotinic acid or nicotinamide (50-300 mg/24 hr) and a high-protein diet results in a favorable response in symptomatic patients with Hartnup disorder. Because of the intermittent nature of the clinical manifestations, the efficacy of these treatments is difficult to evaluate. The prevalence of Hartnup disorder is estimated to be 1 in 20,000 to 1 in 55,000 live births. Normal outcome for both mother and fetus has been reported in several affected women.

The early steps in the degradation of the branched-chain amino acids (BCAAs)—isoleucine, leucine, and valine—are similar (see Fig. 103.4). Under catabolic conditions, BCAAs in the muscle tissue undergo a reversible reaction of transamination catalyzed by BCAA transaminase. α-Ketoacids formed by this reaction then undergo an oxidative decarboxylation step mediated by branched-chain α-ketoacid dehydrogenase (**BCKDH**) complex. The deficiency of BCKDH results in maple syrup urine disease, whereas the deficiency of enzymes mediating more distal steps results in accumulation of enzyme-specific organic acids excreted in the urine, thus giving those inborn errors of metabolism the eponyms **organic acidemias** and **organic acidurias** . These disorders typically cause metabolic acidosis, which usually occurs in the 1st few days of life. Although most of the clinical findings are nonspecific, some manifestations may provide important clues to the nature of the enzyme deficiency. Fig. 103.6 presents an approach to infants suspected of having an organic acidemia. The diagnosis is usually established by identifying and measuring specific organic acids in body fluids (blood, urine), identifying pathogenic variants in a respective gene, and enzyme assay.

Organic acidemias are *not* limited to defects in the catabolic pathways of BCAAs. Disorders causing accumulation of other organic acids include those derived from lysine (see Chapter 103.14), disorders of γ-glutamyl cycle (see Chapter 103.11), those associated with lactic acid (see Chapter 105), and dicarboxylic acidemias associated with defective fatty acid degradation (see Chapter 104.1).

Maple Syrup Urine Disease

Decarboxylation of leucine, isoleucine, and valine is accomplished by a complex enzyme system (BCKDH) using thiamine (vitamin B_1) pyrophosphate as a coenzyme. This mitochondrial enzyme consists of 4 subunits: $E_{1\alpha}$, $E_{1\beta}$, E_2 , and E_3 . The E_3 subunit is shared with 2 other dehydrogenases, pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. Deficiency of any of these subunits causes maple syrup urine disease (**MSUD**) (see Fig. 103.4), a disorder named after the sweet odor of maple syrup found in body fluids, especially urine. Clinical conditions caused by defects in $E_{1\alpha}$, $E_{1\beta}$, E_2 and E_3 are designated as MSUD type IA, type IB, type 2, and type 3, respectively. This classification, however, is not very helpful clinically because the severity of clinical manifestations does not correlate with, or correspond specifically to, any single enzyme subunit. An affected infant with type 1A defect can have clinical manifestations ranging from relatively mild to very severe. A more useful classification, based on clinical findings and response to thiamine administration, delineates 5 phenotypes of MSUD.

Classic Maple Syrup Urine Disease

Classic MSUD has the **most severe** clinical manifestations. The BCKDH complex activity in this group varies between 0% and 2% of controls. Patients with uncontrolled or poorly controlled disease develop signs of acute encephalopathy. The mechanisms underlying this life-threatening complication are complex, but leucine and its derivative, α-ketoisocaproic acid, appear to be the key factors underlying acute encephalopathy. Elevated leucine competitively inhibits the uptake of other amino acids by the large neutral amino acid (LNAA) transporter. Once taken up by the brain tissue, leucine is metabolized by BCAA aminotransferase to α-ketoisocaproic acid, which leads to the disrupted metabolism of neurotransmitters and amino acids (glutamate, GABA, glutamine, alanine, and aspartate). α-Ketoisocaproic acid can reversibly inhibit oxidative phosphorylation and result in cerebral lactic acidosis. Collectively, these processes are detrimental to the normal function of neurons and glia, clinically manifesting as encephalopathy and brain edema and referred to as **leucinosis** . Affected infants who appear healthy at birth develop poor feeding and vomiting in the 1st days of life. Lethargy and coma may ensue within a few days. Physical examination reveals hypertonicity and muscular rigidity with severe opisthotonos. Periods of hypertonicity may alternate with bouts of flaccidity manifested as repetitive movements of the extremities (“boxing” and “bicycling”). Neurologic findings are often mistakenly thought to be caused by generalized sepsis and meningitis. Cerebral edema may be present; convulsions occur in most infants, and hypoglycemia is common. In contrast to most hypoglycemic states, correction of the blood glucose concentration does not improve the clinical condition. Aside from the blood glucose, routine laboratory findings are usually unremarkable, except for varying degrees of ketoacidosis. If left untreated, death can occur in the 1st few weeks or months of life.

Diagnosis is often suspected because of the peculiar odor of maple syrup in urine, sweat, and cerumen. It is usually confirmed by amino acid analysis showing marked elevations in plasma levels of leucine, isoleucine, valine, and alloisoleucine (a stereoisomer of isoleucine not normally found in blood) and depressed level of alanine. Leucine levels are usually higher than those of the other 3 amino acids. Urine contains high levels of leucine, isoleucine, and valine and their respective ketoacids. These ketoacids may be detected qualitatively by adding a few drops of 2,4-dinitrophenylhydrazine reagent (0.1% in 0.1N HCl) to the urine; a yellow precipitate of 2,4-dinitrophenylhydrazone is formed in a positive test. Neuroimaging during the acute state may show cerebral edema, which is most prominent in the cerebellum, dorsal brainstem, cerebral peduncle, and internal capsule. After recovery from the acute state and with advancing age, hypomyelination and cerebral atrophy may be seen in neuroimaging of the brain.

Treatment of the acute state is aimed at hydration and rapid removal of the BCAAs and their metabolites from the tissues and body fluids. Uptake of leucine by the brain and accumulation of the downstream metabolite, α-ketoisocaproic acid, appear to be the key metabolic events underlying MSUD encephalopathy. Therefore, strategies of MSUD management focus on decreasing plasma leucine to control acute and chronic manifestations of the disease.

Because renal clearance of leucine is poor, hydration alone may not produce a rapid improvement. *Hemodialysis* is the most effective mode of therapy in critically ill infants and should be instituted promptly; significant decreases in plasma levels of leucine, isoleucine, and valine are usually seen within 24 hr. Sufficient calories and nutrients should be provided intravenously or orally as soon as possible to reverse patient's catabolic state. Cerebral edema, if present, may require treatment with mannitol, diuretics (e.g., furosemide), or hypertonic saline. Counterintuitively, supplementation with isoleucine and valine is also needed to control plasma leucine level in MSUD patients. Judiciously administered isoleucine and valine will compete with leucine for the LNAA transporter at the blood-brain barrier and thus decrease leucine entry into the central nervous system (CNS) and help in the prevention and treatment of leucine encephalopathy.

Treatment after recovery from the acute state requires a diet low in BCAAs. Synthetic formulas devoid of leucine, isoleucine, and valine are available commercially. Because these amino acids cannot be synthesized endogenously, age-appropriate amounts of BCAAs should be provided in the diet in the form of complete protein. To avoid essential amino acid deficiencies, the amount should be titrated carefully by performing frequent analyses of the plasma amino acids, with close attention to plasma isoleucine, leucine, and valine levels. A clinical condition resembling **acrodermatitis enteropathica** (see Chapter 691) occurs in affected infants whose plasma isoleucine or valine become *very low* ; addition of isoleucine or valine, respectively, to the diet will hasten the recovery of skin rash. Patients with MSUD need to remain on the diet for the rest of their lives. Liver transplantation has been performed in patients with classic MSUD, with promising results.

The long-term prognosis of affected children remains guarded. Severe ketoacidosis, cerebral edema, and death may occur during any stressful situation such as infection or surgery, especially in mid-childhood. Cognitive and other neurologic deficits are common sequelae.

Intermediate (Mild) Maple Syrup Urine Disease

Children with intermediate MSUD develop milder disease after the neonatal period. Clinical manifestations are insidious and limited to the CNS. Patients have mild to moderate intellectual disability with or without seizures. They have the odor of maple syrup and excrete moderate amounts of the BCAAs and their ketoacid derivatives in the urine. Plasma concentrations of leucine, isoleucine, and valine are moderately increased whereas those of lactate and pyruvate tend to be normal. These children are commonly diagnosed during an intercurrent illness, when signs and symptoms of classic MSUD may occur. The dehydrogenase activity is 3–40% of controls. Because patients with thiamine-responsive MSUD usually have manifestations similar to the mild form, a trial of thiamine therapy is recommended. Diet therapy, similar to that of classic MSUD, is needed.

Intermittent Maple Syrup Urine Disease

In intermittent MSUD, seemingly normal children develop vomiting, odor of maple syrup, ataxia, lethargy, and coma during any stress or catabolic state such as infection or surgery. During these attacks, laboratory findings are indistinguishable from those of the classic form, and death may occur. Treatment of the acute attack of intermittent MSUD is similar to that of the classic form. After recovery, although a normal diet can be tolerated, a low-BCAA diet is recommended. The BCKDH activity in patients with the intermittent form is higher than in the classic form and may reach 40% of the control activity.

Thiamine-Responsive Maple Syrup Urine Disease

Some children with mild or intermediate forms of MSUD who are treated with high doses of thiamine have dramatic clinical and biochemical improvement. Although some respond to treatment with thiamine at 10 mg/24 hr, others may require as much as 100 mg/24 hr for at least 3 wk before a favorable response is observed. These patients also require BCAA-restricted diets. The enzymatic activity in these patients can be up to 40% of normal.

Maple Syrup Urine Disease Caused by Deficiency of E_3 Subunit (MSUD Type 3)

Although sometimes referred to as “maple syrup urine disease type 3,” this very rare disorder leads to clinical and biochemical abnormalities that encompass a wide range of mitochondrial reactions. E_3 subunit, dihydrolipoamide dehydrogenase, is a component of the BCKDH complex, pyruvate dehydrogenase complex, and α-ketoglutarate dehydrogenase complex. Pathogenic variants in dihydrolipoamide dehydrogenase cause lactic acidosis, elevated pyruvate, as well as signs and symptoms similar to intermediate MSUD. Progressive neurologic impairment manifested by hypotonia and developmental delay occurs after 2 mo of age. Abnormal movements progress to ataxia or Leigh syndrome. Death may occur in early childhood.

Laboratory findings include persistent lactic acidosis with high levels of plasma pyruvate and alanine. Plasma BCAA concentrations are moderately increased. Patients excrete large amounts of lactate, pyruvate, α-ketoglutarate, and the 3 branched-chain ketoacids in their urine.

No effective treatment is available. BCAA-restricted diets and treatment with high doses of thiamine, biotin, and lipoic acid have been ineffective.

Genetics and Prevalence of Maple Syrup Urine Disease

All forms of MSUD are inherited as an autosomal recessive trait. The gene for each subunit resides on different chromosomes. The gene for $E_{1\alpha}$ *(BCKDHA)* is on chromosome 19q13.2; that for $E_{1\beta}$ *(BCKDHB)* is on chromosome 6q14.1; the gene for E_2 (*DBT*) is on chromosome 1p21.2; and that for E_3 *(DLD)* is on chromosome 7q31.1. Genotype-phenotype correlations are difficult to establish and are usually imprecise. The exception is thiamine-responsive MSUD, shown to be caused by pathogenic variants in *DBT* . Most patients are compound heterozygotes inheriting 2 different pathogenic alleles. Pathogenic variants in *BCKDHA* (45%) and *BCKDHB* (35%) account for approximately 80% of cases. Pathogenic variants in *DBT* are responsible for 20% of MSUD cases.

The prevalence is estimated at 1 in 185,000 live births. Classic MSUD is more prevalent in the Old Order Mennonites in the United States, at an estimated 1 in 380 live births. Affected patients in this population are homozygous for a specific pathogenic variant (c.1312T>A) in *BCKDHA* -encoding $E_{1\alpha}$ subunit.

Early detection of MSUD is feasible by universal newborn screening. In most cases, however, especially those with classic MSUD, the infant may be quite sick by the time screening results become available (see Chapter 102). Prenatal diagnosis has been accomplished by enzyme assay of the cultured amniocytes, cultured chorionic villus tissue, or direct assay of samples of the chorionic villi and by identification of the known pathogenic variants in the affected gene.

Several successful pregnancies have occurred in women with different forms of MSUD. The teratogenic potential of leucine during pregnancy is unknown. Tight control of isoleucine, leucine, and valine before and during the pregnancy is important to minimize the risk of metabolic decompensation and to optimize fetal nutrition. Mothers affected by MSUD require close monitoring and meticulous management of nutrition, electrolytes, and fluids in the postpartum period.

Branched-Chain α-Ketoacid Dehydrogenase Kinase Deficiency

A defect in the regulation of branched-chain α-ketoacid dehydrogenase (BCKDH) by BCKDH kinase (BCKDK), the enzyme responsible for the phosphorylation-mediated inactivation of the BCKDH complex, causes the *reverse* biochemical phenotype of MSUD. Pathogenic variants in *BCKDK* decrease the negative regulation by the kinase, resulting in uncontrolled degradation and depletion of isoleucine, leucine, and valine in plasma and brain. Patients with BCKDK deficiency present with low plasma concentrations of isoleucine, leucine, and valine associated with autism, intellectual impairment, fine motor coordination problems, and seizures.

Branched-Chain Amino Acid Transporter Deficiency

Isoleucine, leucine, and valine are transported across the BBB mainly by the heterodimeric LNAA transporter LAT1 encoded by *SLC7A5* . A defect in LAT1 caused by pathogenic variants in *SLC7A5* results in low brain concentrations of isoleucine, leucine, and valine. Patients with this defect may present clinically similar to BCKDK-deficient patients, with autism, microcephaly, gross motor delays, and in some cases, seizures.

Isovaleric Acidemia

Isovaleric acidemia (**IVA**) is caused by deficiency of isovaleryl–coenzyme A (CoA) dehydrogenase (see Fig. 103.4). Decreased or lost activity of isovaleryl-CoA dehydrogenase results in impaired leucine degradation. Accumulating derivatives of isovaleric acid, isovalerylcarnitine, isovalerylglycine, and 3-hydroxyisovaleric acid can be detected in body fluids and thus enable the biochemical diagnosis and screening. Clinically, the course of IVA is highly variable, ranging from essentially asymptomatic to severe. Introduction of newborn screening and proactive management of IVA changed its outlook and the clinical course. Older siblings of symptomatic newborn infants have been reported with identical genotype and biochemical abnormalities but without clinical manifestations, suggesting that presymptomatic detection of affected patients on the newborn screen can improve clinical outcomes.

Patients with severe IVA can present with vomiting, severe acidosis, hyperammonemia, hypoglycemia, hypocalcemia, and bone marrow suppression in the infantile period. Lethargy, convulsions, and coma may ensue, and death may occur if proper therapy is not initiated. Vomiting may be severe enough to suggest pyloric stenosis. The characteristic odor of *sweaty feet* or *rancid-cheese* may be present. Infants who survive this acute episode are at risk to develop episodes of metabolic decompensation later in life. In the mild form without treatment, typical clinical manifestations of severe IVA (vomiting, lethargy, acidosis or coma) may not appear until the child is a few months or a few years old. Acute episodes of metabolic decompensation may occur during a catabolic state, such as infection, dehydration, surgery, or high-protein intake. Acute episodes may be mistaken for diabetic ketoacidosis. Some patients may experience acute and recurrent episodes of pancreatitis.

Laboratory findings during the acute attacks include ketoacidosis, neutropenia, thrombocytopenia, and occasionally pancytopenia. Hypocalcemia, hypoglycemia, and moderate to severe hyperammonemia may be present in some patients. Increases in plasma ammonia may suggest a defect in the urea cycle (see Chapter 103.12). In urea cycle defects, however, the infant usually shows no significant ketoacidosis (see Fig. 103.6).

Diagnosis is established by demonstrating marked elevations of isovaleric acid metabolites (isovalerylglycine, 3-hydroxyisovaleric acid) in body fluids, especially urine. The main compound in plasma is isovalerylcarnitine (C5-carnitine). C5-carnitine can be measured in dried blood spots, thus enabling universal newborn screen using tandem mass spectrometry. The diagnosis can be confirmed by molecular analysis of the *IVD* gene. In some patients with equivocal results, measurement of the enzyme activity in cultured skin fibroblasts may be necessary.

Treatment of the acute attack is aimed at hydration, reversal of the catabolic state (by providing adequate calories orally or intravenously), correction of metabolic acidosis, and facilitation of the isovaleric acid excretion. L -Carnitine (100 mg/kg/24 hr orally) also increases removal of isovaleric acid by forming isovalerylcarnitine, which is excreted in the urine. Because isovalerylglycine has a high urinary clearance, some centers recommend glycine supplementation (250 mg/kg/24 hr) to enhance the formation of isovalerylglycine. Temporary restriction of protein intake (<24 hr) may be beneficial in some cases. In patients with significant hyperammonemia (blood ammonia >200 µmol/L), measures that reduce blood ammonia should be employed (see Chapter 103.12). Renal replacement therapy may be needed if the previously described measures fail to produce significant clinical and biochemical improvement. Long-term management of IVA patients requires restriction of protein according to age-appropriate intake (recommended dietary allowance of protein). Patients benefit from carnitine supplementation with or without glycine. Normal development can be achieved with early and proper treatment.

Prenatal diagnosis can be accomplished by enzyme assay in cultured amniocytes, or if causative mutations are known, by the *IVD* gene analysis. Successful pregnancies with favorable outcomes have been reported. Universal newborn screening of IVA is used in the United States and other countries (see

Chapter 102). IVA is caused by autosomal recessive pathogenic variants in *IVD* . The prevalence of IVA is estimated from 1 in 62,500 (in parts of Germany) to 1 in 250,000 live births (in the United States).

Multiple Carboxylase Deficiencies (Defects of Biotin Cycle)

Biotin is a water-soluble vitamin that is a cofactor for all 4 carboxylase enzymes in humans: pyruvate carboxylase, acetyl-CoA carboxylase, propionyl-CoA carboxylase, and 3-methylcrotonyl-CoA carboxylase. The latter 2 are involved in the catabolic pathways of leucine, isoleucine, and valine (see Fig. 103.4).

Most of the dietary biotin is bound to proteins. Free biotin is generated in the intestine by the action of digestive enzymes, by intestinal bacteria, and perhaps by biotinidase. **Biotinidase** , which is found in serum and most tissues, is also essential for the recycling of biotin in the body by releasing it from the apoenzymes (carboxylases; see Fig. 103.4). Free biotin must form a covalent bond with the apocarboxylases to produce the activated enzyme (holocarboxylase). This binding is catalyzed by holocarboxylase synthetase. Deficiencies in this enzyme activity or in biotinidase result in malfunction of all the carboxylases and in organic acidemias.

Holocarboxylase Synthetase Deficiency

Infants with this rare autosomal recessive disorder become symptomatic in the 1st few weeks of life. Symptoms may appear as early as a few hours after birth to as late as 8 yr of age. Clinically, shortly after birth, the affected infant develops breathing difficulties (tachypnea and apnea). Feeding problems, vomiting, and hypotonia are also usually present. If the condition remains untreated, *generalized erythematous rash with exfoliation and alopecia* , failure to thrive, irritability, seizures, lethargy, and even coma may occur. Developmental delay is common. Immune deficiency manifests with susceptibility to infection. Urine may have a peculiar odor, which has been described “tomcat urine.” The rash, when present, helps differentiate this condition from other organic acidemias (see Fig. 103.6).

Laboratory findings include metabolic acidosis, ketosis, hyperammonemia, and the presence of a variety of organic acids (lactic acid, 3-methylcrotonic acid, 3-methylcrotonylglycine, tiglylglycine, 3-OH-propionic acid, methylcitric acid, and 3-hydroxyisovaleric acid) in body fluids. **Diagnosis** is confirmed by identification of pathogenic variants in *HLCS* or by the enzyme assay in lymphocytes or cultured fibroblasts. Most pathogenic variants cause the enzyme to have an increased K_m (Michaelis-Menten dissociation constant) for biotin; the enzyme activity in such patients can be restored by the administration of large doses of biotin. Newborn screening can identify holocarboxylase synthetase–deficient infants by detecting elevated C5-OH-carnitine on tandem mass spectrometry. In these infants, biotinidase enzymatic assay would be normal.

Treatment with biotin (10-20 mg/day orally) usually results in an improvement in clinical manifestations and biochemical abnormalities. Early diagnosis and treatment are critical to prevent irreversible neurologic damage. In some patients, however, complete resolution may not be achieved even with large doses (up to 60 mg/day) of biotin.

The gene for holocarboxylase synthetase *(HLCS)* is located on chromosome 21q22.13. **Prenatal diagnosis** can be accomplished by prenatal molecular analysis of the known pathogenic variants in *HLCS* or by assaying enzyme activity in cultured amniotic cells. Pregnant mothers who had previous offspring with holocarboxylase synthetase deficiency have been treated with biotin late in pregnancy. Affected infants were normal at birth, but the efficacy of prenatal treatment remains unclear.

Biotinidase Deficiency

Impaired biotinidase activity results in biotin deficiency. Affected infants may develop clinical manifestations similar to those seen in infants with holocarboxylase synthetase deficiency. Unlike the latter, however, symptoms tend to appear later, when the child is several months or years old. The delay in onset of symptoms presumably results from the presence of free biotin derived from the mother or the diet. Clinical manifestations are mostly confined to skin and the nervous system. Atopic or seborrheic dermatitis, candidiasis, alopecia, ataxia, seizures (usually myoclonic), hypotonia, developmental delay, optic nerve atrophy, sensorineural hearing loss, and immunodeficiency resulting from impaired T-cell function may occur. A small number of children with *intractable seborrheic dermatitis* and *partial* (15–30% activity) biotinidase deficiency, in whom the dermatitis resolved with biotin therapy, have been reported; these children were otherwise asymptomatic. Asymptomatic children and adults with this enzyme deficiency have been identified in screening programs. Most of these individuals have been shown to have partial biotinidase deficiency. With universal newborn screening leading to early identification and treatment of the affected patients, the clinical disease is predicted to become extinct.

Laboratory findings and the pattern of organic acids in body fluids resemble those associated with holocarboxylase synthetase deficiency (see above). **Diagnosis** can be established by measurement of the enzyme activity in the serum or by the identification of the mutant gene. **Treatment** with free biotin (5-20 mg/day) results in a dramatic clinical and biochemical improvement. Treatment with biotin is also suggested for individuals with partial biotinidase deficiency. The prevalence of this autosomal recessive trait is estimated at 1 in 60,000 live births. The gene for biotinidase *(BTD)* is located on chromosome 3p25.1. **Prenatal diagnosis** is possible by identification of the known pathogenic variants in *BTD*, or less frequently by the measurement of the enzyme activity in the amniotic cells, although in practice, a prenatal approach is rarely used.

Multiple Carboxylase Deficiency Caused by Acquired Biotin Deficiency

Acquired deficiency of biotin may occur in infants receiving total parenteral nutrition without added biotin, in patients with prolonged use of antiepileptic drugs (phenobarbital, phenytoin, primidone, carbamazepine), and in children with short bowel syndrome or chronic diarrhea who are receiving formulas low in biotin. Excessive ingestion of raw eggs may also cause biotin deficiency because the protein avidin in egg white binds biotin, decreasing its absorption. Infants with biotin deficiency may develop dermatitis, alopecia, and candidal skin infections. This condition readily responds to treatment with oral biotin.

3-Methylcrotonyl-CoA Carboxylase Deficiency

This enzyme is 1 of the 4 carboxylases requiring biotin as a cofactor (see Fig. 103.4). An isolated deficiency of this enzyme must be differentiated from disorders of biotin metabolism (multiple carboxylase deficiency), which causes diminished activity of all 4 carboxylases (see earlier). 3-Methylcrotonyl-CoA carboxylase (3-MCC) is a heteromeric enzyme consisting of α (biotin containing) and β subunits, encoded by genes *MCCC1* and *MCCC2* , respectively. 3-MCC deficiency can be detected in the newborn period by identifying elevated 3-hydroxyisovalerylcarnitine (C5-OH) in dried blood spots. Universal newborn screening using tandem mass spectrometry has identified an unexpectedly high number of infants with 3-MCC deficiency, with prevalence ranging from 1 : 2,400 to 1 : 68,000.

Clinical manifestations are highly variable, ranging from completely asymptomatic adults (including mothers of affected newborn infants), to children presenting with developmental delay without episodes of metabolic decompensation, to patients with seizures, hyperammonemia, and metabolic acidosis. In severe 3-MCC deficiency the affected infant who has been seemingly normal develops an acute episode of vomiting, hypotonia, lethargy, and convulsions after a minor infection, in some cases progressing to life-threatening complications (e.g., Reye syndrome, coma). In patients prone to developing these symptoms, the onset is usually between 3 wk and 3 yr of age. Among infants identified through newborn screening, 85–90% of children remain apparently asymptomatic. The reason for differences in outcomes is unknown. None of the symptoms reported so far could be clearly attributed to the degree of enzyme deficiency.

Laboratory findings during acute episodes include mild to moderate metabolic acidosis, ketosis, hypoglycemia, hyperammonemia, and elevated serum transaminase levels. Large amounts of 3-hydroxyisovaleric acid and 3-methylcrotonylglycine are found in the urine. Urinary excretion of 3-methylcrotonic acid is not usually increased in this condition because the accumulated 3-methylcrotonyl-CoA is converted to 3-hydroxyisovaleric acid. Plasma acylcarnitine profile shows elevated 3-hydroxyisovalerylcarnitine (C5-OH). Severe secondary carnitine deficiency is common. 3-MCC deficiency should be differentiated biochemically from multiple carboxylase deficiency (see earlier), in which, in addition to 3-hydroxyisovaleric acid, lactic acid and metabolites of propionic acid are also present. **Diagnosis** may be confirmed by molecular analysis or by measurement of the enzyme activity in cultured fibroblasts. Documentation of normal activities of other carboxylases is necessary to rule out multiple carboxylase deficiency.

Treatment of acute episodes is similar to that of isovaleric acidemia (see earlier). Hydration and measures to correct hypoglycemia and severe metabolic acidosis by infusing glucose and sodium bicarbonate should be instituted promptly. Secondary carnitine deficiency, seen in up to 50% of patients, can be corrected with L-carnitine supplementation. For symptomatic patients, some centers recommend keeping protein intake at the recommended dietary allowance in conjunction with the oral administration of L-carnitine and the proactive management of catabolic states. Normal growth and development are expected in most patients.

3-MCC deficiency is an autosomal recessive condition. The gene for α-subunit *(MCCC1)* is located on chromosome 3q27.1, and that for the β-subunit *(MCCC2)* is mapped to chromosome 5q13.2. Pathogenic variants in either of these genes result in the enzyme deficiency with overlapping clinical features.

3-Methylglutaconic Acidurias

The 3-methylglutaconic acidurias are a heterogeneous group of metabolic disorders characterized by excessive excretion of 3-methylglutaconic acid in the urine (Table 103.2). Other metabolites found in 3-methylglutaconic aciduria patients may include 3-methylglutaric acid and 3-hydroxyisovaleric acid. Current classification distinguishes primary and secondary forms. **Primary** 3-methylglutaconic aciduria is caused by the deficiency of mitochondrial 3-methylglutaconyl-CoA hydratase (see Fig. 103.4), formerly *3-methylglutaconic aciduria type I* . **Secondary** 3-methylglutaconic aciduria can be further classified based on the underlying mechanism (e.g., defective phospholipid remodeling vs dysfunction of mitochondrial membrane) or the known molecular cause. Known secondary 3-methylglutaconic aciduria includes *TAZ* -related syndrome (**Barth syndrome**), *OPA3* -related 3-methylglutaconic aciduria (**Costeff syndrome**), *SERAC1* -related syndrome (**MEGDEL syndrome**), *TMEM70* -related syndrome, and *DNAJC19* -related syndrome (**DCMA syndrome**).

Table 103.2

3-Methylglutaconic Acidurias

GROUP	DISORDER	GENE (CHROMOSOME)	PREVIOUS CLASSIFICATION	DISEASE MECHANISM	CLINICAL DESCRIPT
Primary 3-methylglutaconic aciduria	3-Methylglutaconyl-CoA hydratase deficiency	*AUH* (9q22.31)	Type I	Enzyme deficiency in the leucine degradation pathway	Depending o variable pres is seen rangi younger asymptomati patients to ol

					patients with progressive leukoenceph
Secondary 3-methylglutaconic acidurias	Barth syndrome	*TAZ* (Xq28)	Type II	Defective phospholipid remodeling	X-linked inh cardiomyopa endocardial fibroelastosi proximal my failure to thr neutropenia, dysmorphic
	Costeff syndrome	*OPA3* (19q13.32)	Type III	Mitochondrial membrane dysfunction	Progressive nerve atroph chorea, spast paraparesis, cognitive impairment
	MEGDEL syndrome	*SERAC1* (6q25.3)	Type IV	Defective phospholipid remodeling	Progressive deafness, dy spasticity, ba ganglia chan
	TMEM70 -related disorder	*TMEM70* (8q21.11)	Type IV	Mitochondrial membrane dysfunction	Developmen delay, failure thrive, metab decompensat microcephal cardiomyopa dysmorphic
	3-Methylglutaconic aciduria, not otherwise specified	Unknown	Type IV	Unknown	Variable pres
	DCMA syndrome	*DNAJC19* (3q26.33)	Type V	Mitochondrial membrane dysfunction	Cardiomyop ataxia, optic atrophy, failu thrive

Significant and persistent 3-methylglutaconic aciduria with negative molecular evaluation for known genetic causes represents a heterogeneous group called 3-methylglutaconic aciduria **not otherwise specified** awaiting further molecular characterization. Primary and secondary 3-methylglutaconic aciduria should be distinguished from mild and transient urinary elevations of 3-methylglutaconic acid seen in patients affected by other metabolic disorders, such as mitochondrial disorders of diverse etiology.

3-Methylglutaconyl-CoA Hydratase Deficiency

Two main clinical forms of 3-methylglutaconyl-CoA hydratase deficiency have been described (see Fig. 103.4). In the **childhood** form, nonspecific neurodevelopmental findings such as speech delay or regression, choreoathetoid movements, optic nerve atrophy, and mild psychomotor delay may be present. Metabolic acidosis may occur during a catabolic state. In the **adulthood** form, affected individuals may remain asymptomatic until the 2nd or 3rd decade of life, when a clinical picture of *slowly progressing leukoencephalopathy* with optic nerve atrophy, dysarthria, ataxia, spasticity, and dementia occurs. Brain MRI typically shows white matter abnormalities, which may precede the appearance of clinical symptoms by years. Asymptomatic pediatric and adult patients have also been reported. Patients excrete large amounts of 3-methylglutaconic acid and moderate amounts of 3-hydroxyisovaleric and 3-methylglutaric acids in urine. **Treatment** with L -carnitine may help some patients. The effectiveness of a low-leucine diet has not been established. The condition is inherited as an autosomal recessive trait. The gene for the hydratase enzyme *(AUH)* is mapped to chromosome 9q22.31.

Barth Syndrome (*TAZ* -Related Disorder)

This X-linked condition is caused by deficiency of *tafazzin* , a mitochondrial protein, encoded by *TAZ* gene. This enzyme is necessary for remodeling of immature cardiolipin into its mature form. *Cardiolipin,* a mitochondrial phospholipid, is critical for the integrity of inner mitochondrial membrane. **Clinical manifestations** of Barth syndrome, which usually occur in the 1st yr of life in a male infant, include cardiomyopathy, hypotonia, growth retardation, hypoglycemia, and mild to severe neutropenia. The onset of clinical manifestations may be as late as adulthood, but most affected individuals become symptomatic by adolescence. If patients survive infancy, relative improvement may occur with advancing age. Cognitive development is usually normal, although delayed motor function and learning disabilities are possible.

Laboratory findings include mild to moderate increases in urinary excretion of 3-methylglutaconic, 3-methylglutaric, and 2-ethylhydracrylic acids. Unlike primary 3-methylglutaconic aciduria (type I), urinary excretion of 3-hydroxyisovaleric acid is not elevated. The activity of the enzyme 3-methylglutaconyl-CoA hydratase is normal. *Neutropenia is a common finding* . Lactic acidosis, hypoglycemia, low serum cholesterol concentration, low prealbumin, and abnormal mitochondrial ultrastructure have been shown in some patients. Total cardiolipin and subclasses of cardiolipin are very low in skin fibroblast cultures from these patients. The monolysocardiolipin/cardiolipin ratio in cultured fibroblast may be useful for establishing the diagnosis in patients with negative or equivocal molecular results. Because of its nonspecific presentation, the condition could be underdiagnosed and underreported.

The condition is inherited as an *X-linked* recessive trait. The gene *(TAZ)* has been mapped to chromosome Xq28. The modest 3-methylglutaconic aciduria seen in Barth syndrome is thought to be related to the defect in mitochondrial membrane, causing the leakage of this organic acid. *Specific treatment is not available*. Patients with an unsatisfactory response to medical management of cardiomyopathy may benefit from cardiac transplantation. Daily aspirin to reduce the risk of strokes has been described.

OPA3 -Related 3-Methylglutaconic Aciduria (Costeff Syndrome)

Clinical manifestations in patients with Costeff syndrome include early-onset optic nerve atrophy and later development of choreoathetoid movements, spasticity, ataxia, dysarthria, and cognitive impairment. Patients excrete moderate amounts of 3-methylglutaconic and 3-methylglutaric acids. Activity of the enzyme 3-methylglutaconyl-CoA hydratase is normal. The condition is inherited as an autosomal recessive trait. The gene for this condition *(OPA3)* is mapped to chromosome 19q13.32. Pathogenic variants in *OPA3* are thought to cause electron transport chain dysfunction. Treatment is supportive.

Disorders Formerly Described as 3-Methylglutaconic Aciduria Type IV

3-Methylglutaconic aciduria type IV represents a group of disorders with diverse genetic etiology. Two disorders in this group have been linked to specific molecular etiology, while other conditions are still awaiting the discovery of their underlying molecular defect.

MEGDEL syndrome (3-*me* thyl*g* lutaconic aciduria with *d* eafness, *e* ncephalopathy and *L* eigh-like) is an autosomal recessive disorder caused by deleterious mutations in *SERAC1* on chromosome 6q25.3. Affected patients experience progressive deafness, dystonia, spasticity and basal ganglia injury similar to patients with Leigh syndrome. Treatment is symptomatic.

***TMEM70* -related disorder** is also inherited in an autosomal recessive fashion. Pathogenic variants in *TMEM70* result in the mitochondrial complex V deficiency, although the exact mechanism of disease is unknown. Clinical manifestations include developmental delay, developmental regression, Reye syndrome–like episodes, intellectual disability, failure to thrive, microcephaly, cardiomyopathy, and dysmorphic findings. Patients are prone to metabolic decompensation, characterized by hyperammonemia (up to 900 µmol/L) and lactic acidosis, which are more common in the 1st yr of life. **Acute hyperammonemic** episodes are treated with intravenous glucose, lipid emulsion, ammonia-scavenging drugs, and occasionally require hemodialysis. Long-term therapy that has been described includes L -carnitine, coenzyme Q_{10} , and bicarbonate substitution (e.g., citric acid/sodium citrate). Patients require interval echocardiographic and electrocardiographic (ECG) monitoring to enable early diagnosis and management of cardiomyopathy.

DCMA Syndrome (*DNAJC19* -Related Syndrome, 3-Methylglutaconic Aciduria Type V)

DCMA syndrome (*d* ilated *c* ardio*m* yopathy with *a* taxia) is a novel autosomal recessive disorder identified in patients of the Canadian Dariusleut Hutterite ancestry living in The Great Plains of North America. As the disorder's abbreviated name suggests, affected individuals present with dilated cardiomyopathy, long QTc interval, and CNS involvement. Neurologic symptoms include intellectual disability, cerebellar involvement, and optic atrophy. Growth is affected in all patients. Intrauterine growth restriction is seen in up to 50% of patients. Cryptorchidism and hypospadias are frequent findings in affected boys. Urine organic acid assay reveals increased 3-methylglutaconic acid and 3-methylglutaric acid. Pathogenic variants in *DNAJC19* (3q26.33) are the underlying cause of DCMA syndrome. Treatment is symptomatic. Interval echocardiography and ECG can prospectively identify patients requiring treatment of cardiomyopathy and long QTc interval.

β-Ketothiolase (3-Oxothiolase) Deficiency (Mitochondrial Acetoacetyl-CoA Thiolase [T_2] Deficiency)

This reversible mitochondrial enzyme is involved in the final steps of isoleucine catabolism and in ketolysis. In the isoleucine catabolic pathway, the enzyme cleaves 2-methylacetoacetyl-CoA into propionyl-CoA and acetyl-CoA (see Fig. 103.4). In the fatty acid oxidation pathway, the enzyme generates 2 moles of acetyl-CoA from 1 mole of acetoacetyl-CoA (Fig. 103.7). The same enzyme synthesizes 2-methyacetoacetate-CoA and acetoacetyl-CoA in the reverse direction. The hallmark of this disorder is **ketoacidosis** , often triggered by infections, prolonged fasting, and large protein load. The mechanism of ketosis in this condition is incompletely understood, because in this enzyme deficiency one expects impaired ketone formation (Fig. 103.7). It is postulated that excess acetoacetyl-CoA produced from other sources can be used as a substrate for 3-hydroxy-3-methylglutaryl-CoA synthesis in the liver.

Enzymes: *(1)* Mitochondrial acetoacetyl CoA thiolase, *(2)* HMG-CoA synthase, *(3)* HMG-CoA lyase, *(4)* cytosolic acetoacetyl-CoA thiolase, *(5)* HMG-CoA reductase, *(6)* mevalonic kinase, *(7)* succinyl CoA:3-ketoacid CoA transferase (SCOT), *(8)* 3-hydroxybutyrate dehydrogenase.

Clinical manifestations are quite variable, ranging from mild cases showing normal development to severe episodes of acidosis starting in the 1st yr of life causing severe cognitive impairment. Unless identified on the newborn screening, affected children present with intermittent episodes of unexplained ketoacidosis. These episodes usually occur after an intercurrent infection and typically respond promptly to intravenous fluids and bicarbonate therapy. Mild to moderate hyperammonemia may also be present during attacks. Both hypoglycemia and hyperglycemia have been reported in isolated cases. The child may be completely asymptomatic between episodes and may tolerate a normal protein diet. Cognitive development is normal in most children. The episodes may be misdiagnosed as salicylate poisoning because of the similarity of the clinical findings and the interference of elevated blood levels of acetoacetate with the colorimetric assay for salicylate.

Laboratory findings during the acute attack include ketoacidosis, and hyperammonemia. Findings of ketones in the urine and hyperglycemia may be interpreted as diabetic ketoacidosis, and the high index of suspicion is needed to identify this metabolic disorder. Urine organic acid assay can provide clues leading to correct diagnosis. Urine contains large amounts of 2-methylacetoacetate and its decarboxylated products butanone, 2-methyl-3-hydroxybutyrate, and tiglylglycine. Lower concentrations of urinary metabolites can be seen when patients are stable. Mild hyperglycinemia may also be present. Plasma acylcarnitine profile show elevations of C5 : 1 and C5-OH carnitines, although these metabolites can normalize in between catabolic episodes. Minimal elevations of C5 : 1 and C5-OH carnitines can result in false-negative results on the newborn screening of affected infants who were clinically well at the time of blood collection. The clinical and biochemical findings should be differentiated from those seen with propionic and methylmalonic acidemias (see later).

Treatment of acute episodes includes hydration. Recalcitrant metabolic acidosis can be severe enough to require infusion of bicarbonate. A 10% glucose solution with the appropriate electrolytes is used to suppress protein catabolism, lipolysis, and ketogenesis. Restriction of protein intake to age-appropriate physiologic requirements is recommended for long-term therapy. Oral L-carnitine (50-100 mg/kg/24 hr) is also recommended to prevent possible secondary carnitine deficiency. Long-term prognosis for achieving normal quality of life seems very favorable. Successful pregnancy with a normal outcome has been reported.

β-Ketothiolase deficiency is inherited as an autosomal recessive trait and may be more prevalent than previously appreciated. The gene *(ACAT1)* for this enzyme is located on chromosome 11q22.3. **Diagnosis** may be confirmed by molecular analysis of the *ACAT1* gene or using enzyme assay of leukocytes or cultured fibroblasts.

Cytosolic Acetoacetyl-CoA Thiolase Deficiency

This enzyme catalyzes the cytosolic production of acetoacetyl-CoA from two moles of acetyl-CoA (see Fig. 103.7). Cytosolic acetoacetyl-CoA is the precursor of hepatic cholesterol synthesis. Cytosolic acetoacetyl-CoA thiolase should be differentiated from the mitochondrial thiolase (see earlier and Fig. 103.4). Clinical manifestations in patients with this very rare enzyme deficiency have been incompletely characterized. Patients may present with severe progressive developmental delay, hypotonia, and choreoathetoid movements in the 1st few months of life. Laboratory findings are nonspecific; elevated levels of lactate, pyruvate, acetoacetate, and 3-hydroxybutyrate may be found in blood and urine. One patient had normal levels of acetoacetate and 3-hydroxybutyrate. Diagnosis can be aided by demonstrating a deficiency in cytosolic thiolase activity in liver biopsy or in cultured fibroblasts or by DNA analysis. No effective treatment has been described, although a low-fat diet helped to diminish ketosis in one patient.

Mitochondrial 3-Hydroxy-3-Methylglutaryl-CoA Synthase Deficiency

This enzyme catalyzes synthesis of 3-hydroxy-3-methylglutaryl (HMG)-CoA from acetoacetyl-CoA and acetyl-CoA in the mitochondria. This is a critical step in ketone body synthesis in the liver (see Fig. 103.7). A few patients with deficiency of this enzyme have been reported. The principal clinical syndrome is hypoketotic hypoglycemia triggered by physiologic stress, such as infections or fasting. Age at presentation has ranged from infancy to 6 yr. Children tend to be asymptomatic before these episodes and with appropriate management can remain stable after the recovery (except for mild hepatomegaly with fatty infiltration). Future episodes can be prevented by avoiding prolonged fasting during ensuing intercurrent illnesses. Hepatomegaly is a consistent physical finding in these patients. **Laboratory findings** include hypoglycemia, acidosis with mild or no ketosis, elevated levels in liver function tests, and massive dicarboxylic aciduria. The clinical and laboratory findings may be confused with fatty acid metabolism defects (see Chapter 104.1). In contrast to the latter, in patients with HMG-CoA synthase deficiency the blood concentrations of acylcarnitine conjugates are negative for acylcarnitine findings characteristic of fatty acid oxidation disorders. Treatment of the secondary carnitine deficiency with L -carnitine supplementation can result in elevated plasma acetylcarnitine (C2-carnitine), likely reflecting intracellular accumulation of acetyl-CoA. A controlled fasting study can produce the clinical and biochemical abnormalities.

Treatment consists of provision of adequate calories and avoidance of prolonged periods of fasting. No dietary protein restriction was needed.

The condition is inherited as an autosomal recessive trait. The gene *(HMGCS2)* for this enzyme is located on chromosome 1p12. The condition should be considered in any child with fasting hypoketotic hypoglycemia and may be more common than appreciated.

3-Hydroxy-3-Methylglutaryl-CoA Lyase Deficiency (3-Hydroxy-3-Methylglutaric Aciduria)

3-HMG-CoA lyase (see Fig. 103.4) catalyzes the conversion of 3-HMG-CoA to acetoacetate and is a rate-limiting enzyme for ketogenesis (see Fig. 103.7). The deficiency of this enzyme is a rare disorder seen with increased frequency in Saudi Arabia, the Iberian Peninsula, and in Brazil in patients of Portuguese ancestry. Clinically, approximately 30% develop symptoms in the 1st few days of life, and >60% of patients become symptomatic between 3 and 11 mo of age. Infrequently, patients may remain asymptomatic until adolescence. With the addition of 3-HMG-CoA lyase deficiency to the newborn screening using C5-OH-carnitine, many infants are identified presymptomatically in the newborn period. Similar to 3-HMG-CoA synthase deficiency, patients affected by 3-HMG-CoA lyase deficiency may present with acute hypoketotic hypoglycemia. Episodes of vomiting, severe hypoglycemia, hypotonia, acidosis with mild or no ketosis, and dehydration may rapidly lead to lethargy, ataxia, and coma. These episodes often occur during a catabolic state such as prolonged fasting or an intercurrent infection. Hepatomegaly is common. These manifestations may be mistaken for Reye syndrome or fatty acid oxidation defects such as medium-chain acyl-CoA dehydrogenase deficiency. Long-term complications can include dilated cardiomyopathy, hepatic steatosis, and pancreatitis. Development can be normal, but intellectual disability and seizures with abnormalities in the white matter seen on MRI have been observed in patients after prolonged episodes of hypoglycemia.

Laboratory findings include hypoglycemia, moderate to severe hyperammonemia, and acidosis. There is mild or no ketosis (see Fig. 103.7). Urinary excretion of 3-hydroxy-3-methylglutaric acid and other proximal intermediate metabolites of leucine catabolism (3-methylglutaric acid, 3-methylglutaconic acid, and 3-hydroxyisovaleric acid) is markedly increased, causing the urine to smell like *cat urine* . Glutaric and dicarboxylic acids may also be increased in urine during acute attacks. Secondary carnitine deficiency is common. The condition is inherited as an autosomal recessive trait. 3-HMG-CoA lyase is encoded by gene *HMGCL* . **Diagnosis** may be confirmed by molecular analysis of *HMGCL* or by enzyme assay in cultured fibroblasts, leukocytes, or liver specimens. Prenatal diagnosis is possible by molecular DNA analysis if the familial pathogenic variants are known or by enzymatic assay of the cultured amniocytes or a chorionic villi biopsy.

Treatment of acute episodes includes hydration, infusion of glucose to control hypoglycemia, provision of adequate calories, and administration of bicarbonate to correct acidosis. Hyperammonemia should be treated promptly (see Chapter 103.12). Renal replacement therapy may be required in patients with severe recalcitrant hyperammonemia. Restriction of protein and fat intake is recommended for long-term management. Oral administration of L -carnitine (50-100 mg/kg/24 hr) prevents secondary carnitine deficiency. Prolonged fasting should be avoided.

Succinyl-CoA:3-Oxoacid-CoA Transferase Deficiency

Succinyl-CoA:3-oxoacid-CoA transferase (**SCOT**) deficiency and β-ketothiolase deficiency collectively are referred to as **ketone utilization disorders.** SCOT participates in the conversion of ketone bodies (acetoacetate and 3-hydroxybutyrate) generated in liver mitochondria into *acetoacetyl-CoA in* *the nonhepatic tissues* (see Fig. 103.7). A deficiency of this enzyme results in the accumulation of ketone bodies, ketoacidosis, increased utilization of glucose, and hypoglycemia. During fasting, patients tend to have a proportional elevation of plasma free fatty acids. More than 30 patients with SCOT deficiency have been reported to date. The condition may not be rare because many cases may be mild and may remain undiagnosed. SCOT deficiency can be distinguished from β-ketothiolase deficiency by the absence of 2-methylacetoacetate, 2-methyl-3-hydroxybutyrate, and tiglylglycine, characteristic of the latter disorder. Plasma acylcarnitine profile tends to show no specific abnormalities.

A common clinical presentation is an acute episode of severe ketoacidosis in an infant who had been growing and developing normally. About half the patients become symptomatic in the 1st wk of life, and practically all become symptomatic before 2 yr of age. The acute episode is often precipitated by a catabolic state triggered by an infection or prolonged fasting. Without treatment, the ketoacidotic episode can result in death. A chronic subclinical ketosis may persist between the attacks. Development is usually normal, although severe and recurrent episodes of ketoacidosis and hypoglycemia can predispose patients to neurocognitive impairment.

Laboratory findings during the acute episode are nonspecific and include metabolic acidosis and ketonuria with high levels of acetoacetate and 3-hydroxybutyrate in blood and urine. No other organic acids are found in the blood or in the urine. Blood glucose levels are usually normal, but hypoglycemia has been reported in some affected newborn infants with severe ketoacidosis. Plasma amino acids and plasma acylcarnitine profile are usually normal. Severe SCOT deficiency can be accompanied by ketosis even when patients are clinically stable. This condition should be considered in any infant with unexplained bouts of ketoacidosis. **Diagnosis** can be established by molecular analysis of *OXCT1* or by demonstrating a deficiency of enzyme activity in cultured fibroblasts. The condition is inherited as an autosomal recessive trait.

Treatment of acute episodes consists of rehydration with solutions containing dextrose, correction of acidosis, and the provision of a diet adequate in calories. Long-term treatment should include high-carbohydrate diet and avoidance of prolonged fasting and administration of dextrose before anticipated or during established catabolic states.

Mevalonate Kinase Deficiency

Mevalonic acid, an intermediate metabolite of cholesterol synthesis, is converted to 5-phosphomevalonic acid by the action of the enzyme mevalonate kinase (MVK) (see Fig. 103.7). Based on clinical manifestations and degree of enzyme deficiency, 2 conditions have been recognized: mevalonic aciduria and hyperimmunoglobulinemia D syndrome. Both disorders are accompanied by recurrent fever, gastrointestinal symptoms, mucocutaneous manifestations, and lymphadenopathy. Patients with mevalonic aciduria also show growth retardation and nervous system involvement. In practice, the 2 disorders represent the 2 ends of the spectrum.

Mevalonic Aciduria

Clinical manifestations include failure to thrive, growth retardation, intellectual disability, hypotonia, ataxia, myopathy, hepatosplenomegaly, cataracts, and facial dysmorphisms (dolichocephaly, frontal bossing, low-set ears, downward slanting of eyes, long eyelashes). Most patients experience recurrent crises characterized by fever, vomiting, diarrhea, hepatosplenomegaly, arthralgia, lymphadenopathy, edema, and morbilliform rash. These episodes typically last 2-7 days and recur up to 25 times a year. Death may occur during these crises.

Laboratory findings include marked elevation of mevalonic acid in urine; the concentration of urinary mevalonic acid ranges between 500 and 56,000 mmol/mol of creatinine (normal: <0.3 mmol/mol of creatinine). Plasma levels of mevalonic acid are also greatly increased (as high as 540 µmol/L; normal: <0.04 µmol/L). Mevalonic acid levels tend to correlate with the severity of the condition and increase during crises. Serum cholesterol concentration is normal or mildly decreased. Serum concentration of creatine kinase can be greatly increased. Inflammatory markers are elevated during the crises. Brain MRI may reveal progressive atrophy of the cerebellum.

Diagnosis may be confirmed by DNA analysis or by assaying the MVK activity in lymphocytes or cultured fibroblasts. The enzyme activity in this form of the condition is below the detection level. **Treatment** with high doses of prednisone helps in the acute crises, but due to side effects, it is not routinely used long term. *Etanercept* (tumor necrosis factor inhibitor) and *anakinra* (interleukin-1 receptor antagonist) have shown to be effective in bringing significant clinical improvement. The condition is inherited as an autosomal recessive trait. **Prenatal diagnosis** is possible by identifying known familiar pathogenic variants in *MVK*, by measurement of mevalonic acid in the amniotic fluid, or by assaying the enzyme activity in cultured amniocytes or chorionic villi samples. The gene (*MVK*) for the enzyme is on chromosome 12q24.11.

Hyperimmunoglobulinemia D Syndrome (Hyperimmunoglobulinemia D and Periodic Fever Syndrome)

Some pathogenic variants of mevalonic kinase gene *(MVK)* cause milder enzyme deficiency and produce the clinical picture of periodic fever with hyperimmunoglobulinemia D. These patients have periodic bouts of fever associated with abdominal pain, vomiting, diarrhea, arthralgia, arthritis, hepatosplenomegaly, lymphadenopathy, and morbilliform rash (even petechiae and purpura), which usually start before 1 yr of age. The attacks can be triggered by vaccination, minor trauma, or stress and can occur every 1-2 mo, lasting 2-7 days. Patients are free of symptoms between acute attacks. The diagnostic laboratory finding is elevation of serum immunoglobulin D (IgD). IgA is also elevated in 80% of patients. During acute attacks, leukocytosis, increased C-reactive protein, and mild mevalonic aciduria may be present. High concentrations of serum IgD help differentiate this condition from familial Mediterranean fever. See Chapter 188 for treatment recommendations.

Propionic Acidemia (Propionyl-CoA Carboxylase Deficiency)

Propionic acid is an intermediate metabolite of isoleucine, valine, threonine, methionine, odd-chain fatty acids, and side chains of cholesterol. Normally, propionic acid in the form of propionyl-CoA undergoes carboxylation to D -methylmalonyl-CoA, catalyzed by the mitochondrial enzyme propionyl-CoA carboxylase. This enzyme requires biotin as a cofactor; thus the disorders of biotin metabolism, among other findings, can also result in elevation of propionic acid metabolites (see Fig. 103.4). Propionyl-CoA carboxylase is a multimeric enzyme composed of 2 nonidentical subunits, α and β, encoded by 2 genes, *PCCA* and *PCCB* , respectively. Pathogenic variants in propionyl-CoA carboxylase result in the disorder called propionic acidemia.

Clinical findings of propionic acidemia are not specific to this disorder only.

In the severe form, patients develop symptoms in the 1st few days of life. Poor feeding, vomiting, hypotonia, lethargy, dehydration, a sepsis-like picture, and clinical signs of severe ketoacidosis progress rapidly to coma and death. Seizures occur in approximately 30% of affected infants. If an infant survives the first attack, similar episodes of metabolic decompensation may occur during an intercurrent infection, trauma, surgery, prolonged fasting, severe constipation, or after ingestion of a high-protein diet. Moderate to severe intellectual disability and neurologic manifestations reflective of extrapyramidal (dystonia, choreoathetosis, tremor) and pyramidal (paraplegia) dysfunction are common sequelae in the survivors. Neuroimaging shows that these abnormalities, which often occur after an episode of metabolic decompensation, are the result of damage to the basal ganglia, especially to the globus pallidus. This phenomenon has been referred to as **metabolic stroke** . This is the main cause of neurologic sequelae seen in the surviving affected children. Additional long-term complications include failure to thrive, optic nerve atrophy, pancreatitis, cardiomyopathy, and osteopenia.

In the *milder* form, episodes of metabolic decompensation are less frequent, but these children are still at risk to develop intellectual disability, seizures, long QTc interval, and severe cardiomyopathy. Universal newborn screening can identify propionic acidemia by detecting elevated propionylcarnitine (C3) in dried blood spots. However, in patients with the mild form of propionic acidemia, propionylcarnitine could remain below the cutoff value set by the screening laboratory, resulting in a false-negative result. Therefore, physicians should maintain a high index of suspicion for this disorder and follow up with a biochemical evaluation of infants and children presenting with unexplained ketosis or metabolic acidosis.

Laboratory findings during the acute attack include various degrees of metabolic acidosis, often with a large anion gap, ketosis, ketonuria, hypoglycemia, anemia, neutropenia, and thrombocytopenia. Moderate to severe hyperammonemia is common; plasma ammonia concentrations usually correlate with the severity of the disease. In contrast to other causes of hyperammonemia, plasma concentration of glutamine tends to be within normal limits or decreased. Presence of severe metabolic acidosis and normal to reduced plasma glutamine help differentiate propionic academia from hyperammonemia caused by urea cycle defects. Measurement of plasma ammonia is especially helpful in planning therapeutic strategy during episodes of exacerbation in a patient whose diagnosis has been established. Mechanisms of hyperammonemia in propionic acidemia are not well understood but are likely related to the perturbed biochemical and pH environment of the mitochondrial matrix, where the proximal part of urea cycle resides. **Glycine** concentration can be elevated in all body fluids (blood, urine, CSF) and possibly are the result of the inhibited glycine cleavage system in the hepatic mitochondria (Fig. 103.8). Glycine elevation has also been observed in patients with methylmalonic acidemia. These disorders were collectively referred to as *ketotic hyperglycinemia* in the past before the specific enzyme deficiencies were elucidated. Mild to moderate increase in blood lactate and lysine may also be present in these patients. Concentrations of propionylcarnitine, 3-hydroxypropionic acid, and methylcitric acid (presumably formed through condensation of propionyl-CoA with oxaloacetic acid) are greatly elevated in the plasma and urine of infants with propionic acidemia. Propionylglycine and other intermediate metabolites of branched-chain amino acid catabolism, such as tiglylglycine, can also be found in urine. Moderate elevations in blood levels of glycine, and previously mentioned organic acids can persist between the acute attacks. Brain imaging may reveal cerebral atrophy, delayed myelination, and abnormalities in the globus pallidus and other parts of the basal ganglia.

NE, Nonenzymatic; NKH, nonketotic hyperglycinemia.

The **diagnosis** of propionic acidemia should be differentiated from multiple carboxylase deficiencies (see earlier and Fig. 103.6). In addition to propionic acid metabolites, infants with the latter condition excrete large amounts of lactic acid, 3-methylcrotonylglycine, and 3-hydroxyisovaleric acid. The presence of hyperammonemia may suggest a genetic defect in the urea cycle enzymes. Infants with defects in the urea cycle are usually *not* acidotic (see Fig. 103.1) and have elevated levels of plasma glutamine. The definitive diagnosis of propionic acidemia can be established through molecular analysis of *PCCA* and *PCCB* or by measuring the enzyme activity in leukocytes or cultured fibroblasts.

Treatment of acute episodes of metabolic decompensation includes hydration with solutions containing glucose, correction of acidosis, and amelioration of the catabolic state by provision of adequate calories through enteral or parenteral hyperalimentation. A brief restriction of protein intake, no more than 24 hr, is often necessary. Depending on the clinical status, gradual reintroduction of protein is recommended. If enteral feedings cannot be tolerated after 48 hours of protein restriction, parenteral nutrition should be instituted to achieve the age-specific recommended dietary protein intake. Patients unable to tolerate the recommended dietary allowance of protein can receive specialized medical foods free of isoleucine, valine, threonine, and methionine. The composition and the amount of protein vary among patients. The metabolic diet composition can be adjusted by monitoring growth and plasma amino acids drawn 3-4 hr after the typical feeding. Some patients may benefit from the suppression of propionogenic gut microflora. This can be achieved by oral antibiotics such as oral neomycin or metronidazole. Prolonged use of metronidazole should be avoided because it has been associated with reversible peripheral neuropathy and increased QTc interval. The risk of QTc prolongation can be problematic in propionic acidemia patients, who are at risk for cardiomyopathy and long QT interval. Baseline and interval electrocardiograms (ECGs) are recommended before and after initiation of the metronidazole therapy. Patients may benefit from management of constipation.

Patients with propionic acidemia often develop secondary carnitine deficiency, presumably as a result of the urinary loss of propionylcarnitine. Administration of L -carnitine (50-100 mg/kg/24 hr orally or intravenously) helps restore free carnitine in blood. In patients with concomitant hyperammonemia, measures to reduce blood ammonia should be employed (see Chapter 103.12). Very ill patients with severe acidosis and hyperammonemia require hemodialysis to remove ammonia and other toxic compounds rapidly and efficiently. *N* -carbamoylglutamate (carglumic acid) and nitrogen scavengers (sodium benzoate, sodium phenylacetate, sodium phenylbutyrate) can aid in the treatment of acute hyperammonemia. Although no infant with propionic acidemia has been found to be responsive to biotin, this compound should be administered (10 mg/24 hr orally) to all infants during the first attack and until the diagnosis is established and multiple carboxylase deficiency ruled out.

Long-term treatment consists of a low-protein diet meeting age-specific recommended dietary allowance and administration of L -carnitine (50-100 mg/kg/24 hr orally). Some centers manage mild cases of propionic acidemia without medical foods, opting for only restricting the protein intake to recommended dietary allowance. Patients unable to tolerate the recommended dietary intake of protein may require medical foods free of propionate precursors (isoleucine, valine, methionine, and threonine). Excessive use of medical foods while restricting natural-source protein may cause a deficiency of the essential amino acids, especially isoleucine and valine, which may cause a condition resembling **acrodermatitis enteropathica** (see Chapter 691). Overrestriction of methionine, especially in the 1st years of life, may contribute to the reduced brain growth and microcephaly. To avoid this problem, natural proteins should comprise most of the dietary protein. Some patients may require bicarbonate substitution (e.g., citric acid/sodium citrate) to correct chronic acidosis. The concentration of plasma ammonia usually normalizes between attacks, although some patients may experience mild chronic hyperammonemia. Acute attacks triggered by infections, fasting, trauma, stress, constipation, or dietary indiscretions should be treated promptly and aggressively. Close monitoring of plasma ammonia, plasma amino acids obtained 3-4 hr after the last typical meal (especially isoleucine, leucine, valine, threonine, and methionine), and growth parameters is necessary to ensure the diet is appropriate. Orthotopic liver transplantation is used in clinically unstable patients experiencing recurrent hyperammonemia, frequent metabolic decompensations, and poor growth. Liver transplantation does not cure propionic acidemia, and lifelong dietary management and proactive management during periods of significant metabolic stress are recommended.

Long-term **prognosis** is guarded. Death may occur during an acute attack. Normal psychomotor development is possible in the mild form identified through newborn screening. Children identified clinically may manifest some degree of permanent neurodevelopmental deficit, such as tremor, dystonia, chorea, and spasticity despite adequate therapy. These neurologic findings may be the sequelae of a metabolic stroke occurring during an acute decompensation. Long QTc interval as well as cardiomyopathy with potential progression to heart failure, fatal arrhythmias, and death may develop in older affected children despite adequate metabolic control. Acute pancreatitis is a common and severe complication in propionic acidemia. Osteoporosis can predispose to fractures, which can occur even after minimal mechanical stress.

Prenatal diagnosis can be achieved by identification of the known familial pathogenic variants in *PCCA* or *PCCB* or by measuring the enzyme activity in cultured amniotic cells or in samples of uncultured chorionic villi.

Propionic acidemia is inherited as an autosomal recessive trait and has a worldwide prevalence of 1 : 105,000 to 1 : 250,000 live births. It is more prevalent in Greenlandic Inuits (1 : 1,000) and in some Saudi Arabian tribes (1 :

2,000 to 1 : 5,000 live births). The gene for the α-subunit *(PCCA)* is located on chromosome 13q32.3 and that of the β-subunit *(PCCB)* is mapped to chromosome 3q22.3. Pathogenic variants in either gene result in similar clinical and biochemical manifestations. Although pregnancies with normal outcomes have been reported, the perinatal period poses special risks to females with propionic acidemia because of hyperemesis gravidarum, worsening cardiomyopathy, changing protein requirements, and risk of metabolic decompensation.

Isolated Methylmalonic Acidemias

Methylmalonic acidemias are a group of metabolic disorders of diverse etiology characterized by impaired conversion of methylmalonyl-CoA into succinyl-CoA. Propionyl-CoA derived from catabolism of isoleucine, valine, threonine, methionine, side chain of cholesterol, and odd-chain fatty acids is catalyzed by propionyl-CoA carboxylase to form D -methylmalonyl-CoA. Methylmalonyl-CoA epimerase then converts D -methylmalonyl-CoA to its enantiomer L -methylmalonyl-CoA. **Methylmalonyl-CoA epimerase deficiency** is a rare disorder associated with persistent elevations of propionate-related metabolites and methylmalonic acid. It may present with metabolic acidosis, ketosis, but known patients appear more clinically stable than those with severe forms of methylmalonic acidemia.

In the next biochemical step, L -methylmalonyl-CoA is converted to succinyl-CoA by methylmalonyl-CoA mutase (see Fig. 103.4). The latter enzyme requires adenosylcobalamin, a metabolite of vitamin B_{12} , as a coenzyme. Deficiency of either the mutase or its coenzyme results in the accumulation of methylmalonic acid and its precursors in body fluids. Two biochemical forms of methylmalonyl-CoA mutase deficiencies have been identified. These are designated mut^0 , referring to no detectable enzyme activity, and mut^- , indicating residual, although insufficient, mutase activity. Patients with methylmalonic acidemia due to deficiency of the mutase apoenzyme (mut^0) are not responsive to hydroxocobalamin therapy.

In the remaining methylmalonic acidemia patients, the defect resides in the formation of adenosylcobalamin from dietary vitamin B_{12} . The absorption of dietary vitamin B_{12} in the terminal ileum requires *intrinsic factor,* a glycoprotein secreted by the gastric parietal cells. It is transported in the blood by haptocorrin and transcobalamin II. The transcobalamin II–cobalamin complex (TCII-Cbl) is recognized by a specific receptor on the cell membrane (transcobalamin receptor encoded by *CD320*) and enters the cell by endocytosis. In the lysosome, TCII-Cbl is hydrolyzed, and, with the participation of LMBRD1 (*cbl* F) and ABCD4 (*cbl* J), free cobalamin is released into the cytosol (see Fig. 103.4). Pathogenic variants in either *LMBRD1* or *ABCD4* genes result in impaired release of cobalamin from lysosomes. In the cytoplasm, cobalamin binds to the MMACHC protein (see *cbl* C later), which removes a moiety attached to cobalt in the cobalamin molecule and reduces the cobalt from oxidation state +3 (cob[III]alamin) to +2 (cob[II]alamin). It then enters the mitochondria, where it is catalyzed by MMAB (*cbl* B) and MMAA (*cbl* A) to form adenosylcobalamin, a coenzyme for methylmalonyl-CoA mutase. The other arm of the pathway directs cytosolic cobalamin toward methionine synthase reductase (*cbl* E), which forms methylcobalamin, acting as a coenzyme for methionine synthase (*cbl* G, see Fig. 103.3). The MMADHC protein (see *cbl* D) appears to play a role in determining whether cobalamin enters the mitochondria or remains in the cytoplasm.

The uptake of TCII-Cbl by cells is impaired in individuals with pathogenic variants affecting transcobalamin receptor *(CD320)*, which is located on the cell surface. Individuals homozygous for pathogenic variants in the *CD320* gene encoding the transcobalamin receptor may have mild elevations of methylmalonic acid in blood and urine. These patients can be identified by the newborn screen based on the elevated propionylcarnitine (C3). In **transcobalamin receptor deficiency** , methylmalonic acid levels and plasma propionylcarnitine tend to normalize in the 1st yr of life. It is not clear whether there is a long-term clinical phenotype associated with this defect.

Nine different defects in the intracellular metabolism of cobalamin have been identified. These are designated *cbl* A through *cbl* G, *cbl* J, and *cbl* X, where *cbl* stands for a defect in any step of cobalamin metabolism. The *cbl* A, *cbl* B, and *cbl* D variant 2 defects cause methylmalonic acidemia *alone* . In patients with *cbl* C, classic *cbl* D, *cbl* F, *cbl* J, and *cbl* X defects, synthesis of both adenosylcobalamin and methylcobalamin is impaired, resulting in *combined* methylmalonic acidemia and homocystinuria. The *cbl* D variant 1, *cbl* E, and the *cbl* G defects affect only the synthesis of methylcobalamin, resulting in homocystinuria without methylmalonic aciduria (see Chapter 103.3).

Biochemical manifestations of patients with isolated methylmalonic acidemia caused by *mut* ^{0} , *mut* $^{-}$, *cbl* A, *cbl* B, and *cblD* variant 2 overlap. The wide variations in severity of clinical course range from very sick newborn infants to apparently asymptomatic adults. In **severe** forms, lethargy, feeding problems, vomiting, a sepsis-like picture, tachypnea (from metabolic ketoacidosis), and hypotonia may develop in the 1st few days of life and may progress to hyperammonemic encephalopathy, coma, and death if left untreated. Infants who survive the first attack may go on to develop similar acute metabolic episodes during a catabolic state such as infection or prolonged fasting or after ingestion of a high-protein diet. In certain situations, such acute events can cause a sudden injury of the basal ganglia (movement centers in CNS), a metabolic stroke, resulting in a debilitating movement disorder. Between the acute attacks, the patient usually continues to exhibit hypotonia and feeding problems with failure to thrive, while other complications of the disease occur with age, including recurrent episodes of pancreatitis, bone marrow suppression, osteopenia, and optic nerve atrophy. Chronic renal failure and tubulointerstitial nephritis necessitating renal transplant have been reported in older patients. Renal complications are more severe in patients with the *mut* ^{0} and severe *cbl* B forms of methylmalonic acidemia. In milder forms, patients may present later in life with hypotonia, failure to thrive, and developmental delay. Neurocognitive development of patients with mild methylmalonic acidemia may remain within the normal range.

The episodic nature of the condition and its biochemical abnormalities in some patients may be confused with those of *ethylene glycol* (antifreeze) ingestion. The peak of propionate in a blood sample from an infant with methylmalonic acidemia has been mistaken for ethylene glycol when the sample was assayed by gas chromatography without mass spectrometry.

Laboratory findings include ketosis, metabolic acidosis, hyperglycinemia, hyperammonemia, hypoglycemia, anemia, neutropenia, thrombocytopenia, and the presence of large quantities of methylmalonic acid in body fluids (see Fig. 103.6). Metabolites of propionic acid (3-hydroxypropionate and methylcitrate) are also found in the urine. Plasma acylcarnitine profile reveals elevated propionylcarnitine (C3) and methylmalonylcarnitine (C4DC). Hyperammonemia in methylmalonic acidemia may be confused with a urea cycle disorder. However, patients with defects in urea cycle enzymes are typically not acidotic and tend to have high plasma glutamine (see Fig. 103.12). The reason for hyperammonemia is not well understood, but it is likely related to the inhibition of proximal urea cycle in the mitochondrial matrix.

Diagnosis can be confirmed by identifying pathogenic variants in the causal gene, by measuring propionate incorporation with complementation analysis in cultured fibroblasts, and by measuring the specific activity of the mutase enzyme in biopsies or cell extracts.

Treatment of acute attacks is similar to propionic acidemia. Long-term treatment consists of administration of a low-protein diet limited to the recommended dietary allowance, L -carnitine (50-100 mg/kg/24 hr orally). Patients with severe forms of methylmalonic acidemia may require protein diet modifications similar to those prescribed for patients with propionic acidemia. Patients with isolated methylmalonic acidemia caused by defects in the intracellular metabolism of cobalamin (*cbl* A, *cblD* variant 2, and some patients with *cbl* B) respond to parenteral hydroxocobalamin. Chronic bicarbonate replacement therapy is usually required to correct chronic acidosis. Plasma ammonia tends to normalize between the attacks, and chronic treatment of hyperammonemia is rarely needed. Stressful situations that may trigger acute attacks (infection, prolonged fasting, trauma, surgeries, high-protein meals) should be treated promptly.

Inadequate oral intake secondary to poor appetite, protein overrestriction, or essential amino acid deficiencies are common complications in long-term management of these patients. Consequently, enteral feeding through gastrostomy is often recommended early in the course of treatment. Close monitoring of blood pH, essential amino acid levels, blood and urinary concentrations of methylmalonate, and growth parameters is required to ensure the nutritional prescription meets patient's metabolic demands. In addition, frequent monitoring of kidney function, vision, hearing, and bone mineral density are necessary for early recognition and management of chronic complications. Glutathione deficiency responsive to treatment with ascorbate has been described.

Liver, kidney, and combined liver-kidney transplantations have been attempted in an increasing number of affected patients. Liver and liver-kidney transplantation can alleviate but not eliminate the metabolic abnormalities. Liver and liver-kidney transplants do not provide complete protection against the occurrence of metabolic stroke. Kidney transplantation alone can restore the renal function but results in only minor improvement of the clinical stability of patients.

Prognosis depends on the severity of symptoms and the occurrence of complications. In general, patients with complete deficiency of mutase apoenzyme (*mut* ^{0}) and severe forms of *cbl* B deficiency have the least favorable prognosis, and those with *mut*$^{-}$ and *cbl* A defects have a better outcome.

Methylmalonic acidemia can be identified on the universal newborn screening by measuring propionylcarnitine (C3) using tandem mass spectrometry. The prevalence of all forms of methylmalonic aciduria is estimated at 1 : 50,000 to 1 : 100,000 live births. All defects causing isolated methylmalonic acidemia are inherited as autosomal recessive traits. The gene for the mutase *(MUT)* is on the short arm of chromosome 6p12.3. Neonates with methylmalonic acidemia and severe diabetes caused by β-cell agenesis, who have paternal uniparental isodisomy of chromosome 6, have been reported. Pathogenic variants in the genes for *cbl* A (*MMAA,* on chromosome 4q31.21), *cbl* B (*MMAB,* on chromosome 12q24.11), and all forms of *cbl* D (*MMADHC,* on chromosome 2q23.2) have been identified in affected patients. The previously described *cbl* H group is identical to *cbl* D variant 2.

Combined Methylmalonic Aciduria and Homocystinuria (*cbl* C, *cbl* D, *cbl* F, *cbl* J, and *cbl* X Defects)

Combined methylmalonic acidemia and homocystinuria caused by *cbl* C deficiency is the most common type of intracellular cobalamin (vitamin B_{12}) biosynthesis defects. Deficiency of *cbl* C is as common as methylmalonyl-CoA mutase deficiency. The other disorders (*cbl* D, *cbl* F, *cbl* J, *cbl* X) are much rarer (see Figs. 103.3 and 103.4). Neurologic findings are prominent in patients with *cbl* C, *cbl* D and *cbl* X defects. Most patients with the *cbl* C defect present in the 1st mo of life because of failure to thrive, lethargy, poor feeding, developmental delay, nystagmus and seizures. Hyperammonemia may be seen infrequently, while hyperglycinemia is not present, unlike in isolated *mut* -type methylmalonic acidemia. Intrauterine growth restriction and microcephaly suggest that *cbl* C can manifest prenatally in some affected infants. Late-onset patients with sudden development of dementia and myelopathy have been reported, even with presentation in adulthood. Megaloblastic anemia is a common finding in patients with *cbl* C defect. Mild to moderate increases in concentrations of methylmalonic acid and significant elevations in total plasma homocysteine are found in blood. Unlike classic homocystinuria, in untreated *cbl* C patients plasma methionine is low to normal. Retinal abnormalities (e.g., bull's eye maculopathy) resulting in severe progressive vision loss are common and can be seen as early as 3 mo of age, even in prospectively identified and well-treated patients. **Thrombotic microangiopathy** can present as hemolytic uremic syndrome, pulmonary hypertension, and cor pulmonale. Hydrocephalus, and non-compaction cardiomyopathy have been reported as complications in patients with *cbl* C defect.

Similar to *cblC* patients, males with *cbl* X have elevations of both total plasma homocysteine and methylmalonic acid, but they tend to have milder elevations of these metabolites. Unlike *cbl* C-deficient patients, who tend to respond to treatment, *cbl* X-deficient patients experience failure to thrive, severe developmental delay, and intractable epilepsy despite aggressive treatment.

Clinical findings in *cbl* F deficiency are quite variable. Patients may present with poor feeding, growth and developmental delay, and persistent stomatitis manifesting in the 1st mo of life. Delay in diagnosis and treatment can be accompanied by hyperpigmentation of skin, developmental delay, intellectual disability, and short stature. Vitamin B_{12} malabsorption and low plasma vitamin B_{12} has been noted in patients with *cbl* F defect. Clinical manifestations of *cbl* J defect show significant overlap with those of the *cbl* F deficiency. Dysmorphic features and congenital heart disease have been reported in some patients with *cbl* F and *cbl* J defects.

Experience with **treatment** of patients with *cbl* C, *cbl* D, *cbl* F, *cblJ,* and *cbl* X defects is limited. Large doses of hydroxocobalamin (up to 0.3 mg/kg/day) in conjunction with betaine (up to 250 mg/kg/day) produce biochemical improvement with variable clinical effect. Patients with *cbl* F and *cbl* J deficiency typically show favorable biochemical and clinical response to smaller hydroxocobalamin doses (1 mg once weekly to 1 mg daily parenterally). Folic or folinic acid supplementation is recommended. Dietary methionine deficiency should be avoided.

The *cbl* C disorder is caused by pathogenic variants in the *MMACHC* gene (on chromosome 1p34.1). A frameshift variant (c.271dupA) is seen in up to 40% of *MMACHC* alleles and is associated with a less favorable clinical outcome. The *cbl* D disorder is caused by pathogenic variants in the *MMADHC* gene (on chromosome 2q23.2). Pathogenic variants resulting in *cbl* D variant 1 (causing only homocystinuria) affect the C-terminal domain of the gene product; those resulting in *cbl* D variant 2 (causing only methylmalonic aciduria) affect the N-terminus. Patients with classic *cbl* D, with both homocystinuria and methylmalonic acidemia, have pathogenic variants resulting in decreased protein expression. The *cbl* F disorder is caused by pathogenic variants in the *LMBRD1* gene (on chromosome 6q13) encoding a lysosomal membrane protein. The *cbl* J disorder is associated with pathogenic variants in the *ABCD4* gene (on chromosome 14q24.3), encoding an adenosine triphosphate–binding cassette protein localized to the lysosomal membrane. The *cbl* X disorder is caused by pathogenic variants in the *HCFC1* gene on the X chromosome (Xq28), which encodes a transcription factor that appears to be essential for expression of the *MMACHC* gene. This is the only X-linked disorder in the B_{12} intracellular metabolism pathway.

Isolated Homocystinuria

Patients with *cbl* D variant 1, *cbl* E, and *cbl* G deficiency present with isolated homocystinuria without methylmalonic acidemia (see Chapter 103.3 , Homocystinuria Caused by Defects in Methylcobalamin Formation).

Combined Malonic and Methylmalonic Aciduria (*ACSF3* -Related Disorder)

C ombined *m* alonic and *m* ethyl*m* alonic *a* ciduria (**CMAMMA**) is a rare autosomal recessive disorder resulting from pathogenic variants in *ACSF3* . ACSF3 is a putative acyl-CoA synthetase required for the conversion of malonic and methylmalonic acids to their CoA derivatives in the mitochondrial matrix. The disorder can be suspected based on the presence of elevated malonic and methylmalonic acids in urine and plasma. It is distinguished from malonyl-CoA decarboxylase, because methylmalonic acid is about 5-fold greater than malonic acid in the urine. Plasma propionylcarnitine (C3-carnitine) in CMAMMA patients is normal, so universal newborn screening programs using C3-carnitine in blood spots to screen for methylmalonic acidemia would not detect this condition. The clinical phenotype is incompletely understood. Young patients identified prospectively in infancy through urine-based newborn screening were reported to be asymptomatic, but the long-term outcome in this cohort awaits further characterization. Older patients ascertained clinically have highly variable presentations, including metabolic crises, failure to thrive, seizures, memory problems, optic nerve or spinal cord atrophy, and progressive neurodegeneration. Treatment of CMAMMA is supportive and includes avoidance of an excessively high-protein diet. Vitamin B_{12} supplementation does not appear to lower malonic and methylmalonic metabolites in body fluids.

103.7

Glycine

Oleg A. Shchelochkov, Charles P. Venditti

Glycine is a nonessential amino acid synthesized mainly from serine and threonine. Structurally, it is the simplest amino acid. Glycine is involved in many reactions in the body, especially in the nervous system, where it functions as a neurotransmitter (excitatory in the cortex, inhibitory in the brainstem and the spinal cord; see Chapter 103.11). Its main catabolic pathway requires the *glycine cleavage system,* a pyridoxal phosphate–dependent, mitochondrial enzyme complex that converts glycine to carbon dioxide and ammonia and transfers α-carbon to tetrahydrofolate (see Fig. 103.8). The glycine cleavage system is composed of 4 proteins: P protein (glycine decarboxylase), H protein, T protein, and L protein, which are encoded by 4 different genes.

Hypoglycinemia

Defects in the biosynthetic pathway of serine (see Chapter 103.8) cause deficiency of glycine in addition to that of serine in body fluids, especially in the cerebrospinal fluid (CSF). Isolated primary deficiency of glycine has not been reported.

Hyperglycinemia

Elevated levels of glycine in body fluids occur in propionic acidemia, methylmalonic acidemia, isovaleric acidemia, and β-ketothiolase deficiency, which are collectively referred to as *ketotic hyperglycinemia* because of the coexistence of acidosis and ketosis. The pathogenesis of hyperglycinemia in these disorders is not fully understood, but inhibition of the glycine cleavage enzyme system by the various organic acids has been shown to occur in some of these patients. The term **nonketotic hyperglycinemia (NKH)** is reserved for the clinical condition caused by the genetic deficiency of the glycine cleavage enzyme system (see Fig. 103.8). In this condition, hyperglycinemia is present without ketosis.

Nonketotic Hyperglycinemia (Glycine Encephalopathy)

Four forms of NKH have been identified: neonatal, infantile, late onset, and transient.

Neonatal Nonketotic Hyperglycinemia

This is the most common form of NKH. Clinical manifestations develop in the 1st few days of life (between 6 hr and 8 days after birth). Poor feeding, failure to suck, lethargy, and profound hypotonia may progress rapidly to a deep coma, apnea, and death. Convulsions, especially myoclonic seizures and hiccups, are common.

Laboratory findings reveal moderate to severe hyperglycinemia (as high as 8 times normal) and hyperglycinuria. The unequivocal elevation of glycine concentration in CSF (15-30 times normal) and the high ratio of glycine concentration in CSF to that in plasma (a value >0.08, normal <0.02) are diagnostic of NKH. Affected patients' blood pH is usually normal, and urine assay is negative for organic acids. CSF serine levels can be low.

Approximately 30% of NKH infants die despite supportive therapy. Those who survive develop profound psychomotor retardation and intractable seizure disorders (myoclonic and/or grand mal seizures). Hydrocephalus, requiring shunting, and pulmonary hypertension have been noted in some survivors. In some patients the hyperglycemia is transient.

Infantile Nonketotic Hyperglycinemia

These previously normal infants develop signs and symptoms of neonatal NKH after 6 mo of age. Seizures and hypotonia are the common presenting signs. Infantile NKH appears to be a milder form of neonatal NKH; infants usually survive, and intellectual disability is not as profound as in the neonatal form.

Laboratory findings in patients with infantile NKH are identical to those seen in neonatal NKH.

Late-Onset Nonketotic Hyperglycinemia

Clinical manifestations of this atypical form of NKH include progressive spastic diplegia, optic nerve atrophy, and choreoathetotic movements. Age of onset has been between 2 and 33 yr. Symptoms of delirium, chorea, and vertical gaze palsy may occur episodically in some patients during an intercurrent infection. Mental development is usually normal, but mild cognitive impairment and infrequent seizures have been reported in some patients.

Laboratory findings in late-onset NKH are similar but not as pronounced as in neonatal NKH.

All forms of NKH should be differentiated from *ketotic* hyperglycinemia, pyridox(am)ine phosphate oxidase (PNPO) deficiency, ingestion of valproic acid, and transient glycine encephalopathy. Valproic acid can moderately increase blood, CSF, and urinary concentrations of glycine. Repeat assays after discontinuation of the drug will help establish the diagnosis.

Transient Nonketotic Hyperglycinemia

Most clinical and laboratory manifestations of transient NKH are indistinguishable from those of the neonatal form. By 2-8 wk of age, however, a complete clinical recovery may occur, and the elevated glycine levels in plasma and CSF normalize after the patient stops a glycine-lowering medication. Some of these patients develop normally with no neurologic sequelae, but intellectual disability has been noted in others. The etiology of this condition is not known, but it is thought to be a consequence of immaturity of the enzyme system.

Diagnosis and Treatment

Diagnosis of NKH can be suspected based on the findings of elevated glycine in plasma or CSF and the abnormal CSF/plasma ratio of glycine. The diagnosis is confirmed using molecular analysis of the NKH-related genes. Rarely, assay of the enzyme in liver or brain specimens is necessary to establish the diagnosis. Enzyme activity in the neonatal form is close to zero, whereas in the other forms, some residual activity is present. In most patients with neonatal NKH, the enzyme defect resides in the P protein (75%); defects in the T protein account for approximately 20% of cases, whereas <1% are caused by pathogenic variants in the H protein.

No effective treatment is known. Exchange transfusion, dietary restriction of glycine, and administration of sodium benzoate or folate have not altered the neurologic outcome in severe forms of NKH. Patients with attenuated NKH may experience clinical improvement from enteral sodium benzoate. Drugs that counteract the effect of glycine on neuronal cells, such as dextromethorphan and felbamate, have shown some beneficial effects in patients with the mild forms of the condition.

NKH is inherited as an autosomal recessive trait. The prevalence is not known, but high frequency of the disorder has been noted in northern Finland (1 in 12,000 live births) suggesting that this disorder is likely underdiagnosed. The gene for P protein *(GLDC)* is on chromosome 9p24.1. The gene encoding T protein *(AMT)* is on chromosome 3p21.31 and that for H protein *(GCSH)* is mapped to chromosome 16q23.2. The L protein gene *(DLD)* on chromosome 7q31.7 encodes dihydrolipoamide dehydrogenase, the E3 component of α-ketoacid dehydrogenase complexes and is discussed in Chapter 103.6 (Valine, Leucine, Isoleucine, and Related Organic Acidemias). **Prenatal diagnosis** has been accomplished by identification of the known familial pathogenic variants in the affected gene or by performing an assay of the enzyme activity in chorionic villus biopsy specimens.

Sarcosinemia

Increased concentrations of sarcosine (*N* -methylglycine) are observed in both blood and urine, but no consistent clinical picture has been attributed to sarcosinemia. This autosomal recessive metabolic condition is caused by a defect in sarcosine dehydrogenase, the enzyme that converts sarcosine to glycine (see Fig. 103.8). The gene for this enzyme (*SARDH*) is on chromosome 9q34.2.

Primary Trimethylaminuria

Trimethylamine is normally produced in the intestine from the breakdown of dietary choline and trimethylamine oxide by bacteria. Egg yolk and liver are the main sources of choline, and fish is the major source of trimethylamine oxide. Trimethylamine is absorbed and oxidized in the liver by trimethylamine oxidase (flavin-containing monooxygenases) to trimethylamine oxide, which is odorless and excreted in the urine (see Fig. 103.8). Deficiency of this enzyme results in massive excretion of trimethylamine in urine. There is a body odor that resembles that of a fish, which may have significant social and psychosocial ramifications. Transient symptomatic trimethylaminuria can occur in normal individuals following ingestion of large quantities of the above mentioned foods. **Treatment** with oral activated charcoal, short courses of oral metronidazole, neomycin, or lactulose cause temporary reduction in the body odor. Restriction of fish, eggs, liver, and other sources of choline (e.g., nuts, grains) in the diet significantly reduces the odor. Topical use of acidic soaps (pH 5.5) can also help control the odor. The gene for trimethylamine oxidase (*FMO3*) has been mapped to chromosome 1q24.3.

Hyperoxaluria and Oxalosis

Normally, oxalic acid is derived mostly from oxidation of glyoxylic acid and, to a lesser degree, from oxidation of ascorbic acid (see Fig. 103.8). Glyoxylic acid is formed from oxidation of glycolic acid and glycine in the peroxisomes, and catabolism of **hydroxyproline** in the mitochondria (Fig. 103.9). Vegetables and foods containing oxalic acid, such as spinach, rhubarb, and almond milk, are the main *exogenous* sources of glycolic and oxalic acids; most of glyoxylic and oxalic acids are produced endogenously. Normally, a major portion of glyoxylate produced in the body is shuttled to peroxisomes, where it is converted to glycine by the action of the enzyme alanine:glyoxylate transaminase. Deficiency of this enzyme causes hyperoxaluria **type 1** . Most of the remaining glyoxylate in the cytosol is reduced to glycolate by the action of the enzyme glyoxylate reductase/hydroxypyruvate reductase. Deficiency of this enzyme causes hyperoxaluria **type 2** . These 2 pathways protect the body from excessive production of oxalic acid (see Fig. 103.8). Any glyoxylate that cannot be disposed of through these pathways is readily converted to oxalic acid by the action of the enzyme lactate dehydrogenase (LDH). Oxalic acid cannot be further metabolized in humans and is excreted in the urine as oxalates. Calcium oxalate is relatively insoluble in water and precipitates in tissues (kidneys and joints) if its concentration increases in the body.

Secondary hyperoxaluria has been observed in pyridoxine deficiency (cofactor for alanine:glyoxylate transaminase), in patients with inflammatory bowel disease, extensive resection of small bowel, or jejunoileal bypass (*enteric* *hyperoxaluria*), after ingestion of ethylene glycol or high doses of vitamin C, and after administration of the anesthetic agent methoxyflurane (which oxidizes directly to oxalic acid). Acute, fatal hyperoxaluria may develop after ingestion of plants with high oxalic acid content (e.g., sorrel) or intentional ingestion of oxalic acid. Precipitation of calcium oxalate in tissues causes hypocalcemia, liver necrosis, renal failure, cardiac arrhythmia, and death. The lethal dose of oxalic acid is estimated at 5-30 g.

Primary hyperoxaluria is a group of disorders in which large amounts of oxalates accumulate in the body. Three types of primary hyperoxaluria have been identified to date. The term **oxalosis** refers to deposition of calcium oxalate in parenchymal tissues.

Primary Hyperoxaluria Type 1

This rare condition (prevalence of 1 : 120,000 live births in Europe) is the most common form of primary hyperoxaluria. It is caused by deficiency of the peroxisomal enzyme alanine:glyoxylate transaminase, which is expressed only in the liver peroxisomes and requires pyridoxine (vitamin B_6) as a cofactor. In the absence of this enzyme, glyoxylic acid, which cannot be converted to glycine, is transferred to the cytosol, where it is oxidized to oxalic acid (see earlier and Fig. 103.8).

The age of presentation varies widely, from neonatal period to late adulthood. The majority of patients become symptomatic in late childhood or early adolescence. In about 20% of cases, symptoms develop before 1 yr of age. The initial clinical manifestations are related to renal stones and nephrocalcinosis. Renal colic and asymptomatic hematuria lead to a gradual deterioration of renal function, manifested by growth retardation and uremia. If the disorder is left untreated, most patients die before 20 yr of age from renal failure. Other frequent manifestations of the disease include failure to thrive, short stature, arterial calcifications, arrhythmia, heart failure, hypothyroidism, and skin nodules. Acute arthritis is a rare manifestation and may be misdiagnosed as gout because uric acid is usually elevated in patients with type 1 hyperoxaluria. Crystalline retinopathy and optic neuropathy causing visual loss have occurred in a few patients.

A marked increase in urinary excretion of oxalate (normal excretion: 10-50 mg/24 hr) is the most important laboratory finding. The presence of oxalate crystals in urinary sediment is rarely helpful for diagnosis because such crystals can also be seen in normal individuals. Urinary excretion of glycolic acid and glyoxylic acid is increased in most but not all patients. Diagnosis can be confirmed by identification of pathogenic variants in the *AGXT* gene or by performing an enzymatic assay in liver specimens.

Treatment focuses on the reduction of oxalic acid production and on increasing calcium oxalate disposal. Patients with primary hyperoxaluria type 1 should receive a 3-mo trial of pyridoxine treatment to establish pyridoxine responsiveness. In up to 30% of patients (e.g., homozygous for pathogenic variant c.508G>A in *AGXT*), administration of large doses of pyridoxine reduces plasma level and urinary excretion of oxalate. To increase calcium oxalate disposal and prevent nephrolithiasis, high oral fluid intake (2-3 L/m^2 /24 hr while controlling for fluid balance), urine alkalinization, phosphate supplementation, monitoring of vitamin C and vitamin D intake, and avoidance of drugs that increase urinary calcium excretion (e.g., loop diuretics) are recommended. Urinary stones should be managed by experienced urologists because excessive surgical trauma may contribute to renal dysfunction. Renal function replacement strategies (e.g., hemodialysis) are used in some patients (e.g., to bridge patients to transplant or when transplant is not a viable option).

Organ **transplantation** has emerged as the most definitive treatment. The decision to undergo kidney, liver, or liver-kidney transplant is complex and may vary from one medical center to another. Except for older patients with pyridoxine-responsive form of disease, renal transplantation for patients in renal failure may not improve the outcome, because oxalosis will recur in the transplanted kidney. Combined liver-kidney transplants have resulted in a significant decrease in plasma and urinary oxalate and thus may be the most effective treatment strategy in this disorder, particularly in children.

The condition is inherited as an autosomal recessive trait. The gene for this enzyme *(AGXT)* is mapped to chromosome 2q37.3. The most common pathogenic variant in patients with high residual enzyme activity (c.508G>A, p.Gly170Arg) results in mistargeting of the enzyme to the mitochondria instead of the peroxisomes and loss of in vivo function. **Prenatal diagnosis** has been achieved by DNA analysis of chorionic villus samples or by the measurement of fetal hepatic enzyme activity obtained by needle biopsy.

Primary Hyperoxaluria Type 2 (l-Glyceric Aciduria)

This rare condition is caused by a deficiency of the glyoxylate reductase–hydroxypyruvate reductase enzyme complex (see Fig. 103.8). A deficiency in the activity of this complex results in an accumulation of two intermediate metabolites, hydroxypyruvate (the ketoacid derivative of serine) and glyoxylic acid. Both these compounds are further metabolized by LDH to L -glyceric acid and oxalic acid, respectively. A high prevalence of this disorder is reported in the Saulteaux-Ojibway Indians of Manitoba.

Primary hyperoxaluria type 2 results in the deposition of calcium oxalate in the renal parenchyma and urinary tract. Renal stones presenting with renal colic and hematuria may develop before age 2 yr. Renal failure is less common in this condition than in primary hyperoxaluria type 1.

Urinary testing reveals large amounts of L -glyceric acid in addition to high levels of oxalate. Urinary L -glyceric acid is considered a pathognomonic finding in primary hyperoxaluria type 2. Urinary excretion of glycolic acid and glyoxylic acid is not increased. The presence of L -glyceric acid without increased levels of glycolic and glyoxylic acids in urine differentiates this type from type 1 hyperoxaluria. Diagnosis can be confirmed by molecular analysis of *GRHPR* (9p13.2) or by the enzyme assay in liver biopsy.

Principles of therapy are similar to those in primary hyperoxaluria type 1. Renal transplant is used in some patients; no experience with kidney-liver transplantation is available at this time.

Primary Hyperoxaluria Type 3

Approximately 10% of patients with primary hyperoxaluria have deficiency of 4-hydroxy-2-oxoglutarate aldolase 1 (HOGA1), the underlying cause of hyperoxaluria type 3. The enzyme is encoded by *HOGA1* mapped to chromosome 10q24.2. This mitochondrial enzyme catalyzes the final step in the metabolic pathway of hydroxyproline generating pyruvate and glyoxylate from 4-hydroxy-2-oxoglutarate (HOG; see Figs. 103.8 and 103.9). In vitro studies show inhibition of glyoxylate reductase–hydroxypyruvate reductase enzyme activity by high concentration of HOG that accumulates in patients with hyperoxaluria type 3. This inhibition results in a biochemical phenotype similar to hyperoxaluria type 2 (see Fig. 103.8).

Patients with primary hyperoxaluria type 3 usually presented with calcium oxalate kidney stones in early childhood, but asymptomatic older siblings were also identified. Gradually, renal function may decline, infrequently resulting in end-stage renal disease. Increased levels of HOG in urine, serum, and liver biopsy samples of these patients is the distinguishing feature of this disorder. **Treatment** involves high oral fluid intake, management of oral citrate or phosphate intake to prevent calcium oxalate renal stone formation, and avoidance of dehydration to prevent acute kidney injury. In severe forms of this disorder, dialysis and transplantation may be required to address the end-stage renal disease.

Creatine Deficiency Disorders

Creatine is synthesized mainly in the liver, pancreas, and kidneys and to a lesser degree in the brain from arginine and glycine and is transported to muscles and the brain, where there is high activity of the enzyme creatine kinase (Fig. 103.10). Phosphorylation and dephosphorylation of creatine in conjunction with adenosine triphosphate and diphosphate provide high-energy phosphate transfer reactions in these organs. Creatine is nonenzymatically metabolized to creatinine at a constant daily rate and is excreted in the urine. Three genetic conditions are known to cause creatine deficiency in the brain and other tissues. Two enzymes, arginine:glycine amidinotransferase (**AGAT**) and guanidinoacetate methyltransferase (**GAMT** ; Fig. 103.10), are involved in the biosynthesis of creatine. Both conditions may respond to creatine supplementation, especially when the treatment is started in early age. The 3rd condition, an X-linked inherited defect, is caused by deficiency of the creatinine transporter (CRTR) protein mediating uptake of creatine by brain and muscle.

Clinical manifestations of the 3 defects overlap, relate to the brain and muscle, and may appear in the 1st few wk or mo of life. Developmental delay, intellectual disability, speech delay, psychiatric symptoms (autism and psychosis), hypotonia, ataxia, and seizures are common findings. Dystonic movements have been documented in GAMT and CRTR deficiency.

Laboratory findings include decreased creatine in plasma in patients with AGAT and GAMT defects. Plasma creatinine level alone is insufficient to diagnose these disorders. Secondary to impaired reabsorption of creatine in kidneys, the urinary ratio of creatine to creatinine is increased in male patients with a CRTR defect but can also be mildly elevated in female carriers. Marked elevations of guanidinoacetate in blood, urine, and especially in CSF, are diagnostic of GAMT defects. In contrast, low levels of guanidinoacetate can be found in body fluids in the AGAT defect. Absence of creatine and creatine phosphate (in all 3 defects) and high levels of guanidinoacetate (in GAMT defect) can be demonstrated in the brain by magnetic resonance spectroscopy (MRS). Brain MRI may show signal hyperintensity in the globus pallidus. Diagnosis of AGAT deficiency or GAMT deficiency may be confirmed by DNA analysis or by measuring of enzymatic activity in cultured fibroblasts (GAMT) or lymphoblasts (AGAT). Diagnosis of CRTR deficiency can be confirmed by DNA analysis or a creatine uptake assay in fibroblasts.

The outcomes of **treatment** are age-dependent and best with treatment started in the neonatal period or presymptomatically. In AGAT-deficient patients, oral creatine monohydrate (up to 400-800 mg/kg/24 hr) may improve muscle weakness in most and neurocognitive outcomes in some patients. In GAMT-deficient patients, supplementation with oral creatine monohydrate (up to 400-800 mg/kg/24 hr), ornithine (up to 400-800 mg/kg/24 hr), and dietary arginine restriction may result in improved muscle tone and neurocognitive development and may alleviate seizures. In CRTR-deficient patients, administration of creatine and its precursors (arginine and glycine) does not restore creatine in the brain, but some patients may experience improvements of seizures and neurocognitive outcomes.

AGAT and GAMT defects are inherited as autosomal recessive traits. The gene for AGAT *(GATM)* is on chromosome 15q21.1 and that for GAMT *(GAMT)* is on chromosome 19p13.3. CRTR is an X-linked disorder and the gene *(SLC6A8)* is on Xq28. CRTR defect is the most common cause of creatine deficiency, accounting for up to 1–2% of males with intellectual disability of unknown cause.

Neu-Laxova syndrome
serine transporter
ASCT1
SLC1A4

Serine is a nonessential amino acid supplied through dietary sources and through its endogenous synthesis, mainly from glucose and glycine. The endogenous production of serine comprises an important portion of the daily requirement of this amino acid, especially in the synaptic junctions where it contributes to the metabolism of phospholipids as well as D -serine and glycine, both involved in neurotransmission (see Chapter 103.11). Consequently, deficiency of any of the enzymes involved in the biosynthesis of serine or its transport causes neurologic manifestations. The clinical spectrum of serine deficiency disorders is wide and varies from Neu-Laxova syndrome on the severe end of spectrum to epilepsy and developmental delay on the milder end. Affected patients respond favorably to oral supplementation with serine and glycine provided that the treatment is initiated very early in life. Figs. 103.8 and 103.10 show the metabolic pathway for synthesis and catabolism of serine.

3-Phosphoglycerate Dehydrogenase Deficiency

3-Phosphoglycerate dehydrogenase (**PHGDH**) deficiency has a broad range of symptoms and ages of presentation. **Neu-Laxova syndrome type 1** is the most severe manifestation and presents prenatally with intrauterine growth restriction and congenital anomalies, including dysmorphic facial features, microcephaly, CNS malformations, limb deformities, and ichthyosis. Most patients with this form are stillborn or have early neonatal mortality. Infantile-onset PHGDH deficiency presents with feeding problems, failure to thrive, vomiting, irritability, intractable seizures, severe developmental delay, and hypertonia progressing to spastic quadriplegia. Nystagmus, cataracts, hypogonadism, and megaloblastic anemia have been observed in some affected infants. Patients with a milder form of this disorder experience cognitive impairment, behavioral problems, sensorineural polyneuropathy, and childhood-onset seizures.

Laboratory findings include low fasting levels of serine and glycine in plasma and very low levels of serine and glycine in CSF. No abnormal organic acid metabolite is found in the urine. MRI of the brain shows cerebral atrophy with enlarged ventricles, significant attenuation of white matter, and impaired myelination. **Diagnosis** can be confirmed by DNA analysis or by measurement of the enzyme activity in cultured fibroblasts. **Treatment** with high doses of serine (200-700 mg/kg/24 hr orally) and glycine (200-300 mg/kg/24 hr) normalizes the serine levels in the blood and CSF. When started postnatally, this treatment may improve seizures, spasticity, and brain myelination. One case report suggests that developmental delay may be prevented if the treatment commences in the 1st days of life or prenatally.

The condition is inherited as an autosomal recessive trait. The gene for 3-phosphoglycerate dehydrogenase enzyme *(PHGDH)* has been mapped to chromosome 1p12. If familial pathogenic variants are known, molecular **prenatal diagnosis** is possible. Administration of serine to the mother carrying an affected fetus was associated with stabilization of the fetal head circumference, as evidenced by ultrasound. Treatment with supplemental serine has continued postnatally; the patient remained normal neurologically at 4 yr of age. The favorable response of this condition to a relatively straightforward treatment makes this diagnosis an important consideration in any child with microcephaly and neurologic defects such as psychomotor delay or a seizure disorder. Measurements of serine and glycine in the CSF are critical for diagnosis because mild decreases of these amino acids in the plasma can be easily overlooked.

Phosphoserine Aminotransferase Deficiency

Phosphoserine aminotransferase 1 (**PSAT1**) catalyzes conversion of 3-phosphohydroxypyruvate to 3-phosphoserine (see Fig. 103.10). Deficiency of this enzyme may present in the neonatal period with poor feeding, cyanotic episodes, and irritability and may progress to intractable, multifocal seizures and microcephaly. Brain imaging may reveal generalized cerebral and cerebellar atrophy. Laboratory studies done on postprandial plasma samples may reveal normal or mildly decreased levels of serine and glycine. Serine and glycine levels are usually more depressed on the CSF amino acid analysis. **Treatment** with serine and glycine as outlined earlier may result in clinical improvement. The condition is inherited as an autosomal recessive trait, and the gene *(PSAT1)* is mapped to chromosome 9q21.2.

3-Phosphoserine Phosphatase

Deficiency

3-Phosphoserine phosphatase catalyzes the final step in the L -serine synthesis converting 3-phosphoserine to L -serine. Deficiency of this enzyme results in a rare disorder with clinical and biochemical findings indistinguishable from the PHGDH and PSAT1 deficiencies. The disorder is caused by autosomal recessive pathogenic variants in *PSPH* mapped to chromosome 7p11.2.

Proline is a nonessential amino acid synthesized endogenously from glutamic acid, ornithine, and arginine (see Fig. 103.9). Proline and hydroxyproline are found in high concentrations in collagen. Normally, neither of these amino acids is found in large quantities in urine. Excretion of proline and hydroxyproline as *iminopeptides* (dipeptides and tripeptides containing proline or hydroxyproline) is increased in disorders of accelerated collagen turnover, such as rickets or hyperparathyroidism. Proline is also found in synapses, where it can interact with glycine and glutamate receptors (see Chapter 103.11). The catabolic pathway of proline and hydroxyproline produces glyoxylic acid, which can be further metabolized to glycine or oxalic acid (see Fig. 103.8).

Accumulation of proline in tissues is associated with disorders of hyperprolinemia type 1 and hyperprolinemia type 2. Reduced de novo synthesis of proline causes syndromes manifesting with **cutis laxa** (see Fig. 678.8) with **progeroid features** or **spastic paraplegia** . Two types of primary hyperprolinemia have been described.

Hyperprolinemia Type I

This rare autosomal recessive condition is caused by deficiency of proline oxidase (proline dehydrogenase; see Fig. 103.9). Most patients with hyperprolinemia type 1 appear asymptomatic, although some may present with intellectual disability, seizures, and behavioral problems. Hyperprolinemia may also be a risk factor for autism spectrum disorders and schizophrenia. The nature of such wide phenotypic range in this biochemical condition has not been elucidated. The gene encoding proline oxidase *(PRODH)* is mapped to 22q11.2 and is located within the critical region for the **velocardiofacial syndrome** . Laboratory studies reveal high concentrations of proline in plasma, urine, and CSF. Increased urinary excretion of hydroxyproline and glycine is also present, which could be related to saturation of the shared tubular reabsorption mechanism due to massive prolinuria.

No effective treatment has yet emerged. Restriction of dietary proline causes modest improvement in plasma proline with no proven clinical benefit.

Hyperprolinemia Type II

This is a rare autosomal recessive condition caused by the deficiency of Δ^1 -pyrroline-5-carboxylate dehydrogenase (aldehyde dehydrogenase 4; see Fig.

103.9). Intellectual disability and seizures (usually precipitated by an intercurrent infection) have been reported in affected children, but asymptomatic patients have also been described. The cause for such disparate clinical outcomes is incompletely understood. The gene encoding P5C dehydrogenase *(ALDH4A1)* is mapped to chromosome 1p36.13.

Laboratory studies reveal increased concentrations of proline and Δ^1 -pyrroline-5-carboxylic acid (P5C) in blood, urine, and CSF. The presence of P5C differentiates this condition from hyperprolinemia type I. Increased level of P5C in body fluids, especially in the CNS, appears to antagonize vitamin B_6 and lead to vitamin B_6 dependency (see Chapter 103.14). Vitamin B_6 dependency may be the main cause of seizures and neurologic findings in this condition and may explain the variability in clinical manifestations in different patients. **Treatment** with high doses of vitamin B_6 is recommended.

Prolidase Deficiency

During collagen degradation, imidodipeptides are formed and are normally cleaved by tissue prolidase. Deficiency of prolidase, which is inherited as an autosomal recessive trait, results in the accumulation of imidodipeptides in body fluids. Age at onset varies from 6 mo to the 3rd decade of life.

The **clinical manifestations** of this rare condition also vary and include recurrent, severe, and painful skin ulcers, which are typically on hands and legs. Other skin lesions that may precede ulcers by several years may include a scaly erythematous maculopapular rash, purpura, and telangiectasia. Most ulcers become infected. Healing of the ulcers may take months. Other findings include developmental delays, intellectual disability, organomegaly, anemia, thrombocytopenia, and immune dysfunction resulting in increased susceptibility to infections (recurrent otitis media, sinusitis, respiratory infection, splenomegaly). Some patients may have craniofacial abnormalities such as ptosis, ocular proptosis, hypertelorism, small beaked nose, and prominent cranial sutures. Asymptomatic cases have also been reported. Increased incidence of systemic lupus erythematosus has been noted in children. High levels of urinary excretion of imidodipeptides are diagnostic. The gene for prolidase *(PEPD)* has been mapped to chromosome 19q13.11. The diagnosis can be confirmed using DNA analysis. Enzyme assay may be performed in erythrocytes or cultured skin fibroblasts.

Treatment of prolidase deficiency is supportive. Infectious complications can be fatal and warrant close and proactive antibiotic management. Oral supplementation with proline, ascorbic acid, and manganese and topical proline and glycine have not been found to be consistently effective in all patients.

Disorders of De Novo Proline Synthesis

De novo synthesis of proline and ornithine from glutamate appears to be critical in the normal biology of connective tissue and to maintain urea cycle in a repleted state. Correspondingly, clinical manifestations of these disorders encompass connective tissue abnormalities, nervous system abnormalities, and variable biochemical abnormalities reflecting urea cycle dysfunction. This section summarizes clinical and laboratory findings associated with the deficient function of Δ^1 -pyrroline-5-carboxylate (P5C) synthase (see Fig. 103.9) encoded by *ALDH18A1* (mapped to 10q24.1) and PSC reductase encoded by *PYCR1* (mapped to 17q25.3).

Deficient activity of P5C synthase has been associated with several phenotypes, including **de Barsy syndrome** , characterized by cataracts, growth retardation, intellectual disability, a prematurely aged appearance (progeroid features), and cutis laxa. Some patients may show pyramidal signs. Skin biopsy may reveal decreased size of elastic fibers and collagen abnormalities. Brain imaging studies show cortical atrophy, ventriculomegaly, and reduced creatine. Laboratory findings include reduced levels of proline, ornithine, citrulline, and arginine as well as mild fasting hyperammonemia. Patients may show only intermittent abnormalities of plasma amino acids, likely related to the time of blood sampling in relation to the last meal. Interestingly, both autosomal recessive and autosomal dominant forms of inheritance have been described. The diagnosis can be suspected in a patient presenting with cutis laxa, developmental delay, mild hyperammonemia, and amino acid abnormalities. The diagnosis can be confirmed using molecular DNA analysis or using the glutamine loading test on skin fibroblasts. Treatment is supportive, although supplementation with citrulline or arginine to address hyperammonemia and cerebral creatine depletion have been proposed.

Deleterious mutations in *PYCR1* result in the abnormal function of the mitochondrial Δ^1 -pyrroline-5-carboxylate reductase, which catalyzes the last step in the synthesis of proline from P5C. The most consistent finding in patients carrying proven pathogenic variants in *PYCR1* include triangular facies, cutis laxa (**de Barsy–like syndrome**), joint hypermobility, wrinkled skin, gerodermia osteodysplastica, and progeroid features. Skin biopsy reveals reduction of the elastic fibers and infiltration with inflammatory cells. Some patients may have epilepsy, developmental delays, intellectual disability, cataracts, osteopenia, and failure to thrive. However, many of the affected families are consanguineous, thus confounding the phenotype. Of note, plasma amino acid analysis typically reveals no specific abnormalities. The diagnosis depends on the recognition of the skin findings and can be confirmed using molecular DNA analysis. Available pedigrees of families affected by *PYCR1* -related disorder supports the autosomal recessive mode of inheritance.

secondary 5-oxoprolinuria

Glutamic acid and its amide derivative glutamine have a wide range of functions in the body. *Glutamate* plays numerous biologic roles, functioning as a neurotransmitter, an intermediate compound in many fundamental biochemical reactions, and a precursor of an inhibitory neurotransmitter γ-aminobutyric acid (GABA) (see Chapter 103.11). Another major product of glutamate is *glutathione* (γ-glutamylcysteinylglycine). This ubiquitous tripeptide, with its function as the major antioxidant in the body, is synthesized and degraded through a complex cycle called the γ-glutamyl cycle (Fig. 103.11). Because of its free sulfhydryl (–SH) group and its abundance in the cell, glutathione protects other sulfhydryl-containing compounds (e.g., enzymes, coenzyme A) from oxidation. It is also involved in the detoxification of peroxides, including hydrogen peroxide, and in keeping the intracellular milieu in a reduced state. In addition, glutathione participates in amino acid transport across the cell membrane through the γ-glutamyl cycle.

FIG. 103.11 **The γ-glutamyl cycle and related pathways. Defects of the glutathione (GSH) synthesis and degradation are noted. Enzymes: *(1)* γ-Glutamyl transpeptidase (GGT), *(2)* γ-glutamyl cyclotransferase, *(3)* 5-oxoprolinase, *(4)* γ-glutamyl-cysteine synthetase, *(5)* glutathione synthetase, *(6)* glutamate decarboxylase, *(7)* γ-aminobutyric acid (GABA) transaminase, *(8)* succinate-semialdehyde dehydrogenase, *(9)* glutamine synthetase, *(10)* dipeptidase.**

One of the biochemical manifestations of γ-glutamyl cycle deficiency is increased urinary excretion of 5-oxoproline, which could be the result of both genetic and non-genetic causes. 5-Oxoprolinemia should be routinely considered in the differential diagnosis of **high–anion gap metabolic acidosis** (HAGMA). Two metabolic disorders can present with massive 5-oxoprolinuria: **glutathione synthetase deficiency** and **5-oxoprolinase deficiency** (Fig. 103.11). However, a more common clinical scenario is a transient and mild urinary elevation of 5-oxoproline in urine that can be seen in a variety of metabolic and acquired conditions, such as exposure to acetaminophen and some hydrolyzed-protein formulas, severe burns, Stevens-Johnson syndrome, homocystinuria, urea cycle defects, and tyrosinemia type I.

Glutathione Synthetase Deficiency

Three forms of this rare condition have been reported. In the **mild form** , enzyme deficiency causes glutathione deficiency only in erythrocytes. These patients present with hemolytic anemia without chronic metabolic acidosis and demonstrate high residual activity of glutathione synthetase on enzymatic testing. A **moderate form** has also been observed in which the hemolytic anemia is associated with variable degrees of metabolic acidosis and 5-oxoprolinuria. Its **severe form** is distinguished by presence of hemolytic anemia accompanied by severe acidosis, massive 5-oxoprolinuria, and neurologic manifestations.

Glutathione Synthetase Deficiency, Severe and Moderate Forms

Affected newborn infants with this rare condition usually develop acute symptoms of metabolic acidosis, jaundice, and mild to moderate hemolytic anemia in the 1st few days of life. Chronic acidosis continues after recovery. Similar episodes of life-threatening acidosis may occur during an infection (e.g., gastroenteritis) or after a surgical procedure. Progressive neurologic damage develops with age, manifested by intellectual disability, spastic tetraparesis, ataxia, tremor, dysarthria, and seizures. Susceptibility to infections, presumably because of granulocyte dysfunction, is observed in some patients. Patients with the moderate form of glutathione synthetase deficiency have milder acidosis and less 5-oxoprolinuria than is seen in the severe form, with no neurologic manifestations.

Laboratory findings include metabolic acidosis, mild to moderate degrees of hemolytic anemia, and 5-oxoprolinuria. High concentrations of 5-oxoproline are also found in blood. The urinary and blood levels of 5-oxoproline is less pronounced in patients with moderate form of the condition. The glutathione content of erythrocytes is markedly decreased. Increased synthesis of 5-oxoproline in this disorder is thought to be the result of the conversion of γ-glutamylcysteine to 5-oxoproline by the enzyme γ-glutamyl cyclotransferase (see Fig. 103.11). γ-Glutamylcysteine production increases greatly because the normal inhibitory effect of glutathione on the γ-glutamylcysteine synthetase enzyme is removed.

Treatment of acute attack includes hydration, correction of acidosis (by infusion of sodium bicarbonate), and measures to correct anemia and hyperbilirubinemia. Chronic administration of alkali is usually needed indefinitely. Supplementation with vitamin C, vitamin E, and selenium is recommended. Drugs and oxidants known to cause hemolysis and stressful catabolic states should be avoided. Oral administration of glutathione analogs has been tried with variable success.

Prenatal diagnosis can be achieved by the measurement of 5-oxoproline in amniotic fluid, by enzyme analysis in cultured amniocytes or chronic villus samples, or by DNA analysis. Successful pregnancy in an affected female (moderate form) has been reported, with favorable outcomes for both mother and infant.

Glutathione Synthetase Deficiency, Mild Form

The mild form has been reported in only a few patients. Mild to moderate hemolytic anemia has been the only clinical finding. Splenomegaly has been reported in some patients. Cognitive development is normal. Chronic metabolic acidosis typically is not seen. Some patients can have increased concentrations of 5-oxoproline in the urine. Pathogenic variants in the gene for this enzyme *(GSSD)* appear to decrease the half-life of the enzyme, which causes an increased rate of protein turnover without affecting its catalytic function. The expedited rate of enzyme turnover caused by these pathogenic variants is of little or no consequence for tissues with protein synthetic capability. However, inability of mature erythrocytes to synthesize protein results in glutathione deficiency in the erythrocytes. **Treatment** is that of hemolytic anemia and avoidance of drugs and oxidants that can trigger the hemolytic process.

All forms of glutathione synthetase deficiency are inherited as an autosomal recessive trait. *GSSD* is located on chromosome 20q11.22. **Diagnosis** can be confirmed by DNA analysis or enzyme activity in erythrocytes or skin fibroblasts.

5-Oxoprolinase Deficiency

More than 20 patients with 5-oxoprolinuria (4-10 g/day) caused by 5-oxoprolinase (see Fig. 103.11) deficiency have been described. No specific clinical picture has yet emerged; completely asymptomatic affected individuals have also been identified. It is therefore not clear whether 5-oxoprolinase deficiency is of any clinical consequence. *No treatment is currently recommended.* The gene for the enzyme *(OPLAH)* is on chromosome 8q24.3.

γ-Glutamylcysteine Synthetase Deficiency (Glutamate-Cysteine Ligase Deficiency)

Only a few patients with this enzyme deficiency have been reported. The most consistent clinical manifestation has been mild chronic hemolytic anemia. Acute attacks of hemolysis have occurred after exposure to sulfonamides. Peripheral neuropathy and progressive spinocerebellar degeneration have been noted in 2 siblings in adulthood. Laboratory findings of chronic hemolytic anemia were present in all patients. Generalized aminoaciduria is also present because the γ-glutamyl cycle is involved in amino acid transport in cells (see Fig. 103.11). **Treatment** should focus on the management of hemolytic anemia and avoidance of drugs and oxidants that may trigger the hemolytic process. The condition is inherited as an autosomal recessive trait; the gene *(GCLC)* is mapped to chromosome 6p12.1.

γ-Glutamyl Transpeptidase Deficiency (Glutathionemia)

γ-Glutamyl transpeptidase (GGT) is present in any cell that has secretory or absorptive functions. It is especially abundant in the kidneys, pancreas, intestines, and liver. The enzyme is also present in the bile. Measurement of GGT in the blood is frequently performed to evaluate liver and bile duct diseases.

GGT deficiency causes elevation in glutathione concentrations in body fluids, but the cellular levels remain normal (see Fig. 103.11). Because only a few patients with GGT deficiency have been reported, the scope of clinical manifestations has not yet been defined. Mild to moderate intellectual disability and severe behavioral problems were observed in 3 patients. However, 1 of 2 sisters with this condition had normal intelligence as an adult, and the other had

Prader-Willi syndrome.

Laboratory findings include marked elevations in urinary concentrations of glutathione (up to 1 g/day), γ-glutamylcysteine, and cysteine. None of the reported patients has had generalized aminoaciduria, a finding that would have been expected to occur in this enzyme deficiency (see Fig. 103.11).

Diagnosis can be confirmed by measurement of the enzyme activity in leukocytes or cultured skin fibroblasts. *No effective treatment has been proposed.* The condition is inherited as an apparent autosomal recessive trait. γ-Glutamyl transpeptidases represent a large family of enzymes encoded by at least 7 genes.

Genetic Disorders of Metabolism of γ-Aminobutyric Acid

hyperprolinemia

Neurotransmitters are chemical substances released from the axonal end of excited neurons at the synaptic junctions; they mediate initiation and amplification or inhibition of neural impulses. A number of amino acids and their metabolites comprise the bulk of neurotransmitters. Pathogenic variants in genes responsible for the synthesis, transport, or degradation of these substances may cause conditions that manifest neurologic and/or psychiatric abnormalities (Table 103.3). Previously, children affected by disorders of neurotransmitters have been given syndromic diagnoses such as cerebral palsy, epilepsy, parkinsonism, dystonia, or autism. Diagnosis, in most cases, requires specialized laboratory studies of the cerebrospinal fluid (CSF), because some of the neurotransmitters generated in the central nervous system (CNS), dopamine and serotonin, do not cross the blood-brain barrier, and their abnormal concentrations are not detected in the serum or urine. A growing number of these conditions are being identified; diseases once thought to be rare are now diagnosed with increasing frequency.

Table 103.3

Genetic Disorders of Neurotransmitters in Children

TRANSMITTER	SYNTHESIS DEFECTS	DEGRADATION DEFECTS
MONOAMINES		
Dopamine	TH deficiency	MAO deficiency
Serotonin and dopamine	AADC deficiency	MAO deficiency

AADC, Aromatic L -amino acid decarboxylase; BH_4 , tetrahydrobiopterin; DAT, dopamine transporter; DβH, dopamine β-hydroxylase; GABA, γ-aminobutyric acid; GHB, γ-hydroxybutyric acid; HDC, histidine decarboxylase; hyperphe, hyperphenylalaninemia; MAO, monoamine oxidase; NKH, nonketotic hyperglycinemia; 3-PGD, 3-phosphoglycerate dehydrogenase; PSAT, phosphoserine aminotransferase; PSPH, 3-Phosphoserine Phosphatase Deficiency; TH, tyrosine hydroxylase; VMAT2, vesicular monoamine transporter 2.

Tyrosine Hydroxylase Deficiency (Infantile Parkinsonism, Autosomal Recessive Dopa-Responsive Dystonia, Autosomal Recessive Segawa Syndrome)

Tyrosine hydroxylase catalyzes the formation of L -dopa from tyrosine. Deficiency of this enzyme results in deficiencies of dopamine and norepinephrine (see Fig. 103.2). The differential diagnosis includes a wide range of inherited dystonias, including autosomal dominant dystonia caused by GTP cyclohydrolase 1 deficiency.

Clinical manifestations range from mild to very severe. In general, 2 phenotypes have been recognized. In the **mild** form (dopa-responsive dystonia, or **type A**), symptoms of unilateral limb dystonia causing gait incoordination and postural tremor occur in childhood and worsen with age if the condition remains untreated. Diurnal variation of symptoms (worse at the end of the day) may be present. Cognitive development is usually normal.

In the **severe** form of tyrosine hydroxylase deficiency (infantile parkinsonism, infantile encephalopathy, or **type B**), the clinical manifestations occur at birth or shortly thereafter and include microcephaly, developmental delay, involuntary movements of the limbs with spasticity, dystonia, ptosis, expressionless face, oculogyric crises (upward eye-rolling movements), and autonomic dysfunction (temperature instability, excessive sweating, hypoglycemia, salivation, tremor, gastrointestinal reflux, constipation). Brisk reflexes, myoclonus, athetosis, and distal chorea may be present. The patient with the severe form usually shows incomplete response to treatment with L -dopa and is prone to developing L -dopa–induced dyskinesia as a side effect.

Laboratory findings include reduced levels of dopamine and its metabolite homovanillic acid (HVA) and normal concentrations of tetrahydrobiopterin (BH_4), neopterin, and 5-hydroxyindoleacetic acid (5-HIAA, a metabolite of serotonin) in the CSF. Serum prolactin levels are usually elevated. These findings are not diagnostic of the condition; diagnosis should be established by molecular gene analysis.

Treatment with L -dopa/carbidopa results in significant clinical improvement in most patients, but the severe forms are invariably associated with L -dopa–induced dyskinesias. To minimize the side effects of therapy, the treatment should be started with a low dose and increased very slowly, if needed. Other therapeutic interventions include anticholinergics, serotonergic agents, and monoamine oxidase (MAO) B inhibitors, including amantadine, biperiden, and selegiline. Bilateral subthalamic nucleus deep brain stimulation has shown clinical efficacy in one case. Tyrosine hydroxylase deficiency is inherited as an autosomal-recessive trait. Molecular testing for pathogenic variants in the *TH* gene is available clinically.

Aromatic l-Amino Acid Decarboxylase Deficiency

Aromatic L -amino acid decarboxylase (AADC) is a vitamin B_6 –dependent enzyme that catalyzes the decarboxylation of both 5-hydroxytryptophan to form serotonin (see Fig. 103.5) and L -dopa to generate dopamine, (see Fig. 103.2). **Clinical manifestations** are related to reduced availability of dopamine and serotonin. Poor feeding, lethargy, hypotension, hypothermia, oculogyric crises, and ptosis have been observed in affected neonates. Clinical findings in infants and older children include developmental delay, truncal hypotonia with hypertonia of limbs, oculogyric crises, extrapyramidal movements (choreoathetosis, dystonia, myoclonus), and autonomic abnormalities (sweating, salivation, irritability, temperature instability, hypotension). Symptoms may have a diurnal variation, becoming worse by the end of the day.

Laboratory findings include decreased concentrations of dopamine and serotonin and their metabolites (HVA, 5-HIAA, norepinephrine, vanillylmandelic acid [VMA]) and increased levels of 5-hydroxytryptophan, L -dopa, and its metabolite (3-*O* -methyldopa) in body fluids, especially in CSF. Elevated serum concentrations of prolactin (a result of dopamine deficiency) have also been observed. MRI of the brain reveals cerebral atrophy with degenerative changes in the white matter. A urine screening program, focused on 3-*O* -methyl-dopa and VMA, has demonstrated diagnostic promise in high-disease prevalence populations.

Treatment with neurotransmitter precursors has produced limited clinical improvement. Dopamine and serotonin have no therapeutic value because of their inability to cross the blood-brain barrier. Dopamine agonists (L -dopa/carbidopa, bromocriptine), MAO inhibitors (tranylcypromine), serotonergic agents and high doses of pyridoxine, a cofactor for AADC enzyme, have been tried. Pyridoxine supplementation in patients harboring the p.S250F variant in AADC may be beneficial. The recent demonstration of CNS-directed gene therapy with an adeno-associated viral vector has shown benefit in some patients. Preimplantation genetic diagnosis after in vitro fertilization has been achieved in the high-prevalence Taiwanese population. The gene encoding AADC (*DDC*) is on chromosome 7p12.1. The condition is inherited as an autosomal recessive trait.

Tetrahydrobiopterin Deficiency

See Chapter 103.1 .

BH_4 is the cofactor for phenylalanine hydroxylase (see Fig. 103.1), tyrosine hydroxylase (see Fig. 103.2), tryptophan hydroxylase (see Fig. 103.5), and nitric oxide synthase. It is synthesized from GTP in many tissues (see Fig. 103.1). Deficiencies of enzymes involved in the biosynthesis of BH_4 result in inadequate production of this cofactor, which causes deficiencies of monoamine neurotransmitters with or without concomitant hyperphenylalaninemia.

Tetrahydrobiopterin Deficiency With Hyperphenylalaninemia

See Chapter 103.1 .

Tetrahydrobiopterin Deficiency Without Hyperphenylalaninemia

GTP Cyclohydrolase 1 Deficiency (Hereditary Progressive Dystonia, Autosomal Dominant Dopa-Responsive Dystonia, Autosomal Dominant Segawa Syndrome)

This form of dystonia, caused by guanosine triphosphate (GTP) cyclohydrolase 1 deficiency, is inherited as an autosomal dominant trait and is more common in females than males (4 : 1 ratio) (see Chapter 615.4). **Clinical manifestations** usually start in early childhood with tremor and dystonia of the lower limbs (**toe gait**), which may spread to all extremities within a few years. Torticollis, dystonia of the arms, and poor coordination may precede dystonia of the lower limbs. Early development is generally normal. Symptoms have an impressive diurnal variation, becoming worse by the end of the day and improving with sleep. Autonomic instability is not uncommon. Parkinsonism may also be present or develop with advancing age. Late presentation in adult life has also been reported, associated with **action dystonia** ("writer's cramp"), torticollis, or generalized rigid hypertonia with tremor but without postural dystonia. Additionally, limited data on adults suggest symptoms related to serotonin deficiency (sleep disturbance, cognitive impairment, impulsivity).

Laboratory findings show reduced levels of BH_4 and neopterin in the CSF without hyperphenylalaninemia (see Chapter 103.1). Dopamine and its metabolite (HVA) may also be reduced in CSF. The serotonergic pathway is less affected by this enzyme deficiency; thus concentrations of serotonin and its metabolites are usually normal. Plasma phenylalanine is normal, but an oral phenylalanine loading test (100 mg/kg) produces an abnormally high plasma phenylalanine level with an elevated phenylalanine/tyrosine ratio. The ratio, obtained at the 2-3 hr after the load, in combination with urine neopterin level, has optimal diagnostic specificity and sensitivity. The existence of asymptomatic carriers indicates that other factors or genes may play a role in pathogenesis. The asymptomatic carrier may be identified by the phenylalanine loading test. **Diagnosis** may be confirmed by reduced levels of BH_4 and neopterin in CSF, measurement of the enzyme activity, and molecular genetic analysis (see Chapter 103.1). Clinically, the condition should be differentiated from other causes of dystonias and childhood parkinsonism, especially tyrosine hydroxylase, sepiapterin reductase, and aromatic amino acid decarboxylase deficiencies.

Treatment with L -dopa/carbidopa usually produces dramatic clinical improvement. Oral administration of BH_4 is also effective but is rarely used. The gene for GTP cyclohydroxylase 1 (*GCH1*) is located on chromosome 14q22.2.

Sepiapterin Reductase Deficiency

Sepiapterin reductase is involved in conversion of 6-pyruvoyl-tetrahydropterin to BH_4 . It also participates in the salvage pathway of BH_4 synthesis (see Fig. 103.1). Sepiapterin reductase deficiency results in accumulation of 6-lactoyl-tetrahydropterin, which can be converted to sepiapterin nonenzymatically. The majority of sepiapterin is metabolized to BH_4 through the salvage pathway in peripheral tissues (see Fig. 103.1), but because of the low activity of dihydrofolate reductase in brain, the amount of BH_4 remains insufficient for proper synthesis of dopamine and serotonin. This explains the absence of hyperphenylalaninemia and the often-delayed diagnosis.

Clinical manifestations usually appear within a few months of life. Cardinal manifestations include paroxysmal stiffening, oculogyric crises, and hypotonia. Additional findings include motor and language delays, weakness, limb hypertonia, dystonia, hyperreflexia, and early-onset parkinsonism. The symptoms usually have a diurnal variation. Misdiagnosis as cerebral palsy is common and a wide variability of symptoms have been reported. **Diagnosis** is established by measurement of CSF neurotransmitters and pterin metabolites, which reveal decreased dopamine, HVA, norepinephrine, and 5-HIAA and marked elevations of sepiapterin and dihydrobiopterin. The serum concentration of prolactin may be elevated. The phenylalanine loading test may have diagnostic utility. Diagnosis may be confirmed by molecular genetic analysis or enzyme assay in fibroblasts. **Treatment** with slowly increasing doses of L-dopa/carbidopa and 5-hydroxytryptophan usually produces dramatic clinical improvement. The condition is inherited as an autosomal recessive trait; the gene *SPR* encoding sepiapterin reductase is located on chromosome 2p13.2.

Dopamine β-Hydroxylase Deficiency

Dopamine β-hydroxylase catalyzes the conversion of dopamine to norepinephrine (see Fig. 103.2). The deficiency of this enzyme results in reduced or absent synthesis of norepinephrine, leading to dysregulation of the sympathetic function. Infants and children may present with difficulty opening eyes, ptosis, hypotension, hypothermia, hypoglycemia, and nasal stuffiness. Adult patients may present with profound deficits of autonomic regulation, resulting in severe orthostatic hypotension, and sexual dysfunction in males. Presyncopal symptomatology includes dizziness, blurred vision, dyspnea, nuchal discomfort, and chest pain; olfactory function remains relatively intact. The **diagnosis** can be aided by performing autonomic function testing (measurement of the sinus arrhythmia ratio, blood pressure studies during controlled hyperventilation, Valsalva maneuver, cold pressor, handgrip exercise). **Laboratory findings** include decreased or absent norepinephrine and epinephrine and their metabolites, with elevated levels of dopamine and its metabolite (HVA), in plasma, CSF, and urine. Elevated plasma dopamine may be pathognomonic for this disease. MRI of the brain shows decreased brain volume, consistent with the neurotrophic role of norepinephrine. **Treatment** with L -dihydroxyphenylserine, which is converted to norepinephrine directly in vivo by the action of AADC, leads to significant improvement in orthostatic hypotension and normalizes noradrenaline and its metabolites. The condition is inherited as an autosomal recessive trait; the gene *(DBH)* encoding dopamine β-hydroxylase resides on chromosome 9q34.2.

Monoamine Oxidase a Deficiency

Human genome encodes 2 monoamine oxidase (MAO) isoenzymes: MAO A and MAO B. Both enzymes catalyze oxidative deamination of most biogenic amines in the body, including serotonin (see Fig. 103.5), norepinephrine, epinephrine, and dopamine (see Fig. 103.2). The genes for both isoenzymes are on the X chromosome (Xp11.3), residing in close proximity. A deletion of both genes can also encompass a neighboring gene, *NDP,* resulting in a contiguous deletion syndrome, which can present as an atypical **Norrie disease** (see Chapter 640). Male patients with MAO A deficiency manifest borderline intellectual deficiency and impaired impulse control. The consequences of the isolated MAO B deficiency are incompletely understood. Combined MAO A and B deficiency causes severe intellectual disability and behavioral problems and can be associated with pronounced laboratory abnormalities (e.g., 4-6–fold serotonin elevation in physiologic fluids, elevated *O* -methylated amine metabolites, and reduced deamination products [VMA, HVA]). Dietary intervention (low tyramine, phenylethylamine, and L -dopa/dopamine intake) did not improve patients' blood serotonin levels. Inheritance of MAO deficiency is X-linked. **Treatment** of MAO A deficiency is supportive.

Disorders of γ-Aminobutyric Acid (GABA) Metabolism

GABA is the main inhibitory neurotransmitter synthesized in the synapses through decarboxylation of glutamic acid by glutamate decarboxylase (GAD). The same pathway is responsible for production of GABA in other organs, especially the kidneys and the β-cells of the pancreas. GAD enzyme requires pyridoxine (vitamin B_6) as cofactor. Two GAD enzymes, GAD1 (GAD_{67}) and GAD2 (GAD_{65}) have been identified. **GAD1** is the main enzyme in the brain, and **GAD2** is the major enzyme in the β-cells. Antibodies against GAD_{65} and GAD_{67} have been implicated in the development of type 1 diabetes and **stiff-person syndrome** , respectively. GABA is catabolized to succinic acid by 2 enzymes, GABA transaminase and succinic semialdehyde dehydrogenase (SSADH) (see Fig. 103.11).

γ-Aminobutyric Acid Transaminase Deficiency

Clinical manifestations in the 2 index infant siblings included severe psychomotor retardation, hypotonia, hyperreflexia, lethargy, refractory seizures, and increased linear growth likely related to GABA-mediated increased secretion of growth hormone. Increased concentrations of GABA and β-alanine were found in CSF (see Fig. 103.11). Evidence of leukodystrophy was noted in the postmortem examination of the brain. A 3rd patient showed severe psychomotor retardation, recurrent episodic lethargy, and intractable seizures with comparable CSF metabolite abnormalities to those of the index probands. GABA transaminase deficiency is demonstrated in brain and lymphocytes. **Treatment** is symptomatic. Intervention with vitamin B_6 , the cofactor for the enzyme, was without therapeutic benefit. The gene *(ABAT)*, maps to chromosome 16p13.2; the condition is inherited as an autosomal recessive trait.

Succinic Semialdehyde Dehydrogenase

Deficiency (γ-Hydroxybutyric Aciduria)

Clinical manifestations of SSADH deficiency usually begin in infancy with developmental delays with a disproportionate deficit in expressive language, hypotonia, and ataxia; seizures occur in approximately 50% of patients (see Fig. 103.11). Many patients also carry the diagnosis of **autism spectrum disorder** . Neuropsychiatric comorbidity (especially oppositional defiance, obsession-compulsion, and hyperactivity) can be disabling, particularly in adolescents and adults. Abnormal EEG findings include background slowing and generalized spike-wave paroxysms, with variable lateralization in hemispheric onset and voltage predominance. Photosensitivity and electrographic status epilepticus of sleep have been reported in combination with difficulties in sleep maintenance and excessive daytime somnolence. MRI of the brain shows an increased T2-weighted hyperintensity involving the globus pallidi, cerebellar dentate nuclei, and subthalamic nuclei, usually in a bilaterally symmetric distribution.

The biochemical hallmark, γ-hydroxybutyric acid (GHB), is elevated in physiologic fluids (CSF, plasma, urine) in all patients. Increased concentrations of GABA are also found in CSF. Heightened diagnostic suspicion evolves through documentation of elevated urinary GHB, and confirmation is achieved by molecular genetic testing.

Treatment remains elusive; vigabatrin (GABA-transaminase inhibitor) has been employed empirically, with mixed outcomes, and there is concern with its use as it further elevates CNS GABA in an already hyper-GABAergic disorder. Additionally, vigabatrin can cause constriction of the visual field and long-term use is contraindicated.

The gene for SSADH *(ALDH5A1)* is located on chromosome 6p22, and inheritance follows an autosomal-recessive pattern. **Prenatal diagnosis** has been achieved by measurement of GHB in the amniotic fluid, assay of the enzyme activity in the amniocytes, chorionic villus sampling, or DNA analysis.

Defects in Neurotransmitter Transporter Proteins

More than 20 different proteins are involved in transporting different neurotransmitters across the neuronal membranes. The main function of most of these transporters is to remove the excess neurotransmitters from the synaptic junction back into the presynaptic neurons (reuptake). This recycling process not only regulates the precise effect of neurotransmitters at the synaptic junction, but also resupplies the presynaptic neurons with neurotransmitters for future use. A few transporter proteins are involved in shuttling neurotransmitters from the neuronal cytoplasm across the membrane of synaptic vesicles for storage (vesicular transporters). On neuronal stimulation, these vesicles release a bolus of neurotransmitters through exocytosis. As expected, pathogenic variants in transporter proteins interfere with the proper reuptake and storage of neurotransmitters and may result in clinical manifestations similar to those seen in deficiencies of neurotransmitters metabolism. Several conditions caused by pathogenic variants of neurotransmitter protein transporters have been described, including dopamine transporter protein deficiency and dopamine-serotonin vesicular transporter disease.

Dopamine Transporter Protein Deficiency

This transporter protein is involved in reuptake of dopamine by the presynaptic neurons, and its deficiency causes depletion of dopamine and thus a dopamine deficiency state. Dopamine transporter protein (DAT) is encoded by *SLC6A3* gene on chromosome 5p15.33. Pathogenic variants of this gene has been reported in 13 children. These children presented with symptoms of infantile **parkinsonism-dystonia syndrome** . Irritability and feeding difficulties started shortly after birth and progressed to hypotonia, lack of head control, parkinsonism, dystonia, and global developmental delay by early infancy. Brain MRI usually shows no abnormalities.

CSF examination revealed elevation of HVA and normal level of 5-HIAAs. The urinary level of HVA and serum concentration of prolactin were increased. Diagnosis was established by demonstrating the loss-of-function mutation in the *SLC6A3* gene. *No effective treatment* has been identified; L -dopa/carbidopa did not result in improvements in clinical or biochemical parameters.

Dopamine-Serotonin Vesicular Transporter Disease (Vesicular Monoamine Transporter Deficiency)

This autosomal recessive condition, described in 8 children from a consanguineous Saudi Arabian family, is caused by a pathogenic variant in the

SLC18A2 gene. This gene encodes the vesicular monoamine transporter 2 (VMAT2), which is involved in transporting dopamine and serotonin from the cytoplasm into the synaptic storage vesicles located in the axonal terminals of the presynaptic neurons. Most affected children presented in the 1st yr of life with symptoms consistent with deficiencies of dopamine (hypotonia progressing into dystonia, parkinsonism, oculogyric crises), serotonin (sleep and psychiatric disturbances), and norepinephrine-epinephrine (excessive sweating, tremors, temperature instability, postural hypotension, ptosis). Neurocognitive delays become apparent in the 1st yr of life. No diurnal variation of the symptoms was noted. Brain imaging studies were within normal limits. Changes in the levels of CNS neurotransmitters and their metabolites have been inconsistent.

The phenotype resembles that seen in AADC and BH_4 deficiencies (see earlier). Diagnosis requires molecular analysis of *SLC18A2* (located on chromosome 10q25.3). **Treatment** with L -dopa/carbidopa caused exacerbation of symptoms, whereas pramipexole, a dopamine receptor agonist, resulted in a promising clinical response.

Histidine Decarboxylase Deficiency

Decarboxylation of histidine by histidine decarboxylase produces histamine, which functions as a neurotransmitter in the brain. Deficiency of this enzyme (expressed mainly in the posterior hypothalamus) results in deficiency of histamine in the CNS and in one family caused an autosomal dominant form of Tourette syndrome (see Chapter 103.13).

Hyperprolinemia

Intellectual disability and seizures are common findings in most patients with hyperprolinemia types I and II. Patients with **type I** hyperprolinemia typically show a benign clinical course but could have an increased risk of developing schizophrenia. The contribution of increased concentration of proline to the mechanisms of schizophrenia, however, remains unclear. The neurologic abnormalities observed in hyperprolinemia **type II** are mainly caused by development of vitamin B_6 dependency in this condition (see Chapter 103.9). Dietary intervention in hyperprolinemias type I and II is neither feasible nor recommended.

3-Phosphoglycerate Dehydrogenase Deficiency

See Chapter 103.8 .

Phosphoserine Aminotransferase Deficiency

See Chapter 103.8 .

Nonketotic Hyperglycinemia

See Chapter 103.7 .

Catabolism of amino acids results in the production of free ammonia, which in high concentration is toxic to the CNS. Mammals detoxify ammonia to urea through a series of reactions known as the **urea cycle** (Fig. 103.12), which is composed of 5 enzymes: carbamoyl phosphate synthetase 1 (**CPS1**), ornithine transcarbamylase (**OTC**), argininosuccinate synthetase (**ASS**), argininosuccinate lyase (**ASL**), and arginase 1. A 6th enzyme, *N* -acetylglutamate (NAG) synthetase (**NAGS**), catalyzes synthesis of NAG, which is an obligatory activator (effector) of the CPS1 enzyme. Individual deficiencies of these enzymes have been observed and, with an overall estimated prevalence of 1 in 35,000 live births, they are the most common genetic causes of hyperammonemia in infants.

HHH syndrome, Hyperammonemia-hyperornithinemia-homocitrullinemia.

Genetic Causes of Hyperammonemia

Hyperammonemia, sometimes severe, occurs in inborn errors of metabolism other than the urea cycle defects (Table 103.4 ; see also Table 102.5). The mechanisms of hyperammonemia in some of these conditions are diverse and include accumulation of toxic metabolites (e.g., organic acids), impaired transport of urea cycle intermediates (e.g., HHH syndrome), or depletion of urea cycle intermediates (e.g., lysinuric protein intolerance), leading to compromised function of the urea cycle.

Table 103.4

Inborn Errors of Metabolism Causing Hyperammonemia

- Deficiencies of the urea cycle enzymes
    - Carbamyl phosphate synthetase 1
    - Ornithine transcarbamylase
    - Argininosuccinate synthetase
    - Argininosuccinate lyase
    - Arginase 1

    - 3-Hydroxy-3-methylglutaric aciduria
- Lysinuric protein intolerance
- Hyperammonemia-hyperornithinemia-homocitrullinemia syndrome
- Transient hyperammonemia of the newborn
- Congenital hyperinsulinism with hyperammonemia

Clinical Manifestations of Hyperammonemia

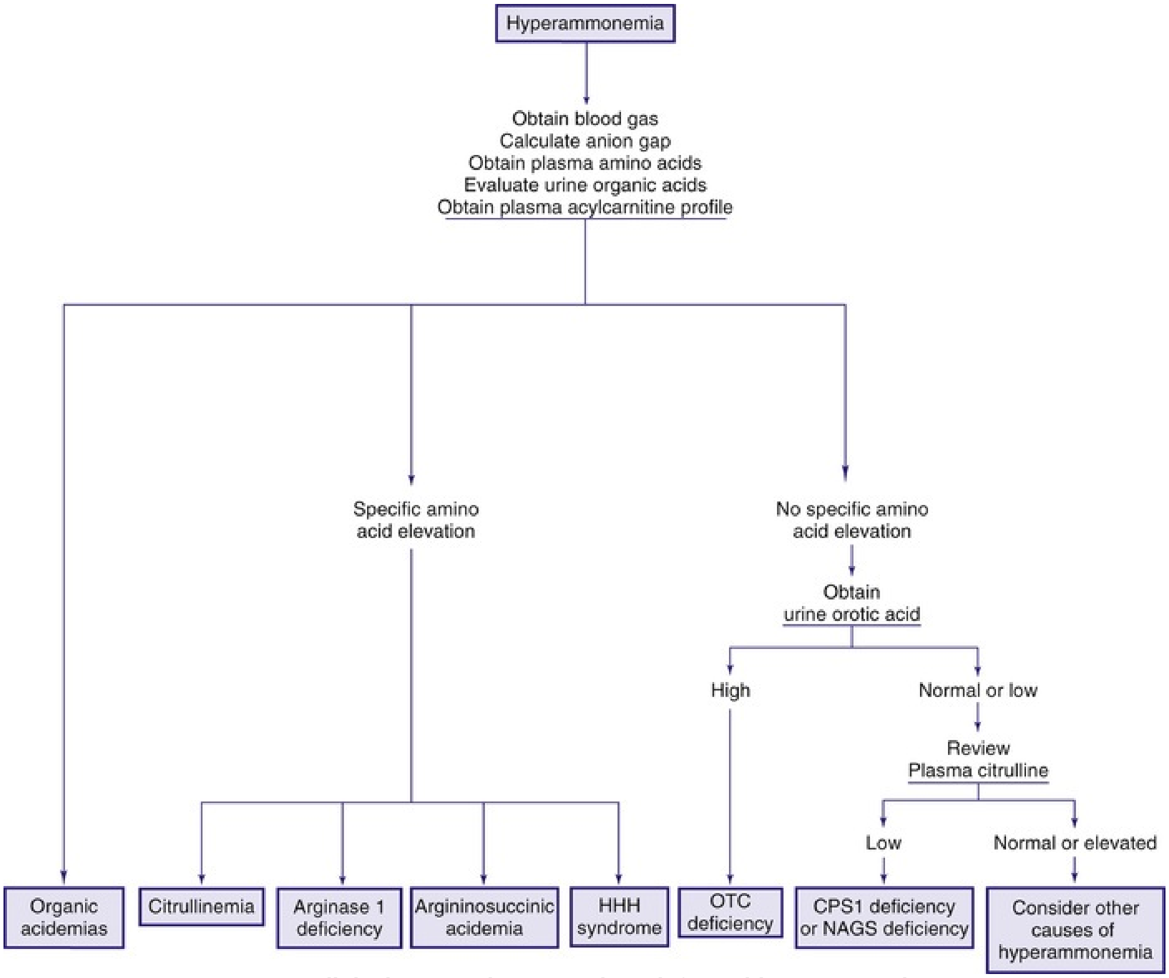
In the **neonatal period** , symptoms and signs are mostly related to brain dysfunction and are similar regardless of the cause of the hyperammonemia. The affected infant appears normal at birth but becomes symptomatic following the introduction of dietary protein. Refusal to eat, vomiting, tachypnea, and lethargy can quickly progress to a deep coma. Seizures are common. Physical examination may reveal hepatomegaly in addition to obtundation. Hyperammonemia can trigger increased intracranial pressure that may be manifested by a bulging fontanelle and dilated pupils.

In **infants and older children** , acute hyperammonemia is manifested by vomiting and neurologic abnormalities such as ataxia, confusion, agitation, irritability, combativeness, and psychosis. These manifestations may alternate with periods of lethargy and somnolence that may progress to coma.

Routine laboratory studies show no specific findings when hyperammonemia is caused by defects of the urea cycle enzymes. Blood urea nitrogen is usually low in these patients. Some patients may initially present with unexplained elevated serum alanine transaminase (ALT) and aspartate transaminase (AST) and even meet the criteria for acute liver failure. In infants with organic acidemias, hyperammonemia is commonly associated with severe *acidosis* as well as *ketonuria* . Newborn infants with hyperammonemia are often misdiagnosed as having sepsis; they may succumb without a correct diagnosis. Neuroimaging may reveal cerebral edema. Autopsy may reveal microvesicular steatosis, mild cholestasis, and fibrosis of the liver. Thus, because of the nonspecific presentation or urea cycle disorders, it is imperative to measure plasma ammonia levels in any ill infant with severe sepsis, unexplained liver dysfunction, recurrent emesis, or progressive encephalopathy.

Diagnosis

The main criterion for diagnosis is hyperammonemia. Each clinical laboratory should establish its own normal values for blood ammonia. Normal newborn values are higher than those of the older child or adult. Levels as high as 100 µmol/L can occur in healthy term infants. An ill infant usually manifests a blood ammonia level >150 µmol/L. Fig. 103.13 illustrates an approach to the differential diagnosis of hyperammonemia in the newborn infant. Careful inspection of individual plasma amino acids usually reveals abnormalities that may help the diagnosis. In patients with deficiencies of CPS1, OTC, or NAGS, frequent findings include elevations in plasma glutamine and alanine with concurrent decrements in citrulline and arginine. These disorders cannot be differentiated from one another by the plasma amino acid levels alone. A marked increase in urinary orotic acid in patients with OTC deficiency helps differentiate this defect from CPS1 deficiency. Differentiation between the CPS1 deficiency and the NAGS deficiency may require an assay of the respective enzymes or molecular analysis of the relevant genes. Clinical improvement occurring after oral administration of carbamylglutamate, however, may suggest NAGS deficiency. Patients with a deficiency of ASS, ASL, or arginase 1 have marked increases in the plasma levels of citrulline, argininosuccinic acid, or arginine, respectively. The combination of hyperammonemia and marked hypercitrullinemia or argininosuccinic acidemia is virtually pathognomonic for these disorders. Children with urea cycle defects often self-select a low-protein, high-carbohydrate diet, especially those with late-onset disease or symptomatic females with partial OTC deficiency.



Hyperammonemia

FIG. 103.13 Clinical approach to a newborn infant with symptomatic hyperammonemia. CPS1, Carbamoyl phosphate synthetase 1; HHH syndrome, hyperornithinemia-hyperammonemia-homocitrullinemia; NAGS, *N* -acetylglutamate synthetase; OTC, ornithine carbamoyltransferase.

Mass screening of newborn infants identifies patients with ASS, ASL, and arginase 1 deficiencies.

Treatment of Acute Hyperammonemia

Clinical outcome depends mainly on the severity and the duration of hyperammonemia. Serious neurologic sequelae are likely in newborns with severe elevations in blood ammonia (>300 µmol/L) for more than 12 hr. Thus, acute hyperammonemia should be treated promptly and vigorously. The goal of therapy is to lower the concentration of ammonia. This is accomplished by (1) removal of ammonia from the body in a form other than urea and (2) minimizing endogenous protein breakdown and favoring endogenous protein synthesis by providing adequate calories and essential amino acids (Table 103.5). Fluid, electrolytes, glucose (10–15%), and lipids (1-2 g/kg/24 hr) should be infused intravenously, together with minimal amounts of protein (0.25 g/kg/24 hr), preferably including essential amino acids. Oral feeding with a low-protein formula (0.5-1.0 g/kg/24 hr) through a nasogastric tube should be started as soon as sufficient improvement is seen.

Table 103.5

Treatment of Acute Hyperammonemia in an Infant

1. Provide adequate calories, fluid, and electrolytes intravenously (10% glucose, NaCl* and intravenous lipids 1 g/kg/24 hr). Add minimal amounts of protein preferably as a mixture of essential amino acids (0.25 g/kg/24 hr) during the 1st 24 hr of therapy.
2. Give priming doses of the following compounds:
   (To be added to 20 mL/kg of 10% glucose and infused within 1-2 hr)
   - Sodium benzoate 250 mg/kg †
   - Sodium phenylacetate 250 mg/kg †
   - Arginine hydrochloride 200-600 mg/kg as a 10% solution
3. Continue infusion of sodium benzoate † (250-500 mg/kg/24 hr), sodium phenylacetate † (250-500 mg/kg/24 hr), and arginine (200-600 mg/kg/24 hr ‡) following the above priming doses. These compounds should be added to the daily intravenous fluid.
4. Initiate peritoneal dialysis or hemodialysis if above treatment fails to produce an appreciable decrease in plasma ammonia.

[*] The concentration of sodium chloride should be calculated to be 0.45–0.9%, including the amount of the sodium in the drugs.

[†] Sodium from these drugs should be included as part of the daily sodium requirement.

[‡] The higher dose is recommended in the treatment of patients with citrullinemia and argininosuccinic aciduria. Arginine is not recommended in patients with arginase deficiency and in those whose hyperammonemia is secondary to organic acidemia. Sodium benzoate and sodium phenylacetate should be used with caution in patients with organic acidemias.

Because the kidneys clear ammonia poorly, its removal from the body must be expedited by formation of compounds with a high renal clearance. An important advance in the treatment of hyperammonemia has been the introduction of **acylation therapy** by using an exogenous organic acid that is acylated endogenously with nonessential amino acids to form a nontoxic compound with high renal clearance. The main organic acids used for this purpose are sodium salts of benzoic acid and phenylacetic acid. **Benzoate** forms hippurate with endogenous glycine in the liver (see Fig. 103.12). Each mole of benzoate removes 1 mole of ammonia as glycine. **Phenylacetate** conjugates with glutamine to form phenylacetylglutamine, which is readily excreted in the urine. One mole of phenylacetate removes 2 moles of ammonia as glutamine from the body (see Fig. 103.12). Sodium phenylbutyrate, metabolized to phenylacetate, is the primary oral formulation. For intravenous (IV) use, a combined formulation of benzoate and phenylacetate (Ammonul) is commercially available.

Another valuable therapeutic adjunct is IV infusion of **arginine** , which is effective in all patients (except those with arginase deficiency). Arginine administration supplies the urea cycle with ornithine (see Fig. 103.12). In patients with citrullinemia, 1 mole of arginine reacts with 1 mole of ammonia (as carbamoyl phosphate) to form citrulline. In patients with argininosuccinic acidemia, 2 moles of ammonia (as carbamoyl phosphate and aspartate) react with arginine to form argininosuccinic acid. Citrulline and argininosuccinate are less toxic than ammonia and more readily excreted by the kidneys. In patients with CPS1 or OTC deficiencies arginine administration is indicated because this amino acid is not produced in sufficient amounts to enable endogenous protein synthesis. For enteral therapy, patients with OTC deficiency benefit from supplementation with *citrulline* (200 mg/kg/24 hr) because 1 mole of citrulline reacts with 1 mole of ammonia (through aspartic acid) to form arginine. Administration of arginine or citrulline is contraindicated in patients with **arginase deficiency** , a rare condition in which the usual presenting clinical picture is spastic diplegia rather than hyperammonemia. Arginine therapy is of no benefit if hyperammonemia is secondary to an organic acidemia. In a newborn infant with an initial episode of hyperammonemia, arginine should be used until the diagnosis is established (see Table 103.5).

Benzoate, phenylacetate, and arginine may be administered together for maximal therapeutic effect. A priming dose of these compounds is followed by continuous infusion until recovery from the acute state occurs. Both benzoate and phenylacetate are usually supplied as concentrated solutions and should be properly diluted (1–2% solution) for IV use. The recommended therapeutic doses of both compounds deliver a substantial amount of sodium to the patient; this amount should be included in calculation of the daily sodiumn requirement. Benzoate and phenylacetate (or the combined formulation, Ammonul) should be used with caution in newborn infants with hyperbilirubinemia because they may displace bilirubin from albumin; however, there are no documented cases of kernicterus (see Chapter 123.4) reported in neonates with hyperammonemia who have received such therapies. In infants at risk, it is advisable to reduce bilirubin to a safe level while considering IV administration of benzoate or phenylacetate.

If the initial ammonia level is <500 µmol/L, and if the foregoing therapies fail within 4-6 hr to produce any appreciable change in the blood ammonia level, **hemodialysis** should be used. For patients presenting with an ammonia level >500 µmol/L, extracorporeal detoxification is the initial method of ammonia removal. Exchange transfusion has little effect on reducing total body ammonia. It should be used only if dialysis cannot be employed promptly or when the patient is a newborn infant with hyperbilirubinemia (see earlier). Hemodialysis dramatically lowers blood ammonia within a few hours, but if it is unavailable or technically unfeasible, peritoneal dialysis may be used as an alternative. When hyperammonemia is caused by an organic acidemia and hemodialysis is not available, peritoneal dialysis can be used to remove both the offending organic acid and ammonia.

Oral administration of **neomycin** limits growth of intestinal bacteria that can produce ammonia. However, this modality is of limited use in patients (e.g., affected neonates) in whom reduction of hyperammonemia is an urgent priority.

Oral **lactulose** acidifies the intestinal lumen, thereby reducing the diffusion of ammonia across the intestinal epithelium. This agent is of limited applicability in newborns, who have a high risk of acidemia and dehydration.

There has been interest in the use of **cooling** as a therapeutic adjunct in newborn infants with metabolic encephalopathy such as that caused by hyperammonemia. Clinical studies are in progress to evaluate the efficacy of this approach. There may be considerable lag between the normalization of ammonia level and an improvement in the patient's neurologic status. Several days may be needed before the infant becomes fully alert.

Long-Term Therapy

Once the infant is alert, therapy should be tailored to the underlying cause of the hyperammonemia. In general, all patients, regardless of the enzymatic defect, require protein restriction limited to age-adjusted recommended dietary allowance (RDA). In pediatric patients with defects in the urea cycle, chronic administration of sodium benzoate (250 mg/kg/24 hr), sodium phenylbutyrate (250-500 mg/kg/24 hr), and arginine (200-400 mg/kg/24 hr) or citrulline (in patients with OTC deficiency, 200-400 mg/kg/24 hr) is effective in maintaining blood ammonia levels within the normal range (shown doses are for patients who weigh <20 kg). Arginine and citrulline are contraindicated in patients with argininemia. Patients who have difficulty taking sodium phenylbutyrate can receive a trial of glycerol phenylbutyrate. This compound conceals the offensive odor of sodium phenylbutyrate and may help with patient adherence. Glycerol phenylbutyrate is not yet approved for use in children <2 months of age. Benzoate and phenylacetate may lower carnitine levels, but clinical signs of carnitine deficiency or benefit from carnitine supplementation have not yet been demonstrated. These compounds have been used during pregnancy without obvious teratogenic effect. However, experience is still limited, and appropriate caution should be exercised.

Growth parameters, especially head circumference, and nutritional indices (blood albumin, prealbumin, pH, electrolytes, amino acids, zinc, selenium) should be followed closely. Long-term care of these patients is best achieved by a team of experienced professionals (pediatrician, nutritionist, child neurologist, metabolic geneticist). Skin lesions resembling **acrodermatitis enteropathica** (see Chapter 691) have been noted in a few patients with different types of urea cycle defects, presumably from deficiency of essential amino acids, caused by overzealous dietary protein restriction. Catabolic states (infections, fasting) that may trigger hyperammonemia should be avoided. They must be treated vigorously if they occur. It is important that all children with urea cycle defects avoid valproic acid because this drug can elevate blood ammonia even in some healthy individuals. In patients with CPS1, OTC, or ASS deficiency, acute hyperammonemic attacks may be precipitated by valproate administration.

Carbamoyl Phosphate Synthetase 1 and *N* -Acetylglutamate Synthase Deficiencies

Deficiencies of these 2 enzymes produce similar clinical and biochemical manifestations (see Figs. 103.12 and 103.13). There is a wide variation in severity of symptoms and in the age at presentation. In near-complete enzymatic deficiency, symptoms appear during the 1st few days or even hours of life with signs and symptoms of hyperammonemia (refusal to eat, vomiting, lethargy, convulsion, coma). Increased intracranial pressure is frequent. Late forms (as late as the 4th decade of life) may present as an acute bout of hyperammonemia (lethargy, headache, seizures, psychosis) in a seemingly normal individual. Coma and death may occur during these episodes (a previously asymptomatic 26-yr-old female died from hyperammonemia during childbirth). Diagnostic confusion with migraine is common. Intermediate forms with intellectual disability and chronic subclinical hyperammonemia interspersed with bouts of acute hyperammonemia have also been observed.

Laboratory findings include hyperammonemia. The plasma amino acid analysis typically shows a marked increase of glutamine and alanine with relatively low levels of citrulline and arginine. These are nondiagnostic changes that occur in hyperammonemia of diverse cause. Urinary orotic acid is usually low or may be absent (see Fig. 103.13).

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are previously outlined (see Table 103.5). Patients with NAGS deficiency benefit from oral administration of carbamylglutamate. It is therefore important to differentiate between CPS1 and NAGS deficiencies by gene sequencing. Deficiency of NAGS is rare in North America.

CPS1 and NAGS deficiencies are inherited as an autosomal recessive trait; the

CPS1 enzyme is normally present in liver and intestine. The gene *(CPS1)* is mapped to chromosome 2q34. The prevalence of the condition is approximately 1 : 1,300,000. The gene for NAG synthetase *(NAGS)* is located on chromosome 17q21.31. Neither of these conditions is identified by the mass screening of the newborn infants.

Ornithine Transcarbamylase Deficiency

In this X-linked disorder, the hemizygous males are more severely affected than heterozygous females (see Figs. 103.12 and 103.13). The heterozygous females may have a mild form of the disease, but the majority (approximately 75%) remain asymptomatic, although investigations indicate subtle neurologic defects even in women without a frank history of hyperammonemia. Ornithine transcarbamylase (OTC) deficiency is the most common form of all the urea cycle disorders, comprising approximately 40% of cases of urea cycle disorders.

Clinical manifestations in a male newborn are usually those of **severe** hyperammonemia (see earlier) occurring in the 1st few days of life. **Mild forms** , such as in some heterozygous females, characteristically have episodic manifestations, which may occur at any age (usually after infancy). Episodes of hyperammonemia, manifested by vomiting and neurologic abnormalities (e.g., ataxia, mental confusion, agitation, combativeness, frank psychosis), are separated by periods of wellness. These episodes usually occur after ingestion of a high-protein diet or as a result of a catabolic state such as infection. Hyperammonemic coma, cerebral edema, and death may occur during one of these attacks. Cognitive development may proceed normally. Mild to moderate intellectual disability, however, is common. Gallstones have been seen in the survivors; the mechanism remains unclear.

The major **laboratory finding** during the acute attack is hyperammonemia accompanied by marked elevations of plasma concentrations of glutamine and alanine with low levels of citrulline and arginine. The blood level of urea is usually low. A marked increase in the urinary excretion of orotic acid differentiates this condition from CPS1 deficiency (see Fig. 103.13). Orotate may precipitate in urine as pink-colored gravel or stones. In the **mild form** , these laboratory abnormalities may revert to normal between attacks. This form should be differentiated from all the episodic conditions of childhood. In particular, patients with lysinuric protein intolerance (see Chapter 103.14) may demonstrate some features of OTC deficiency, but the former can be differentiated by increased urinary excretion of lysine, ornithine, and arginine and elevated blood concentrations of citrulline.

The **diagnosis** is most conveniently confirmed by gene analysis. As many as 20% of affected patients demonstrate a normal sequence, perhaps because the pathogenic variant involves copy number variants and pathogenic variants involving introns or a promoter region. Copy number variants can be evaluated using a chromosomal microarray, and if positive, a contiguous gene deletion should be considered. If the molecular diagnostic approach is negative, a liver biopsy may be indicated. Prenatal diagnosis is feasible by analysis of DNA in amniocytes or chorionic villus samples. Increase in urinary excretion of orotidine after an allopurinol loading test can identify female carriers. Mild cerebral dysfunction may be present in asymptomatic female carriers. The importance of a detailed family history should be emphasized. A history of migraine or protein aversion is common in maternal female relatives of the proband. Indeed, careful scrutiny of the family history may reveal a pattern of unexplained deaths in male newborns in the maternal lineage.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are previously outlined. For enteral use, citrulline is used in place of arginine in patients with OTC deficiency. Liver transplantation is a successful treatment for patients with severe OTC deficiency.

The gene for OTC has been mapped to the X chromosome (Xp21.1). Many disease-causing pathogenic variants (>300) have been identified. The prevalence of OTC deficiency is 1 : 56,000-1 : 77,000 live births. Genotype and the resulting degree of enzyme deficiency determine severity of the phenotype in most cases. Mothers of affected infants are expected to be carriers of the mutant gene unless a de novo pathogenic variant has occurred. A mother who gave birth to 2 affected male offspring was found to have a normal genotype, suggesting that gonadal mosaicism can be seen in some families. This condition is not identified by the mass screening of newborn infants.

Citrullinemia

Two clinically and genetically distinct forms of citrullinemia have been identified. The classic form (**type I**) is caused by the deficiency of the ASS enzyme. Citrullinemia **type II** is caused by the deficiency of a mitochondrial transport protein named *citrin* . (See Figs. 103.12 and 103.13 .)

Citrullinemia Type I (Argininosuccinate Synthetase Deficiency, Classic Citrullinemia)

This condition is caused by the deficiency of ASS (see Fig. 103.12) and has variable clinical manifestations depending on the degree of the enzyme deficiency. Two major forms of the condition have been identified. The **severe** or **neonatal form** , which is most common, appears in the 1st few days of life with signs and symptoms of hyperammonemia (see earlier). In the **subacute or mild form** , clinical findings such as failure to thrive, frequent vomiting, developmental delay, and dry, brittle hair appear gradually after 1 yr of age. Acute hyperammonemia, triggered by an intercurrent catabolic state, may bring the diagnosis to light.

Laboratory findings are similar to those found in patients with OTC deficiency, except that the plasma citrulline concentration is greatly elevated (50-100 times normal) (see Fig. 103.13). Urinary excretion of orotic acid is moderately increased; crystalluria may also occur as a result of precipitation of orotates. The diagnosis is confirmed by DNA analysis or less frequently by assay of enzyme activity in cultured fibroblasts. Prenatal diagnosis is feasible with enzyme assay in cultured amniotic cells or by DNA analysis of cells obtained from chorionic villus biopsy.

Treatment of acute hyperammonemic attacks and long-term therapy are outlined earlier (see Table 103.5). Plasma concentration of citrulline remains elevated at all times and may increase further after administration of arginine. Patients can do well on a protein-restricted diet in conjunction with sodium benzoate, phenylbutyrate, and arginine therapy. Mild to moderate cognitive impairment is a common sequela, even in a well-treated patient.

Citrullinemia is inherited as an autosomal recessive trait. The gene *(ASS1)* is located on chromosome 9q34.11. The majority of patients are compound heterozygotes for 2 different alleles. The prevalence of the condition is 1 : 250,000 live births. The recent introduction of neonatal screening for urea cycle defects has shown that some affected patients are ostensibly asymptomatic even with ingestion of a regular diet. Long-term follow-up is needed to be certain that these individuals do not sustain neurologic sequelae.

Citrin Deficiency (Citrullinemia Type II)

Citrin (aspartate-glutamate carrier protein) is a mitochondrial transporter encoded by a gene *(SLC25A13)* located on chromosome 7q21.3. One of this protein's functions is to transport aspartate from mitochondria into cytoplasm and replenish the cytosolic aspartate pool required for converting citrulline to argininosuccinic acid (see Fig. 103.12). If aspartate is unavailable to the cytoplasmic component of the urea cycle, urea will not be formed at a normal rate, and citrulline will accumulate. ASS activity is diminished in the liver of these patients, but no pathogenic variant in the *ASS1* gene has been found. It is postulated that citrin deficiency interferes with translation of messenger RNA for ASS enzyme in the liver. The condition initially was reported in Japan, but non-Japanese patients have also been identified. Two clinical forms of citrin deficiency have been described.

Neonatal Intrahepatic Cholestasis (Citrullinemia Type II, Neonatal Form)

Clinical and laboratory manifestations, which usually start before 1 yr of age, include cholestatic jaundice with mild to moderate direct (conjugated) hyperbilirubinemia, marked hypoproteinemia, clotting dysfunction (increased prothrombin time and partial thromboplastin time), and increased serum γ-glutamyltransferase and alkaline phosphatase activities; liver transaminases are usually normal. Plasma concentrations of ammonia and citrulline are usually normal, but moderate elevations have been reported. There may be increases in plasma concentrations of methionine, tyrosine, alanine, and threonine. Elevated levels of serum galactose have been found, even though the enzymes of galactose metabolism are normal. The reason for hypergalactosemia is not known. Marked elevation in the serum level of α-fetoprotein is also present. These findings resemble those of tyrosinemia type I, but unlike the latter condition, urinary excretion of succinylacetone is not elevated (see Chapter 103.2). Liver biopsy shows fatty infiltration, cholestasis with dilated canaliculi, and a moderate degree of fibrosis. The condition is usually self-limiting, and the majority of infants recover spontaneously by 1 yr of age with supportive and symptomatic treatment. Hepatic failure requiring liver transplantation has occurred in a few cases. Although the condition is commonly seen in Japan, the diagnosis should be considered in any case of unexplained neonatal hepatitis with cholestasis. Data on the long-term prognosis and the natural history of the condition are limited; development into the adult form of the condition after several years of seemingly asymptomatic hiatus has been observed.

Citrullinemia Type II, Adult Form (Adult-Onset Citrullinemia; Citrullinemia Type II, Mild Form)

This form of citrullinemia type II starts acutely in a previously apparently normal individual and manifests with neuropsychiatric symptoms such as disorientation, delirium, delusion, aberrant behavior, tremors, and frank psychosis. Moderate degrees of hyperammonemia and hypercitrullinemia are present. The age at onset is usually between 20 and 40 yr (range: 11 to >100 yr). Patients who recover from the 1st episode may have recurrent attacks. Pancreatitis, hyperlipidemia, and hepatoma are major complications among the survivors. Medical **treatment** has been mostly ineffective for prevention of future attacks. Diet enriched for protein and lipids helps restore cytosolic aspartate pool and stimulate ureagenesis. Indeed, some have speculated that the administration of large amounts of glucose might even prove deleterious, because the citrin transporter is important to the glycolytic pathway. Although liver transplantation appears to be effective in preventing future episodes of hyperammonemia, enteral supplementation with arginine, pyruvate, and medium-chain triglycerides can be tried first to improve hyperammonemic episodes and growth.

Several disease-causing mutations of the gene have been identified in affected Japanese and non-Japanese families. Although the frequency of homozygosity is relatively high in Japan (1 : 20,000 people), the clinical condition has a frequency of only 1 : 100,000 to 1 : 230,000. This indicates that a substantial number of homozygous individuals remain asymptomatic.

Argininosuccinate Lyase Deficiency (Argininosuccinic Aciduria)

The severity of the clinical and biochemical manifestations varies considerably (see Figs. 103.12 and 103.13). In severe form of ASL deficiency, signs and symptoms of severe hyperammonemia (see earlier) develop in the 1st few days of life, and without treatment, mortality can be high. Clinical course of ASL deficiency in patients who survive the initial acute episode can be characterized by intellectual disability, failure to thrive, hypertension, gallstones, liver fibrosis, and hepatomegaly. A common finding in untreated patients is dry and brittle hair (**trichorrhexis nodosa**). Acute attacks of severe hyperammonemia may occur during a catabolic state.

Laboratory findings include hyperammonemia, moderate elevations in liver enzymes, nonspecific increases in plasma levels of glutamine and alanine, a moderate increase in plasma levels of citrulline (less than in citrullinemia), and marked increase in the concentration of argininosuccinic acid in plasma, urine, and CSF. The CSF levels are usually higher than those in plasma. The enzyme is normally present in erythrocytes, the liver, and cultured fibroblasts. **Prenatal diagnosis** is possible by measurement of the enzyme activity in cultured amniotic cells or by identification of pathogenic variants in the *ASL* gene. Argininosuccinic acid is also elevated in the amniotic fluid of affected fetuses.

Treatment of acute hyperammonemic attacks and the long-term therapy of the condition are outlined earlier in this chapter. Intellectual disability, persistent hepatomegaly with mild increases in liver enzymes, and bleeding tendencies as a result of abnormal clotting factors are common sequelae. This deficiency is inherited as an autosomal recessive trait with a prevalence of about 1 in 220,000 live births. The gene *(ASL)* is located on chromosome 7q11.21. Early detection is achieved through mass screening of newborn infants.

Arginase 1 Deficiency (Hyperargininemia)

This defect is inherited as an autosomal recessive trait (see Figs. 103.12 and 103.13). There are 2 genetically distinct arginases in humans. One is cytosolic (ARG1) and is expressed in the liver and erythrocytes, and the other (ARG2) is found in renal and brain mitochondria. The gene for ARG1, the enzyme that is deficient in patients with arginase 1 deficiency, is mapped to chromosome 6q23.2. The role of the mitochondrial enzyme is not well understood; its activity increases in patients with argininemia but has no protective effect.

Clinical manifestations of this rare distal urea cycle disorder are somewhat different from those of other urea cycle enzyme defects, although acute neonatal form with intractable seizures, cerebral edema, and death has also been reported. The onset arginase 1 deficiency often is insidious; the infant can remain asymptomatic in the 1st few mo or yr of life. A **progressive spastic diplegia** with scissoring of the lower extremities, choreoathetotic movements, loss of developmental milestones, and failure to thrive in a previously normal infant may suggest a degenerative disease of the CNS. Some children were treated for years as cases of cerebral palsy before their arginase 1 deficiency was confirmed.

Intellectual disability is progressive; seizures are common, but episodes of severe hyperammonemia are not as frequent as in the more proximal urea cycle defects. Hepatomegaly may be present.

Laboratory findings include marked elevations of arginine in plasma and CSF (see Fig. 103.13). Urinary orotic acid can be increased. Determination of amino acids in plasma is a critical step in the diagnosis of argininemia. The guanidino compounds (α-keto-guanidinovaleric acid and α-keto-argininic acid) are markedly increased in urine. The diagnosis is confirmed by assaying arginase activity in erythrocytes or by the identification of the mutant gene.

Treatment consists of a low-protein diet providing the RDA. The composition of the diet and the daily intake of protein should be monitored by frequent plasma amino acid determinations. Sodium benzoate or sodium phenylbutyrate are also effective in controlling hyperammonemia and lowering plasma arginine levels. Intellectual disability is a common sequela of the condition. One patient developed type 1 diabetes by 9 yr of age while his argininemia was under good control. Liver transplantation has produced promising results, but experience with long-term outcome is limited. Early detection is feasible through mass screening of newborn infants.

Transient Hyperammonemia of the Newborn

The blood concentration of ammonia in full-term infants may be as high as 100 µmol/L, or 2-3 times greater than that of the older child or adult. Blood levels approach the adult normal values after a few weeks of life (see Fig. 103.13).

Severe transient hyperammonemia is observed in some newborn infants. The majority of affected infants are premature and have mild respiratory distress syndrome. Hyperammonemic coma may develop within 2-3 days of life, and the infant may succumb to the disease if treatment is not started immediately. Laboratory studies reveal marked hyperammonemia (plasma ammonia as high as 4,000 µmol/L) with moderate increases in plasma levels of glutamine and alanine. Plasma concentrations of urea cycle intermediate amino acids are usually normal except for citrulline, which may be moderately elevated. The cause of the disorder is unknown. Urea cycle enzyme activities are normal. **Treatment** of hyperammonemia should be initiated promptly and continued vigorously. Recovery without sequelae is common, and hyperammonemia does not recur even with a normal protein diet.

Disorders of Ornithine Metabolism

Ornithine, a key intermediate of the urea cycle, is not incorporated into natural proteins. Rather, it is generated in the cytosol from arginine and must be transported into mitochondria, where it becomes a substrate for the reaction catalyzed by OTC that forms citrulline. Excess ornithine is catabolized by 2 enzymes, ornithine aminotransferase, which is a mitochondrial enzyme converting ornithine to a proline precursor, and ornithine decarboxylase, which resides in the cytosol and converts ornithine to putrescine (see Fig. 103.12). Two genetic disorders feature **hyperornithinemia** : gyrate atrophy of the retina and hyperammonemia-hyperornithinemia-homocitrullinemia syndrome.

Gyrate Atrophy of the Retina and Choroid

This rare, autosomal recessive disorder is caused by deficiency of ornithine aminotransferase (see Fig. 103.12). Approximately 30% of the reported cases are from Finland. Clinical manifestations may include hyperammonemia in the 1st mo of life in some patients. Findings that define the phenotype of ornithine aminotransferase deficiency include night blindness, myopia, loss of peripheral vision, and posterior subcapsular cataracts. These eye changes start between 5 and 10 yr of age and progress to complete blindness by the 4th decade of life. Atrophic lesions in the retina resemble cerebral gyri. These patients usually have normal intelligence. Besides the characteristic 10-20–fold increase in plasma levels of ornithine (400-1,400 µmol/L), plasma levels of glutamate, glutamine, lysine, creatine, and creatinine can be moderately decreased. Some patients respond partially to high doses of pyridoxine. An arginine-restricted diet in conjunction with supplemental lysine, proline, and creatine has been successful in reducing plasma ornithine concentration and has produced some clinical improvement. The gene for ornithine aminotransferase *(OAT)* is mapped to chromosome 10q26.13. Many (at least 60) pathogenic variants have been identified in different families.

Hyperammonemia-Hyperornithinemia-Homocitrullinemia Syndrome

In this rare autosomal recessive disorder the defect is in the transport system of ornithine from the cytosol into the mitochondria, resulting in accumulation of ornithine in the cytosol and a depletion of this amino acid in mitochondria. The former causes hyperornithinemia, and the latter results in disruption of the urea cycle and hyperammonemia (see Fig. 103.12). Homocitrulline is presumably formed from the reaction of mitochondrial carbamoyl phosphate with lysine, which can become a substrate for the OTC reaction when ornithine is deficient. Clinical manifestations of hyperammonemia may develop shortly after birth or may be delayed until adulthood. Acute episodes of hyperammonemia manifest as refusal to feed, vomiting, and lethargy; coma may occur during infancy. Progressive neurologic signs, such as lower limb weakness, increased deep tendon reflexes, spasticity, clonus, seizures, and varying degrees of psychomotor retardation may develop if the condition remains undiagnosed. No clinical ocular findings have been observed in these patients. Laboratory findings reveal marked increases in plasma levels of ornithine and homocitrulline in addition to hyperammonemia (see Fig. 103.13). Acute episodes of hyperammonemia should be treated promptly (see earlier). Restriction of protein intake improves hyperammonemia. Oral supplementation with arginine (or citrulline) has produced clinical improvement in some patients. The gene for this disorder *(SLC25A15)* is located on chromosome 13q14.11.

Congenital Glutamine Deficiency

Glutamine is synthesized endogenously from glutamate and ammonia by a ubiquitous enzyme, glutamine synthetase (see Fig. 103.11). Glutamine is known to be involved in several important functions, including detoxification of ammonia. Deficiency of this enzyme, resulting in glutamine deficiency, has been reported in 3 infants from 3 unrelated families. All affected infants manifested multiorgan involvement, including significant brain malformations (abnormal gyrations, hypomyelination), facial abnormalities (broad nasal root, low-set ears), hypotonia and seizures at birth. Two of the patients died from multiorgan failure (respiratory and heart failure) in the neonatal period. One child was alive at 3 yr of age with severe developmental delay. Glutamine was absent in plasma, urine, and CSF, but plasma levels of glutamic acid were normal. Genetic defects of this enzyme underline the critical role of glutamine in embryogenesis, especially for normal brain development. The condition is inherited as an autosomal recessive trait; the gene for glutamine synthetase *(GLUL)* is mapped to chromosome 1q25.3.

Histidine

Oleg A. Shchelochkov, Charles P. Venditti

Keywords

histidine
L -histidine decarboxylase
urocanic acid

Histidine is degraded through the urocanic acid pathway to glutamic acid. Several genetic biochemical aberrations involving the degradative pathway of histidine have been reported, but the clinical significance of elevated histidine levels has not been established.

Decarboxylation of histidine by histidine decarboxylase produces histamine. Deficiency of this enzyme has been implicated in the familial form of **Tourette syndrome** (see Chapter 103.11).

GCDH
lysinuric protein intolerance
SLC7A7

Lysine is catabolized through 2 pathways. In the 1st pathway, lysine is condensed with α-ketoglutaric acid to form saccharopine. Saccharopine is then catabolized to α-aminoadipic semialdehyde and glutamic acid. These 1st 2 steps are catalyzed by α-aminoadipic semialdehyde synthase, which has 2 activities: lysine-ketoglutarate reductase and saccharopine dehydrogenase (Fig. 103.14). In the 2nd pathway, lysine is first transaminated and then condensed to its cyclic forms, pipecolic acid and piperideine-6-carboxylic acid (**P6C**). P6C and its linear form, α-aminoadipic semialdehyde, are oxidized to α-aminoadipic acid by the enzyme **antiquitin** . This is the major pathway for D -lysine in the body and for the L -lysine in the brain.

FIG. 103.14 Pathways in the metabolism of lysine. Enzymes: *(1)* Lysine ketoglutarate reductase, *(2)* saccharopine dehydrogenase, *(3)* α-aminoadipic semialdehyde/piperidine-6-carboxylic acid (P6C) dehydrogenase (antiquitin), *(4)* α-aminoadipic acid transferase, *(5)* α-ketoadipic acid dehydrogenase, *(6)* glutaryl-CoA-dehydrogenase. NE, Nonenzymatic; PDE, pyridoxine-dependent epilepsy.

Hyperlysinemia-saccharopinuria and **α-aminoadipic-α-ketoadipic acidemia** are biochemical conditions caused by inborn errors of lysine degradation. Individuals with these conditions are usually asymptomatic.

Pyridoxine (Vitamin B_6)–Dependent

Epilepsy

Pyridoxal 5′-phosphate (**P5P**), the active form of pyridoxine, is the cofactor for many enzymes including those involved in the metabolism of neurotransmitters. Intracellular P5P deficiency in the brain may result in a seizure disorder that is refractory to common anticonvulsant agents but is responsive to high doses of pyridoxine. These pyridoxine-responsive phenotypes are seen in the following genetic metabolic conditions:

Antiquitin (α-Aminoadipic Semialdehyde Dehydrogenase) Deficiency

This is the most common cause of pyridoxine-dependent epilepsy. Deficiency of antiquitin results in accumulation of P6C in brain tissue (see Fig. 103.14); P6C reacts with P5P and renders it inactive. Large doses of pyridoxine are therefore needed to overcome this inactivation. The condition is inherited as an autosomal recessive trait; the gene for antiquitin *(ALDH7A1)* is on chromosome 5q31.

Pyridox(am)ine 5′-Phosphate Oxidase (PNPO) Deficiency

PNPO deficiency clinically overlaps with antiquitin deficiency. PNPO-deficient patients often present with neonatal-onset seizures, developmental delays, spastic tetraplegia, and nonspecific findings on brain imaging (delayed myelination, cerebral atrophy, and abnormal signals in basal ganglia). Developmental regression, optic disc pallor, and retinopathy have been reported infrequently. Plasma and CSF amino acid analysis may reveal elevated glycine, prompting evaluation for nonketotic hyperglycinemia (see Chapter 103.7) and lead to a delay in initiating treatment with P5P. CSF neurotransmitter assay revealed inconsistent changes in the levels of 3-*O* -methyldopa, homovanillic acid, and 5-hydroxyindoleacetic acid. Normal CSF level of P5P was reported in one patient, suggesting that a therapeutic trial with P5P and molecular analysis may be a prudent strategy in some patients irrespective of the CSF studies. The lowest effective dose of P5P should be used to avoid toxicity. The disorder is caused by autosomal recessive pathogenic variants in *PNPO* .

Sulfite Oxidase Deficiency and Molybdenum Cofactor Deficiency

In this rare condition (see Chapter 103.4), accumulation of sulfites causes inhibition of enzymatic activity of antiquitin and accumulation of P6C, which in turn causes inactivation of P5P and vitamin B_6 dependency.

Hyperprolinemia Type II

In this condition, accumulation of Δ1-pyrroline-5-carboxylate (P5C) in brain tissue causes inactivation of P5P, leading to pyridoxine dependency (see Chapter 103.9 and Fig. 103.9).

Hypophosphatasia

Pyridoxal-5′-phosphate is the main circulating form of pyridoxine. Alkaline phosphatase (ALP) is required for dephosphorylation of P5P to generate free pyridoxine, which is the only form of vitamin B_6 that can cross the blood-brain barrier and enter the brain cells. Pyridoxine is rephosphorylated intracellularly to form P5P. In the infantile form of hypophosphatasia, P5P cannot be dephosphorylated to free pyridoxine because of marked deficiency of tissue-nonspecific ALP. This results in deficiency of pyridoxine in the brain and pyridoxine-dependent epilepsy (see Chapters 611 and 724).

The main **clinical manifestation** of pyridoxine-dependent epilepsy caused by antiquitin deficiency is generalized seizures, which usually occur in the first days of life and are unresponsive to conventional anticonvulsant therapies. Some mothers of affected fetuses report abnormal intrauterine fluttering movements. The seizures are usually tonic-clonic in nature but can be almost any type. Other manifestations such as dystonia, respiratory distress, and abdominal distention with vomiting, hepatomegaly, hypoglycemia and hypothermia may be present. Learning problems and speech delay are common sequelae. Late-onset forms of the condition (as late as 5 years of age) have been reported. Consequently, a trial with vitamin B_6 is recommended in any infant with intractable convulsions (see Chapters 611.04 and 611.06).

Laboratory findings show increased concentrations of α-aminoadipic semialdehyde and pipecolic acid in the CSF, plasma, and urine. EEG abnormalities may normalize after treatment. Neuroimaging may be normal but cerebellar and cerebral atrophy, periventricular hyperintensity, intracerebral hemorrhage, and hydrocephalus have been reported.

Treatment with vitamin B_6 (50-100 mg/day) usually results in a dramatic improvement of both seizures and the EEG abnormalities. High doses of pyridoxine can result in peripheral neuropathy, and doses >500 mg/day should be avoided. The pyridoxine dependency and thus the therapy are lifelong. The therapeutic benefit of a lysine-restricted diet is being evaluated.

Glutaric Aciduria Type 1 (Glutaryl-CoA Dehydrogenase Deficiency)

Glutaric acid is an intermediate in the degradation of lysine (see Fig. 103.14), hydroxylysine, and tryptophan. Glutaric aciduria **type 1** , a disorder caused by a deficiency of glutaryl-CoA dehydrogenase, should be differentiated from glutaric aciduria **type 2** , a distinct clinical and biochemical disorder caused by defects in the mitochondrial electron transport chain (see Chapter 104.1).

Clinical Manifestations

Macrocephaly is a common but nonspecific finding in patients with glutaric aciduria type 1. It develops in the 1st yr of life but can also be present at birth and precede the onset of neurologic manifestations. Some affected infants may also show subtle neurologic symptoms, such as delayed onset of motor milestones, irritability, and feeding problems, during this seemingly asymptomatic period. The onset of the condition is usually heralded by **acute encephalopathic findings** , such as loss of normal developmental milestones (head control, rolling over, or sitting), seizures, generalized rigidity, opisthotonos, choreoathetosis, and dystonia caused by acute striatal injury. These symptoms may occur suddenly in an apparently normal infant after a minor infection. Brain imaging reveals increased extraaxial (particularly frontal) fluid with stretched bridging veins, striatal lesions, dilated lateral ventricles, cortical atrophy (mainly in frontotemporal region), and fibrosis. Recovery from the 1st attack usually occurs slowly, but some residual neurologic abnormalities may persist, especially dystonia and choreoathetosis. Without treatment, additional acute attacks resembling the first can occur during subsequent episodes of intercurrent infections or catabolic states. In some patients these signs and symptoms may develop gradually in the 1st few yr of life. Hypotonia and choreoathetosis may gradually progress into rigidity and dystonia (**insidious form**). Acute episodes of metabolic decompensation with vomiting, ketosis, seizures, and coma also occur in this form after infection or other catabolic states. Without treatment, death may occur in the 1st decade of life during one of these episodes. Affected infants are prone to development of subdural hematoma and retinal hemorrhage following minor falls and head traumas. This can be misdiagnosed as child abuse. The intellectual abilities usually remain relatively normal in most patients.

Laboratory Findings

During acute episodes, mild to moderate metabolic acidosis and ketosis may occur. Hypoglycemia, hyperammonemia, and elevations of serum transaminases are seen in some patients. High concentrations of glutaric acid are usually found in urine, blood, and CSF. 3-Hydroxyglutaric acid may also be present in the body fluids. Acylcarnitine profile shows elevated glutarylcarnitine (C5-DC) in blood and urine. Plasma concentrations of amino acids are usually within normal limits. Laboratory findings may be unremarkable between attacks. Glutaric aciduria type 1 can be identified on the newborn screen by measuring glutarylcarnitine levels in blood spots. The sensitivity of this screening method depends on the cutoff value used by a newborn screen program, and some patients can be missed. For example, it can happen in a subset of patients with glutaric aciduria type 1 who may present with normal plasma and urinary levels of glutaric acid and variably elevated plasma glutarylcarnitine. This type of glutaric aciduria type 1 referred to as a “low-excretor” phenotype carries the same risk of developing brain injury as in a “high-excretor” phenotype. In some low-excreting patients, glutaric acid is elevated only in CSF. Urinary glutarylcarnitine appears to be a more sensitive screening method to identify affected low-excreting patients. In any child with progressive dystonia and dyskinesia, activity of the enzyme glutaryl-CoA dehydrogenase and molecular analysis of *GCDH* should be performed.

Treatment

Patients require lysine- and tryptophan-restricted diet while meeting physiologic requirements for protein, micronutrients, and vitamins. Increased dietary arginine may decrease cellular uptake of lysine and decrease the endogenous formation of glutaryl-CoA. Patients should be routinely evaluated for lysine and tryptophan deficiency by monitoring plasma amino acids and growth. L -Carnitine supplementation (50-100 mg/kg/24 hr orally) is recommended in all cases. Emergency treatment during acute illness, including temporary cessation of protein intake for 24 hr, replacement of lost calories using carbohydrates or lipids, IV L -carnitine, IV dextrose, prompt treatment of infection, and control of fever, is critical to decreasing the risk of striatal injury. All patients should be provided with an emergency letter describing the underlying diagnosis, recommended evaluation, and treatment. Early diagnosis through newborn screening with prevention and aggressive treatment of intercurrent catabolic states (infections) can help minimize striatal injury and ensure a more favorable prognosis. Patients with movement disorder and spasticity may require treatment with baclofen, diazepam, trihexyphenidyl, and injectable botulinum toxin A.

Glutaric aciduria type 1 is inherited as an autosomal recessive trait. The prevalence is estimated at 1 : 100,000 live births worldwide. The condition is more prevalent in some ethnic populations (Canadian Oji-Cree Indians, Irish Travelers, black South Africans, Swedes, and the Old Order Amish population in the United States). The gene for glutaryl-CoA dehydrogenase *(GCDH)* is located on chromosome 19p13.2. Molecular analysis of *GCDH* can aid in identifying patients with a low-excretor phenotype associated with specific pathogenic variants (e.g., p.M405V, p.V400M, p.R227P). High prevalence of known pathogenic variants in specific ethnic populations can enable a cost-effective molecular evaluation and counseling.

Prenatal diagnosis can be accomplished by demonstrating increased concentrations of glutaric acid in amniotic fluid, by assay of the enzyme activity in amniocytes or chorionic villus samples, or by identification of the known pathogenic variants in *GCDH* .

Lysinuric Protein Intolerance (Familial Protein Intolerance)

This rare autosomal recessive disorder is caused by a defect in the transport of the cationic amino acids lysine, ornithine, and arginine in both intestine and kidneys. Deficiency of the transporter protein (Y+L amino acid transporter 1) in this condition causes multisystem manifestations, which start initially with gastrointestinal (GI) symptoms. The transport defect in this condition resides in the basolateral (antiluminal) membrane of enterocytes and renal tubular epithelia. This explains the observation that cationic amino acids are unable to cross these cells even when administered as dipeptides. Lysine in the form of dipeptide crosses the luminal membrane of the enterocytes but hydrolyzes to free lysine molecules in the cytoplasm. Free lysine, unable to cross the basolateral membrane of the cells, diffuses back into the lumen.

Refusal to feed, nausea, aversion to protein, vomiting, and mild diarrhea, which may result in failure to thrive, wasting, and hypotonia, may be seen shortly after birth. Breastfed infants usually remain asymptomatic until soon after weaning, possibly because of the low-protein content of breast milk. Episodes of hyperammonemia may occur after ingestion of a high-protein meal. Mild to moderate hepatosplenomegaly, osteoporosis, sparse brittle hair, thin extremities with moderate centripetal adiposity, and growth retardation are common physical findings in patients whose condition has remained undiagnosed. Neurocognitive status is usually normal, but moderate intellectual disability has been observed in some patients.

Progressive interstitial pneumonitis with bouts of acute exacerbation often occurs in these patients. This usually progresses to severe alveolar proteinosis. Clinical manifestations include progressive exertional dyspnea, fatigue, cough, diminished breath sound, and inspiratory rales; cyanosis may develop in older patients. Some patients have remained undiagnosed until the appearance of pulmonary manifestations. Radiographic evidence of pulmonary fibrosis has been observed in up to 65% of patients without clinical manifestations of pulmonary involvement.

Renal involvement is manifested initially by proteinuria, hematuria, and elevation of serum creatinine, which may progress to end-stage renal failure. Renal tubular involvement with laboratory findings of renal Fanconi syndrome may also be present. Renal biopsy reveals pathologic findings consistent with glomerulonephritis and tubulointerstitial nephritis. Hematologic findings of anemia, leukopenia, thrombocytopenia, and elevated ferritin may also be present. A condition resembling hemophagocytic lymphohistiocytosis/macrophage activation syndrome has also been reported. Immunologic abnormalities (impaired lymphocyte function, abnormalities in immune globulins, hypocomplementemia) and acute pancreatitis are frequent features of lysinuric protein intolerance.

Laboratory findings may reveal hyperammonemia and an elevated concentration of urinary orotic acid, which develop after high-protein feeding. Plasma concentrations of lysine, arginine, and ornithine are usually mildly decreased, but urinary levels of these amino acids, especially lysine, are greatly increased. The pathogenesis of hyperammonemia is likely related to the depletion of urea cycle intermediates caused by poor absorption and the increased renal loss of ornithine and arginine. Plasma concentrations of alanine, glutamine, serine, glycine, and proline are usually increased. Anemia, increased serum levels of ferritin, lactate dehydrogenase (LDH), thyroxine-binding globulin, hypercholesterolemia, and hypertriglyceridemia are common findings. This condition should be differentiated from hyperammonemia caused by urea cycle defects (see Chapter 103.12), especially in heterozygous females with OTC deficiency, in whom increased urinary excretion of lysine, ornithine, and arginine is not seen.

Treatment with a low-protein diet providing the RDA of protein and supplemented with oral citrulline (50-100 mg/kg/day) can produce biochemical and clinical improvements. Episodes of hyperammonemia should be treated promptly (see Chapter 103.12). Supplementation with lysine (10-30 mg/kg/day) given in small and frequent doses helps improve plasma levels. The dose of lysine should be titrated down if patients develop abdominal pain and diarrhea. Treatment with high doses of prednisone has been effective in the management of acute pulmonary complications in some patients. **Bronchopulmonary lavage** is the treatment of choice for patients with alveolar proteinosis. The condition is more prevalent in Finland and Japan, where the prevalence is 1 : 60,000 and 1 : 57,000 live births, respectively.

The gene for lysinuric protein intolerance *(SLC7A7)* is mapped to chromosome 14q11.2. Pregnancies in affected mothers have been complicated by anemia, thrombocytopenia, toxemia, and bleeding, but offspring have been normal.

N -Acetylaspartic Acid (Canavan Disease)

Reuben K. Matalon, Joseph M. Trapasso

Keywords

Canavan disease
atypical Canavan disease
N -acetylaspartic acid
NAA
ASPA
aspartoacylase
recombinant adeno-associated viruses
rAAVs
blood-brain barrier
leukodystrophy
progressive macrocephaly

N -Acetylaspartic acid (**NAA**), a derivative of aspartic acid, is synthesized in the brain and is found in a high concentration similar to glutamic acid. Studies suggest that NAA has multiple functions, such as serving as an acetate reservoir for myelin synthesis and being an organic osmolyte that helps regulate cerebral osmolality. However, the complete function of NAA is not yet fully understood. **Aspartoacylase** cleaves the *N* -acetyl group from NAA. Deficiency of aspartoacylase leads to **Canavan disease** , a severe **leukodystrophy** characterized by excessive excretion of NAA and spongy degeneration of the white matter of the brain. Canavan disease is an autosomal recessive disorder and is more prevalent in individuals of Ashkenazi Jewish descent than in other ethnic groups. The defective gene for Canavan disease *(ASPA)* is located on chromosome 17, and genetic testing can be offered for patients, family members, and at-risk populations.

Etiology and Pathology

The deficiency of the enzyme aspartoacylase leads to NAA accumulation in the brain, especially in white matter, and massive urinary excretion of this compound. Excessive amounts of NAA are also present in the blood and CSF. Brain biopsies of patients with Canavan disease show spongy degeneration of the myelin fibers, astrocytic swelling, and elongated mitochondria. There is striking vacuolization and astrocytic swelling in white matter. Electron microscopy reveals distorted mitochondria. As the disease progresses, the ventricles enlarge because of cerebral atrophy.

Clinical Manifestations

The severity of Canavan disease covers a wide spectrum. Infants usually appear normal at birth and may not manifest symptoms of the disease until 3-6 mo of age, when they develop **progressive macrocephaly** , severe hypotonia, persistent head lag, and delayed milestones. As the disease progresses, there is spasticity, joint stiffness, and contractures. Optic atrophy and seizures develop. Feeding difficulties, poor weight gain, and gastroesophageal reflux may occur in the 1st yr of life; swallowing deteriorates, and nasogastric feeding or permanent gastrostomy may be required. In the past, most patients died in the 1st decade of life, but with the advances in medical technology and improved supportive care, now they often survive to the 2nd or 3rd decade.

Atypical Canavan Disease

Juvenile or **mild** Canavan disease is less common than **infantile** Canavan disease and is most prevalent in non-Ashkenazi Jews. Affected patients with juvenile Canavan disease usually present with mild speech and motor delay and may have **retinitis pigmentosa** . The other typical features of Canavan disease are usually not present. These children have moderately increased urinary excretion of NAA, which suggests Canavan disease. Brain MRI demonstrates increased signal intensity in the basal ganglia rather than global white matter disease, sometimes leading to confusion with mitochondrial disease.

Diagnosis

In a typical patient with Canavan disease, CT scan and MRI reveal diffuse white matter degeneration, primarily in the cerebral hemispheres, with less involvement of the cerebellum and brainstem (Fig. 103.15). Repeated evaluations may be required. MRS performed at the time of MRI can be done to show the high peak of NAA, suggesting Canavan disease. The diagnosis can also be established by finding elevated amounts of NAA in the urine or blood. NAA is found only in trace amounts (24 ±16 µmol/mmol creatinine) in the urine of unaffected individuals, whereas in patients with Canavan disease its concentration is in the range of 1,440 ±873 µmol/mmol creatinine. High levels of NAA can also be detected in plasma, CSF, and brain tissue. Aspartoacylase in fibroblasts is often used to confirm the diagnosis but is not necessary. The activity of aspartoacylase in the fibroblasts of obligate carriers is half or less the activity found in normal individuals. Genotyping of patients with Canavan disease should always be done and will show mutations of *ASPA* . The differential diagnosis of Canavan disease should include **Alexander disease** , which is another leukodystrophy associated with macrocephaly. Alexander disease is caused by a defect in the synthesis of glial fibrillary acidic protein, and the diagnosis can be ruled out by molecular diagnosis on blood lymphocytes.

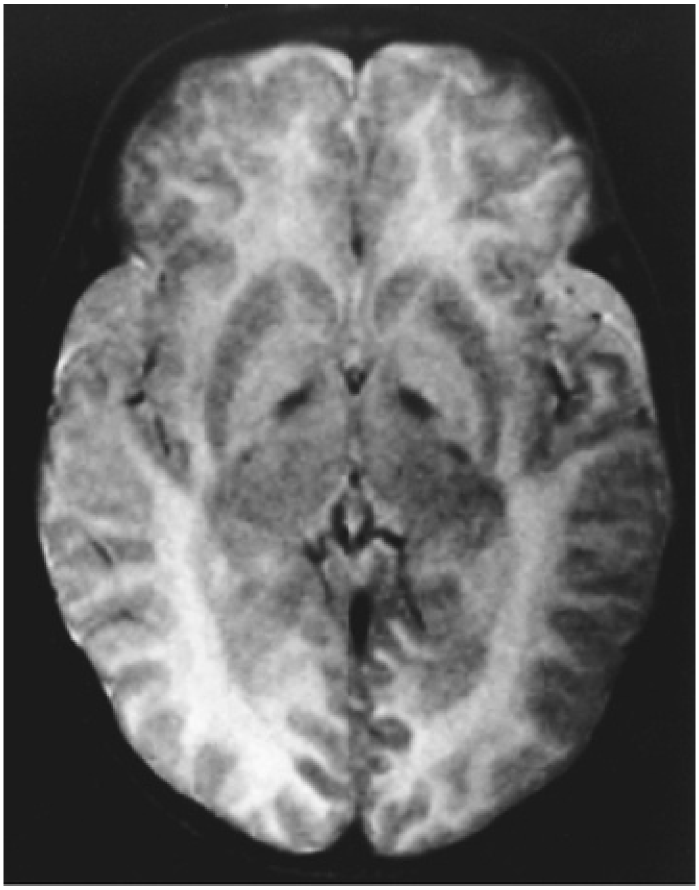

FIG. 103.15 Axial T-weighted MRI of a 2 yr old patient with Canavan disease. Extensive thickening of the white matter is seen.

There are 2 predominant pathogenic variants leading to Canavan disease in the Ashkenazi Jewish population. The first is an amino acid substitution (E285A) in which glutamic acid is substituted for alanine. This mutation is the most frequent and encompasses 83% of 100 mutant alleles examined in Ashkenazi Jewish patients. The 2nd common pathogenic variant is a change from tyrosine to a nonsense mutation, leading to a stop in the coding sequence (Y231X). This accounts for 13% of mutant alleles. In the non-Jewish population, more diverse pathogenic variants have been observed, and the 2 variants common in Jewish people are rare. A different mutation (A305E), the substitution of alanine for glutamic acid, accounts for 40% of 62 mutant alleles in non-Jewish patients. More than 50 pathogenic variants are described in the non-Jewish population. With Canavan disease, it is important to obtain a molecular diagnosis because this will lead to accurate counseling and prenatal guidance for the family. If the mutations are not known, **prenatal diagnosis** relies on the NAA level in the amniotic fluid. In Ashkenazi Jewish patients, the carrier frequency can be as high as 1 : 40, which is close to that of Tay-Sachs disease. Carrier screening for Canavan disease is available for Jewish individuals. Genotype phenotype correlation and aspartoacylase expression show that expression studies may aid in understanding the disease.

Patients with juvenile or mild forms of Canavan disease have been compound heterozygotes with a mild pathogenic variant on one allele and a severe variant on the other allele. Mild variants include p.Tyr288Cys and p.Arg71His.

Treatment and Prevention

No specific treatment is currently available. Recent studies of gene therapy using recombinant adeno-associated viruses (**rAAVs**) have shown some positive results in rescuing knockout mice but have yet to be tested in humans. Feeding problems and seizures should be treated on an individual basis. Genetic counseling, carrier testing, and prenatal diagnosis are the only methods of prevention. Gene therapy attempts in children with Canavan disease have shown lack of long-term adverse events, some decrease in the brain elevation of *N* -acetylaspartic acid, improved seizure frequency, and stabilization of overall clinical status.

CHAPTER 104

Defects in Metabolism of Lipids

104.1

Disorders of Mitochondrial Fatty Acid β-Oxidation

Charles A. Stanley, Michael J. Bennett

Keywords

fatty acid oxidation defects
carnitine cycle
newborn screening
hypoglycemia
medium-chain acyl-CoA dehydrogenase deficiency
liver disease
cardiomyopathy
rhabdomyolysis
fasting intolerance
mitochondrial metabolism
Reye syndrome

Mitochondrial β-oxidation of fatty acids is an essential energy-producing pathway. It is particularly important during prolonged periods of starvation and during periods of reduced caloric intake caused by gastrointestinal illness or increased energy expenditure during febrile illness. Under these conditions, the body switches from using predominantly *carbohydrate* to predominantly *fat* as its major fuel. Fatty acids are also important fuels for exercising skeletal muscle and are the preferred substrate for normal cardiac metabolism. In these tissues, fatty acids are completely oxidized to carbon dioxide and water. The end products of hepatic fatty acid oxidation are the ketone bodies β-*hydroxybutyrate* and *acetoacetate*. These cannot be oxidized by the liver but are exported to serve as important fuels in peripheral tissues, particularly the brain, where ketone bodies can partially substitute for glucose during periods of fasting.

Genetic defects have been identified in almost all the known steps in the fatty acid oxidation pathway; all are recessively inherited (Table 104.1).

Table 104.1

Mitochondrial Fatty Acid Oxidation Disorders—Clinical and Biochemical Features

ENZYME DEFICIENCY	GENE	CLINICAL PHENOTYPE	LABORATORY FINDINGS
Carnitine transporter	*OCTN2* *SLC22A5*	Cardiomyopathy, skeletal myopathy, liver disease, sudden death, endocardial fibroelastosis, prenatal and newborn screening diagnosis reported	↓ Total and free carnitine, normal acylcarnitines, acylglycine, and organic acids
Long-chain fatty acid transporter	*FATP1-6*	Rare, acute liver failure in childhood requiring liver transplantation	↓ intracellular C_{14} -C_{18} fatty acids, ↓ fatty acid oxidation
Carnitine palmitoyl transferase-I	*CPT-IA*	Liver failure, renal tubulopathy, and sudden death. Prenatal and newborn screening diagnosis reported, maternal preeclampsia, HELLP syndrome association described in a few patients.	Normal or ↑ free carnitine, normal acylcarnitines, acylglycine, and organic acids
Carnitine acylcarnitine translocase	*CACT* *SLC25A20*	Chronic progressive liver failure, persistent ↑ NH_3 , hypertrophic cardiomyopathy. Newborn screening diagnosis reported.	Normal or ↓ free carnitine, abnormal acylcarnitine profile
Carnitine palmitoyl transferase-II	*CPT-II*	Early and late onset types. Liver failure, encephalopathy, skeletal myopathy, cardiomyopathy, renal cystic changes, newborn screening diagnosis reported. Adult form with acute rhabdomyolysis, myoglobinuria.	Normal or ↓ free carnitine, abnormal acylcarnitine profile
Short-chain acyl-CoA dehydrogenase	*SCAD* *ACADS*	Clinical phenotype unclear. Many individuals appear to be normal. Others have a variety of inconsistent signs and symptoms. Subset may have severe manifestations of unclear relationship to biochemical defects. Newborn screening diagnosis reported; significance	Normal or ↓ free carnitine, elevated urine ethylmalonic acid, inconsistently abnormal acylcarnitine profile

		being questioned.	
Medium-chain acyl-CoA dehydrogenase	*MCAD* *ACADM*	Hypoglycemia, hepatic encephalopathy, sudden death. Newborn screening diagnosis possible, maternal preeclampsia, HELLP syndrome association described rarely, possible long Qt interval.	Normal or ↓ free carnitine, ↑ plasma acylglycine, plasma C_6-C_{10} free fatty acids, ↑ C_8-C_{10} acyl-carnitine
Very long-chain acyl-CoA dehydrogenase	*VLCAD* *ACADVL*	Dilated cardiomyopathy, arrhythmias, hypoglycemia, and hepatic steatosis. Late-onset, stress-induced rhabdomyolysis, episodic myopathy. Prenatal and newborn screening diagnosis possible.	Normal or ↓ free carnitine, ↑ plasma $C_{14:1}$, C_{14} acylcarnitine, ↑ plasma C_{10}-C_{16} free fatty acids
ETF dehydrogenase*	*ETF-DH*	Nonketotic fasting hypoglycemia, congenital anomalies, milder forms of liver disease, cardiomyopathy, and skeletal myopathy. Newborn screening diagnosis reported.	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ acylcarnitine, urine organic acid and acylglycines
ETF-α*	*α-ETF*	Nonketotic fasting hypoglycemia, congenital anomalies, liver disease, cardiomyopathy, and skeletal myopathy also described. Newborn screening diagnosis reported.	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ acylcarnitine, urine organic acid and acylglycines
ETF-β*	*β-ETF*	Fasting hypoglycemia, congenital anomalies, liver disease, cardiomyopathy, and skeletal myopathy also described. Newborn screening diagnosis reported.	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ acylcarnitine, urine organic acid and acylglycines
Short-chain L-3-hydroxyacyl-CoA dehydrogenase	*SCHAD* *HAD1*	Hyperinsulinemic hypoglycemia, cardiomyopathy, myopathy. Newborn screening diagnosis reported.	Normal or ↓ free carnitine, elevated free fatty acids, inconsistently abnormal urine organic acid, ↑ 3-OH glutarate, ↑ plasma C_4-OH acylcarnitine
Long-chain L-3-hydroxyacyl-CoA dehydrogenase	*LCHAD* *HADH-A*	Newborn screening diagnosis reported, maternal preeclampsia, HELLP syndrome, and AFLP association described frequently. See also MTP below for clinical manifestations.	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ free fatty acids, ↑ C_{16}-OH and C_{18}-OH carnitines
MTP	*HADH-A*, *HADH-B*	Severe cardiac and skeletal myopathy, hypoglycemia, acidosis, hyper NH_3, sudden death, elevated liver enzymes, retinopathy. Maternal preeclampsia, HELLP syndrome, and AFLP association described frequently.	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ free fatty acids, ↑ C_{16}-OH and C_{18}-OH carnitines
Long-chain 3-ketoacyl-CoA thiolase	*LKAT* *HADH-B*	Severe neonatal presentation, hypoglycemia, acidosis, ↑ creatine kinase, cardiomyopathy, neuropathy, and early death	Normal or ↓ free carnitine, increased ratio of acyl:free carnitine, ↑ free fatty acids, ↑ 2-*trans*, 4-*cis*-decadienoylcarnitine
Short-chain 2,3-enoyl-CoA hydratase	*ECHS1*	Leigh disease, lactic acidosis, seizures, cystic degeneration of white matter, microcephaly, metabolic acidosis, extrapyramidal dystonia, dilated cardiomyopathy	Abnormal organic acids, 2-methacrylglycine, 2-methyl-2,3 dihydroxybutyrate, also S-(2-carboxypropyl)cysteine, S-(2-carboxyethyl) cysteamine. Acylcarnitine shows ↑ C4OH (inconsistently).
2,4-Dienoyl-CoA reductase	*DECR1*	Only 1 patient described, hypotonia in the newborn, mainly severe skeletal myopathy	Normal or ↓ free carnitine, ↑ acyl:free carnitine ratio,

		and respiratory failure. Hypoglycemia rare.	normal urine organic acids and acylglycines
HMG CoA synthetase	*HMGCS2*	Hypoketosis and hypoglycemia, rarely myopathy	↑ total plasma fatty acids, enzyme studies in biopsied liver may be diagnostic, genetic testing preferred
HMG CoA lyase	*HMGCL*	Hypoketosis and hypoglycemia, rarely myopathy	Normal free carnitine, ↑ C_5 -OH, and methylglutarylcarnitine, enzymes studies in fibroblasts may be diagnostic
Monocarboxylate transporter 1 (MCT1)	*SLC16A1*	Severe fasting induced ketoacidosis, rarely hypoglycemia	Profound ketoacidosis; no specific biomarkers yet identified

[*] Also known as glutaric acidemia type II or multiple acyl-CoA dehydrogenase defect (MADD).

AFLP, Acute fatty liver of pregnancy; CoA, coenzyme A; ETF, electron transport flavoprotein; HELLP, hemolysis, elevated liver enzymes, low platelets; MTP, mitochondrial trifunctional protein; NH_3 , ammonia.

From Shekhawat PS, Matern D, Strauss AW: Fetal fatty oxidation disorders, their effect on maternal health and neonatal outcome: impact of expanded newborn screening on their diagnosis and management, *Pediatr Res* 57:78R–84R, 2005.

Clinical manifestations characteristically involve tissues with a high β-oxidation flux, including liver, skeletal, and cardiac muscle. The most common presentation is an acute episode of life-threatening coma, hepatic encephalopathy, and hypoglycemia induced by a period of fasting resulting from defective hepatic ketogenesis. Other manifestations may include chronic cardiomyopathy and muscle weakness or exercise-induced acute rhabdomyolysis. The fatty acid oxidation defects can often be asymptomatic during periods when there is no fasting stress or increased energy demand. Acutely presenting disease may be misdiagnosed as **Reye syndrome** or, if fatal, as **sudden unexpected infant death** . Fatty acid oxidation disorders are easily overlooked because the only specific clue to the diagnosis may be the finding of inappropriately low concentrations of plasma or urinary ketones in an infant who has hypoglycemia, unless specialized metabolic testing is performed. Genetic defects in ketone body utilization may also be overlooked because ketonemia is an expected finding with fasting hypoglycemia. In some circumstances, clinical manifestations appear to arise from toxic effects of fatty acid metabolites rather than inadequate energy production. These circumstances include certain long-chain fatty acid oxidation disorders (deficiencies of long-chain 3-hydroxyacyl dehydrogenase [**LCHAD**], carnitine palmitoyltransferase-IA [**CPT-IA**], or mitochondrial trifunctional protein [**MTP** ; also known as TFP]) in which the presence of a homozygous affected fetus increases the risk of a life-threatening illness in the heterozygote mother, resulting in **acute fatty liver of pregnancy** (AFLP) or **preeclampsia with HELLP** (hemolysis, elevated liver enzymes, low platelets) syndrome. The mechanism of these obstetric complications is likely accumulation of toxic intermediates. Malformations of the brain and kidneys have been described in severe deficiencies of electron transfer flavoprotein (**ETF**), ETF dehydrogenase (**ETF-DH**), and carnitine palmitoyltransferase-II (**CPT-II**), which might reflect in utero toxicity of fatty acid metabolites or a developmental role for these enzymes. Progressive retinal degeneration, peripheral neuropathy, and chronic progressive liver disease have been identified in LCHAD and MTP deficiency. Newborn screening programs using tandem mass spectrometry detect characteristic plasma acylcarnitine profiles in most of these disorders, allowing early and presymptomatic diagnosis. Screening programs have demonstrated that all the fatty acid oxidation disorders combined are among the most common inborn errors of metabolism, at least in predominantly Caucasian populations.

Figs. 104.1 and 104.2 outline the steps involved in the oxidation of a typical long-chain fatty acid. In the *carnitine cycle* , long-chain fatty acids are transported across the barrier of the inner mitochondrial membrane as acylcarnitine esters. (Medium-chain fatty acids, which are commonly provided as medium-chain triglyceride supplementation in infants who are failing to thrive, can bypass the carnitine cycle and enter the mitochondrial β-oxidation cycle directly.) Within the mitochondria, successive turns of the 4-step *β-oxidation cycle* convert the **coenzyme A (CoA)** –activated fatty acids to acetyl-CoA units. Two or 3 different specific isoenzymes are needed for each of these β-oxidation steps to accommodate the different chain-length fatty acyl-CoA species. The electrons generated in the first β-oxidation step (acyl-CoA dehydrogenase) are carried by the *electron transfer pathway* to the *electron transport chain* at the level of coenzyme Q for adenosine triphosphate production; while electrons generated from the 3rd step (3-hydroxyacyl-CoA dehydrogenase) enter the *electron transport chain* at the level of complex 1. Most of the acetyl-CoA generated from fatty acid β-oxidation in the liver flows through the *pathway of ketogenesis* to form β-hydroxybutyrate and acetoacetate, whereas in muscle and heart the fatty acids are completely oxidized to CO_2 and water.

FIG. 104.1 **Mitochondrial fatty acid oxidation. Carnitine enters the cell through the action of the organic cation/carnitine transporter (OCTN2). Palmitate, a typical 16-carbon long-chain fatty acid, is transported across the plasma membrane and can be activated to form a long-chain (LC) fatty acyl coenzyme A (CoA). It then enters into the carnitine cycle, where it is transesterified by carnitine palmitoyltransferase-I (CPT-I), translocated across the inner mitochondrial membrane by carnitine/acylcarnitine translocase (TRANS), and then reconverted into a long-chain fatty acyl-CoA by carnitine palmitoyltransferase-II (CPT-II) to undergo β-oxidation. Very-long-chain acyl-CoA dehydrogenase (VLCAD/LCAD) leads to the production of $(C_{16} -C_{10})$ 2,3-enoyl CoA. Mitochondrial trifunctional protein (MTP) contains the activities of enoyl CoA hydratase (hydratase), 3-OH-hydroxyacyl-CoA dehydrogenase (3-OH-ACD), and β-ketothiolase (thiolase). Acetyl-CoA, reduced form of flavin adenine dinucleotide (FADH), and reduced form of nicotinamide adenine dinucleotide (NADH) are produced. Medium- and short-chain fatty acids (C8-4) can enter the mitochondrial matrix independent of the carnitine cycle. Medium-chain acyl-CoA dehydrogenase (MCAD), short-chain acyl-CoA dehydrogenase (SCAD), and short-chain hydroxy acyl-CoA dehydrogenase (SCHAD) are required. Acetyl-CoA can then enter the Krebs (TCA) cycle. Electrons are transported from FADH to the respiratory chain via the electron transfer flavoprotein (ETF) and the electron transfer flavoprotein dehydrogenase (ETF-DH). NADH enters the electron transport chain through complex I. In liver, acetyl-CoA can be converted into hydroxymethylglutaryl (HMG) CoA by β-hydroxy-β-methylglutaryl-CoA synthase (HMG CoA synthase) and then the ketone body acetoacetate by the action of β-hydroxy-β-methylglutaryl-CoA lyase (HMG-CoA lyase).**

Defects in the β-Oxidation Cycle

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase (**MCAD**) deficiency is the most common fatty acid oxidation disorder. The disorder shows a strong founder effect; most patients have a northwestern European ancestry, and the majority of these patients are homozygous for a single common MCAD missense mutation, an A-G transition at cDNA position 985 (c.985A>G) that changes a lysine to glutamic acid at residue 329 (p.K329E).

Clinical Manifestations

Previously undiagnosed affected patients usually present in the 1st 3 mo to 5 yr of life with episodes of acute illness triggered by prolonged fasting (>12-16 hr). Signs and symptoms include vomiting and lethargy, which rapidly progress to coma or seizures and cardiorespiratory collapse. Sudden unexpected infant death may occur. The liver may be slightly enlarged with fat deposition. Attacks are rare until the infant is beyond the 1st few mo of life, presumably because of more frequent feedings at a younger age. Affected older infants are at higher risk of illness as they begin to fast through the night or are exposed to fasting stress during an intercurrent childhood illness. Presentation in the 1st days of life with neonatal hypoglycemia has been reported in newborns who were fasted inadvertently or were being breastfed. Diagnosis of MCAD has occasionally been documented in previously healthy teenage and adult individuals, indicating that even patients who have been asymptomatic in infancy are still at risk for metabolic decompensation if exposed to sufficient periods of fasting. An unknown number of patients may remain asymptomatic. Prior to routine newborn screening testing, as many as 25% of MCAD-deficient patients died or suffered severe brain damage from their first episode. Most patients are now diagnosed in the newborn period by **blood spot acylcarnitine screening** , allowing the initiation of early treatment and prevention of many of the severe signs and symptoms. In some reports, newborns with MCAD deficiency presented acutely before newborn screening results were obtained; neonates who are exclusively breastfed are at higher risk because of early poor caloric intake.

Laboratory Findings

During acute episodes, hypoglycemia is usually present. Plasma and urinary ketone concentrations are inappropriately low (**hypoketotic hypoglycemia**). Because of the hypoketonemia, there is little or no metabolic acidosis, which is expected to be present in many children with hypoglycemia. Liver function tests (LFTs) are abnormal, with elevations of liver enzymes (alanine transaminase, aspartate transaminase), elevated blood ammonia, and prolonged prothrombin and partial thromboplastin times. Liver biopsy at times of acute illness shows microvesicular or macrovesicular steatosis from triglyceride accumulation. During fasting stress or acute illness, urinary organic acid profiles by gas chromatography/mass spectrometry show inappropriately low concentrations of ketones and elevated levels of medium-chain dicarboxylic acids (adipic, suberic, and sebacic acids) that derive from microsomal and peroxisomal omega oxidation of accumulated medium-chain fatty acids. Plasma and tissue concentrations of total carnitine are reduced to 25–50% of normal, and the fraction of total esterified carnitine is increased. This pattern of **secondary carnitine deficiency** is seen in most fatty acid oxidation defects and reflects competition between increased acylcarnitine levels and free carnitine for transport at the renal tubular plasma membrane. Significant exceptions to this rule are the plasma membrane carnitine transporter, CPT-IA, and β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) synthase deficiencies, which do not manifest secondary carnitine deficiency.

Diagnostic metabolite patterns for MCAD deficiency include increased plasma $C_{6:0}$, $C_{8:0}$, $C_{10:0}$, and $C_{10:1}$ acylcarnitine species and increased urinary acylglycines, including hexanoylglycine, suberylglycine, and 3-phenylpropionylglycine. Newborn screening, which almost all babies born in the United States receive, can detect presymptomatic MCAD deficiency based on these abnormal acylcarnitines in filter paper blood spots. The diagnosis can be confirmed by finding the common A985G mutation or sequencing the *MCAD* gene. A 2nd common variant, T199C, has been detected in infants identified by newborn screening. Interestingly, this allele has not been seen to date in symptomatic MCAD patients; it may represent a milder mutation.

Treatment

Acute illnesses should be promptly treated with intravenous (IV) fluids containing 10% dextrose to correct or prevent hypoglycemia and to suppress lipolysis as rapidly as possible (see Chapter 111). Chronic therapy consists of avoiding fasting. This usually requires simply adjusting the diet to ensure that overnight fasting periods are limited to <10-12 hr. Restricting dietary fat or treatment with carnitine is controversial. The need for active therapeutic intervention for individuals with the T199C variant has not yet been established.

Prognosis

Up to 25% of unrecognized patients may die during their first attack of illness. There is frequently a history of a previous sibling death that is presumed to be from an unrecognized MCAD deficiency. Some patients may sustain permanent brain injury during an attack of profound hypoglycemia. For survivors without brain damage, the prognosis is excellent because progressive cognitive impairment or cardiomyopathy does not occur in MCAD deficiency. Fasting tolerance improves with age, and the risk of illness decreases. Because as many as 35% of affected patients have never had an episode, testing of siblings of affected patients is important to detect asymptomatic family members.

Very-Long-Chain Acyl-CoA Dehydrogenase Deficiency

Very-long-chain acyl-CoA dehydrogenase (**VLCAD**) deficiency is the second most commonly diagnosed disorder of fatty acid oxidation. It was originally termed “long-chain acyl-CoA dehydrogenase deficiency” before the existence of the inner mitochondrial membrane-bound VLCAD was known. *All patients previously diagnosed as having long-chain acyl-CoA dehydrogenase deficiency have* VLCAD *gene defects.* Patients with VLCAD deficiency have no ability to oxidize physiologic long-chain fatty acids and are usually more severely affected than those with MCAD deficiency, who have a milder oxidative defect. VLCAD deficiency presents earlier in infancy and has more chronic problems with muscle weakness or episodes of muscle pain and rhabdomyolysis. Cardiomyopathy may be present during acute attacks provoked by fasting. The left ventricle may be hypertrophic or dilated and may show poor contractility on echocardiography. Sudden unexpected death has occurred in several patients, but most who survive the initial episode show improvement, including normalization of cardiac function. Other physical and routine laboratory features are similar to those of MCAD deficiency, including secondary carnitine deficiency. The urinary organic acid profile shows a nonketotic dicarboxylic aciduria with increased levels of $C_{6\text{-}12}$ dicarboxylic acids. Diagnosis may be suggested by an abnormal acylcarnitine profile with plasma or blood spot $C_{14:0,\ 14:1,\ 14:2}$ acylcarnitine species. However, the specific diagnosis requires mutational analysis of the *VLCAD* gene. Treatment is based primarily on avoidance of fasts for >10-12 hr. Continuous intragastric feeding is useful in some patients.

Short-Chain Acyl-CoA Dehydrogenase Deficiency

A small number of patients with 2 null mutations in the short-chain acyl-CoA dehydrogenase *(SCAD)* gene have been described with variable phenotype. Most individuals classified as being SCAD deficient actually have polymorphic DNA changes in the *SCAD* gene; for example, 2 common polymorphisms are G185S and R147W, which are homozygously present in 7% of the population. Some investigators argue that these variants may be susceptibility factors, which require a 2nd, as yet unknown, genetic mutation to express a clinical phenotype; many other investigators believe that SCAD deficiency is a harmless biochemical condition. This autosomal recessive disorder presents with neonatal hypoglycemia and may have normal levels of ketone bodies. The diagnosis is indicated by elevated levels of butyrylcarnitine (C4-carnitine) on newborn blood spots or plasma and increased excretion of urinary ethylmalonic acid and butyrylglycine. These metabolic abnormalities are most pronounced in patients with null mutations and are variably present in patients who are homozygous for the common polymorphisms.

The need for treatment in SCAD deficiency has not yet been established. It has been proposed that long-term evaluation of asymptomatic individuals is necessary to determine whether this is or is not a real disease. Most individuals with SCAD deficiency remain asymptomatic throughout life, but there may be a subset of individuals with **severe manifestations** , including dysmorphic facial features, feeding difficulties/failure to thrive, metabolic acidosis, ketotic hypoglycemia, lethargy, developmental delay, seizures, hypotonia, dystonia, and myopathy.

Long-Chain 3-Hydroxyacyl-CoA Dehydrogenase/Mitochondrial Trifunctional Protein Deficiency

The LCHAD enzyme is part of the MTP, which also contains 2 other steps in β-oxidation: long-chain 2,3-enoyl CoA hydratase and long-chain β-ketothiolase. MTP is a hetero-octameric protein composed of 4 α and 4 β chains derived from distinct contiguous genes sharing a common promoter region. In some patients, only the LCHAD activity of the MTP is affected (**LCHAD deficiency**), whereas others have deficiencies of all 3 activities (**MTP deficiency**).

Clinical manifestations include attacks of acute hypoketotic hypoglycemia similar to MCAD deficiency; however, patients often show evidence of more severe disease, including cardiomyopathy, muscle cramps and weakness, and abnormal liver function (cholestasis). Toxic effects of fatty acid metabolites may produce pigmented retinopathy leading to blindness, progressive liver failure, peripheral neuropathy, and rhabdomyolysis. Life-threatening obstetric complications (AFLP, HELLP syndrome) have been observed in heterozygous mothers carrying homozygous fetuses affected with LCHAD/MTP deficiency. Sudden unexpected infant death may occur. The **diagnosis** is indicated by elevated levels of blood spot or plasma 3-hydroxy acylcarnitines of chain lengths C_{16} -C_{18} . Urinary organic acid profile in patients may show increased levels of 3-hydroxydicarboxylic acids of chain lengths C_6 -C_{14} . Secondary carnitine deficiency is common. A common mutation in the α subunit, E474Q, is seen in more than 60% of LCHAD-deficient patients. This mutation in the fetus is especially associated with the obstetric complications, but other mutations in either subunit may also be linked to maternal illness.

Treatment is similar to that for MCAD or VLCAD deficiency; that is, avoiding fasting stress. Some investigators have suggested that dietary supplements with medium-chain triglyceride oil to bypass the defect in long-chain fatty acid oxidation and docosahexaenoic acid (for protection against the retinal changes) may be useful. Liver transplantation has been attempted in patients with severe liver failure, but does not ameliorate the metabolic abnormalities or prevent the myopathic or retinal complications.

Short-Chain 3-Hydroxyacyl-CoA Dehydrogenase

Deficiency

Only 14 patients with proven mutations of short-chain 3-hydroxyacyl-CoA dehydrogenase (**SCHAD**) have been reported. Most cases with recessive mutations of the *SCHAD* gene have presented with episodes of hypoketotic hypoglycemia that was caused by hyperinsulinism. In contrast to those with other forms of fatty acid oxidation disorders, these patients required specific therapy with diazoxide for hyperinsulinism to avoid recurrent hypoglycemia. A single patient with compound heterozygous mutations presented with fulminant hepatic failure at age 10 mo. The SCHAD protein has a nonenzymatic function in which it directly interacts with glutamate dehydrogenase (GDH) to inhibit its activity. In the absence of SCHAD protein, this inhibition is removed, leading to upregulation of GDH enzyme activity, a recognized cause of hyperinsulinism usually from activating mutations of the *GDH* gene. Severe deficiency of SCHAD protein often presents predominantly as protein-sensitive hypoglycemia rather than as fasting hypoglycemia. It appears that if SCHAD protein is present, inhibition of GDH is maintained even when there is no SCHAD enzyme activity; these patients may present with a more traditional fatty acid oxidation defect. Specific metabolic markers for SCHAD deficiency include elevated plasma C4-hydroxy acylcarnitine and urine 3-hydroxyglutaric acid. Successful newborn screening for SCHAD deficiency has been recorded, but the sensitivity of the process has not yet been established.

Treatment of SCHAD-deficient patients with hyperinsulinism is with diazoxide. There is insufficient experience with the nonhyperinsulinemic form of SCHAD deficiency at present to recommend treatment modalities, but prevention of fasting seems advisable.

Short-Chain 2,3-Enoyl-CoA Hydratase Deficiency

This disorder, resulting from mutations in the *ECHS1* gene, has only recently been defined. Many patients were identified through exome sequencing, and currently there are approximately 20 cases in the literature. The disorder affects a shared pathway of short-chain fatty acid and valine metabolism. The clinical phenotypes are more characteristic of mitochondrial disorders of pyruvate metabolism with predominantly a Leigh-like disease (see Chapter 616.2) with profound and often-fatal lactic acidosis. Currently, no treatment modalities or specific biomarkers have been established. Several patients were found to excrete increased levels of methacrylylglycine, a highly reactive and potentially toxic intermediate; 2-methyl-2.3 dihydroxybutyrate; *S* -(2-carboxypropyl) cysteine; and *S* -(2-carboxpropyl) cysteamine.

Defects in the Carnitine Cycle

Plasma Membrane Carnitine Transport Defect (Primary Carnitine Deficiency)

Primary carnitine deficiency is the only genetic defect in which carnitine deficiency is the cause, rather than the consequence, of impaired fatty acid oxidation. The most common presentation is progressive **cardiomyopathy** with or without **skeletal muscle weakness** beginning at age 1-4 yr. A smaller number of patients may present with fasting hypoketotic hypoglycemia in the 1st yr of life, before the cardiomyopathy becomes symptomatic. The underlying defect involves the plasma membrane sodium gradient–dependent carnitine transporter that is present in heart, muscle, and kidney. This transporter is responsible both for maintaining intracellular carnitine concentrations 20-50–fold higher than plasma concentrations and for renal conservation of carnitine.

Diagnosis of the carnitine transporter defect is aided by patients having extremely reduced carnitine levels in plasma and muscle (1–2% of normal). Heterozygote parents have plasma carnitine levels approximately 50% of normal. Fasting ketogenesis may be normal because liver carnitine transport is normal, but it may become impaired if dietary carnitine intake is interrupted. The fasting urinary organic acid profile may show a hypoketotic dicarboxylic aciduria pattern if hepatic fatty acid oxidation is impaired, but is otherwise unremarkable. The defect in carnitine transport can be demonstrated clinically by the severe reduction in renal carnitine threshold or by in vitro assay of carnitine uptake using cultured fibroblasts or lymphoblasts. Mutations in the organic cation/carnitine transporter *(OCTN2)* underlie this disorder. **Treatment** with pharmacologic doses of oral carnitine (100-200 mg/kg/day) is highly effective in correcting the cardiomyopathy and muscle weakness, as well as any impairment in fasting ketogenesis. Muscle total carnitine concentrations remain <5% of normal on treatment.

Carnitine Palmitoyltransferase-IA Deficiency

Several dozen infants and children have been described with a deficiency of the liver and kidney CPT-I isozyme (CPT-IA). **Clinical manifestations** include fasting-induced hypoketotic hypoglycemia, occasionally with extremely abnormal LFTs and rarely with renal tubular acidosis. The heart and skeletal muscle are not involved because the muscle isozyme is unaffected. Fasting urinary organic acid profiles sometimes show a hypoketotic C_6 -C_{12} dicarboxylic aciduria but may be normal. Plasma acylcarnitine analysis demonstrates mostly free carnitine with very little acylated carnitine. This observation has been used to identify CPT-IA deficiency on newborn screening by tandem mass spectrometry. CPT-IA deficiency is the only fatty acid oxidation disorder in which plasma total carnitine levels may be elevated, often to 150–200% of normal. This phenomenon is explained by the absence of inhibitory effects of long-chain acylcarnitines on the renal tubular carnitine transporter in CPT-IA deficiency. The enzyme defect can be demonstrated in cultured fibroblasts or lymphoblasts. CPT-IA deficiency in the fetus has been associated in a single case report with AFLP in the mother. A common variant in the *CPTIA* gene (c.1436C>t, p.P479L) has been identified in individuals of Inuit background in the United States, Canada, and Greenland. This variant is associated with an increased risk for sudden infant death syndrome (SIDS) in the Inuit population. The variant can be detected by newborn screening; enzyme activity is reduced by 80%, and regulation by malonyl-CoA is lost. It has not been established whether CPT-IA (c.1436C>t, p.P479L) is a pathologic enzyme variant or an adaptation to ancient Inuit high-fat diets. **Treatment** for the severe form of CPT-IA deficiency that is found in non-Inuit populations is similar to that for MCAD deficiency, with avoidance of situations where fasting ketogenesis is necessary. The need for treatment of the Inuit variant has not yet been determined.

Carnitine:Acylcarnitine Translocase Deficiency

This defect of the inner mitochondrial membrane carrier protein for long-chain acylcarnitines blocks the entry of long-chain fatty acids into the mitochondria for oxidation. The clinical phenotype of this disorder is characterized by a severe and generalized impairment of fatty acid oxidation. Most newborn patients present with attacks of fasting-induced hypoglycemia, hyperammonemia, and cardiorespiratory collapse. All symptomatic newborns have had evidence of cardiomyopathy and muscle weakness. Several patients with a partial translocase deficiency and milder disease without cardiac involvement have also been identified. No distinctive urinary or plasma organic acids are noted, although increased levels of plasma long-chain acylcarnitines of chain lengths C_{16} -C_{18} are reported. **Diagnosis** can be confirmed using genetic analysis. Functional carnitine:acylcarnitine translocase activity can be measured in cultured fibroblasts or lymphoblasts. **Treatment** is similar to that of other long-chain fatty acid oxidation disorders.

Carnitine Palmitoyltransferase-II Deficiency

Three forms of CPT-II deficiency have been described. A **severe neonatal lethal** presentation associated with a profound enzyme deficiency and early death has been reported in several newborns in association with dysplastic kidneys, cerebral malformations, and mild facial anomalies. A milder defect is associated with an **adult presentation** of episodic rhabdomyolysis. The first episode usually does not occur until late childhood or early adulthood. Attacks are frequently precipitated by prolonged exercise. There is aching muscle pain and myoglobinuria that may be severe enough to cause renal failure. Serum levels of creatine kinase are elevated to 5,000-100,000 units/L. Hypoglycemia has not been described, but fasting may contribute to attacks of myoglobinuria. Muscle biopsy shows increased deposition of neutral fat. This adult myopathic presentation of CPT-II deficiency is associated with a common mutation, c.338C>T, p.S113L. This mutation produces a heat-labile protein that is unstable to increased muscle temperature during exercise resulting in the myopathic presentation. The 3rd, **intermediate form** of CPT-II deficiency presents in infancy or early childhood with fasting-induced hepatic failure, cardiomyopathy, and skeletal myopathy with hypoketotic hypoglycemia, but is not associated with the severe developmental changes seen in the neonatal lethal presentation. This pattern of illness is similar to that seen in VLCAD deficiency, and management is identical.

Diagnosis of all forms of CPT-II deficiency can be made by a combination of molecular genetic analysis and demonstrating deficient enzyme activity in muscle or other tissues and in cultured fibroblasts.

Defects in the Electron Transfer Pathway

Electron Transfer Flavoprotein and Electron

Transfer Flavoprotein Dehydrogenase Deficiencies (Glutaric Acidemia Type 2, Multiple Acyl-CoA Dehydrogenation Defects)

ETF and ETF-DH function to transfer electrons into the mitochondrial electron transport chain from dehydrogenation reactions catalyzed by VLCAD, MCAD, and SCAD, as well as by glutaryl-CoA dehydrogenase and 4 enzymes involved in branched-chain amino acid (BCAA) oxidation. Deficiencies of ETF or ETF-DH produce illness that combines the features of impaired fatty acid oxidation and impaired oxidation of several amino acids. Complete deficiencies of either protein are associated with severe illness in the newborn period, characterized by acidosis, hypoketotic hypoglycemia, coma, hypotonia, cardiomyopathy, and an unusual odor of sweaty feet caused by isovaleryl-CoA dehydrogenase inhibition. Some affected neonates have had congenital facial dysmorphism and polycystic kidneys similar to that seen in severe CPT-II deficiency, which suggests that toxic effects of accumulated metabolites may occur in utero.

Diagnosis can be made from the newborn blood spot acylcarnitine profile and urinary organic acids; both tests show abnormalities corresponding to blocks in the oxidation of fatty acids (ethylmalonate and C_6 -C_{10} dicarboxylic acids), lysine (glutarate), and BCAAs (isovaleryl-, isobutyryl-, and α-methylbutyryl-glycine). The diagnosis can be confirmed by genetic testing for ETF (2 genes, A and B) and ETF dehydrogenase. Most severely affected infants do not survive the neonatal period.

Partial deficiencies of ETF and ETF-DH produce a disorder that may mimic MCAD deficiency or other milder fatty acid oxidation defects. These patients have attacks of fasting hypoketotic coma. The urinary organic acid profile reveals primarily elevations of dicarboxylic acids and ethylmalonate, derived from short-chain fatty acid intermediates. Secondary carnitine deficiency is present. Some patients with mild forms of ETF/ETF-DH deficiency may benefit from treatment with high doses of *riboflavin,* a precursor of the various flavoproteins involved in electron transfer.

Defects in the Ketone Synthesis Pathway

The final steps in production of ketones from mitochondrial fatty acid β-oxidation convert acetyl-CoA to acetoacetate through 2 enzymes of the HMG-

CoA pathway (Fig. 104.2).

β-Hydroxy-β-Methylglutaryl-CoA Synthase Deficiency

See Chapter 103.6 .

HMG-CoA synthase is the rate-limiting step in the conversion of acetyl-CoA derived from fatty acid β-oxidation in the liver to ketones. Several patients with this defect have been identified. The presentation is one of fasting hypoketotic hypoglycemia without evidence of impaired cardiac or skeletal muscle function. Urinary organic acid profile shows only a nonspecific hypoketotic dicarboxylic aciduria. Plasma and tissue carnitine levels are normal, in contrast to all the other disorders of fatty acid oxidation. A separate synthase enzyme, present in cytosol for cholesterol biosynthesis, is not affected. The HMG-CoA synthase defect is expressed only in the liver (and kidney) and cannot be demonstrated in cultured fibroblasts. The **diagnosis** can be made by genetic mutation analysis. *Avoiding fasting is usually a successful treatment.*

β-Hydroxy-β-Methylglutaryl-CoA Lyase Deficiency (3 Hydroxy-3-Methylgutaric Aciduria)

See Chapter 103.6 .

Defects in Ketone Body Utilization

The ketone bodies, β-hydroxybutyrate and acetoacetate, are the end products of hepatic fatty acid oxidation and are important metabolic fuels for the brain during fasting. Three defects in utilization of ketones in brain and other peripheral tissues present as episodes of **hyperketotic coma** , with or without hypoglycemia.

Monocarboxylate Transporter-1 Deficiency

About 10 patients have been described with recurrent episodes of potentially lethal ketoacidosis, with or without hypoglycemia, caused by deficiency of monocarboxylate transporter 1 (MCT1), a plasma membrane carrier encoded by

SLC16A1 that is required to transport ketones into tissues from plasma. Although the first cases identified were homozygous for inactivating mutations of *MCT1*, heterozygous carriers can also be affected. Affected patients developed severe ketoacidosis provoked by fasting or infections in their 1st years of life; hypoglycemia was not always present. The differential includes ketotic hypoglycemia associated with milder forms of glycogen storage disease, such as phosphorylase or phosphorylase kinase deficiency (see Chapter 105). **Treatment** for acute episodes includes IV dextrose to suppress lipolysis and inhibit ongoing ketogenesis. Long-term treatment includes avoidance of prolonged fasting stress. The **diagnosis** can be suspected by unusually severe ketosis and delayed suppression of ketones after starting treatment with dextrose. There are no specific metabolic markers or newborn screening methods. The diagnosis can be established by genetic sequencing of *SLC16A1* .

Succinyl-CoA:3-Ketoacid-CoA Transferase Deficiency

See Chapter 103.6 .

Several patients with succinyl-CoA:3-ketoacid-CoA transferase (**SCOT**) deficiency have been reported. The characteristic presentation is an infant with recurrent episodes of severe ketoacidosis induced by fasting. Plasma acylcarnitine and urine organic acid abnormalities do not distinguish SCOT deficiency from other causes of ketoacidosis. **Treatment** of episodes requires infusion of glucose and large amounts of bicarbonate until metabolically stable. Patients usually exhibit inappropriate hyperketonemia even between episodes of illness. SCOT is responsible for activating acetoacetate in peripheral tissues, using succinyl CoA as a donor to form acetoacetyl-CoA. Deficient enzyme activity can be demonstrated in the brain, muscle, and fibroblasts from affected patients. The gene has been cloned, and numerous mutations have been characterized.

β-Ketothiolase Deficiency

See Chapter 103.6 .

very-long-chain fatty acids
VLCFAs
peroxisome
Zellweger syndrome
adrenoleukodystrophy

Peroxisomal Disorders

Disorders of very-long-chain fatty acids (VLCFAs) fall within the broader group of peroxisomal diseases. The **peroxisomal diseases** are genetically determined disorders caused either by the failure to form or maintain the peroxisome or by a defect in the function of a single protein that is normally located in this organelle. These disorders cause serious disability in childhood and occur more frequently and present a wider range of phenotypes than recognized in the past. Many, but not all, peroxisomal disorders are associated with elevations of VLCFAs. This discussion addresses the broader group of peroxisomal disorders with a focus on pediatric presentations.

Etiology

Peroxisomal disorders are subdivided into two major categories (Table 104.2). In the **peroxisomal biogenesis disorders (PBDs)** the basic defect is the failure to import 1 or more proteins into the organelle. In the other group, defects affect a single peroxisomal protein (**single-enzyme defects**). The *peroxisome* is present in all cells except mature erythrocytes and is a subcellular organelle surrounded by a single membrane; >50 peroxisomal enzymes are identified. Some enzymes are involved in production and decomposition of hydrogen peroxide and others in lipid and amino acid metabolism. Most peroxisomal enzymes are first synthesized in their mature form on free polyribosomes and enter the cytoplasm. Proteins that are destined for the peroxisome contain specific **peroxisome targeting sequences** (PTSs). Most peroxisomal matrix proteins contain **PTS1** , a 3-amino acid sequence at the carboxyl terminus. **PTS2** is an aminoterminal sequence that is critical for the import of enzymes involved in plasmalogen and branched-chain fatty acid metabolism. Import of proteins involves a complex series of reactions that involves at least 23 distinct proteins. These proteins, referred to as *peroxins*, are encoded by *PEX* genes.

Table 104.2

Classification of Peroxisomal Disorders

PEROXISOMAL BIOGENESIS DISORDERS	SINGLE-ENZYME DEFECTS
Zellweger spectrum disorder	X-linked adrenoleukodystrophy Acyl-CoA oxidase deficiency Bifunctional enzyme deficiency 2-Methylacyl-CoA racemase deficiency DHAP acyltransferase deficiency Alkyl-DHAP synthase deficiency Adult Refsum disease
Zellweger syndrome Neonatal adrenoleukodystrophy (ALD) Infantile Refsum disease	
Rhizomelic chondrodysplasia punctata (RCDP) and other *PEX7* conditions	

Epidemiology

Except for X-linked **adrenoleukodystrophy (ALD)** , all the peroxisomal disorders listed in Table 104.2 are **autosomal recessive diseases** . ALD is the most common peroxisomal disorder, with an estimated incidence of 1 in 17,000 live births. The combined incidence of the other peroxisomal disorders is estimated to be 1 in 50,000 live births, although with broader newborn screening it is expected that the actual incidences of all of the disorders of very-long-chain fatty acids will be more accurately established.

Pathology

Absence or reduction in the number of peroxisomes is pathognomonic for disorders of peroxisome biogenesis. In most disorders, membranous sacs contain peroxisomal integral membrane proteins, which lack the normal complement of matrix proteins; these are peroxisome “ghosts.” Pathologic changes are observed in most organs and include profound and characteristic defects in neuronal migration, micronodular cirrhosis of the liver, renal cysts, chondrodysplasia punctata, sensorineural hearing loss, retinopathy, congenital heart disease, and dysmorphic features.

Pathogenesis

All pathologic changes likely are secondary to the peroxisome defect. Multiple peroxisomal enzymes fail to function in the PBDs (Table 104.3). The enzymes that are diminished or absent are synthesized but are degraded abnormally fast because they may be unprotected outside the peroxisome. It is not clear how defective peroxisome functions lead to the widespread pathologic manifestations.

Table 104.3

Abnormal Laboratory Findings Common to Zellweger Spectrum Disorders

Peroxisomes absent to reduced in number
Catalase in cytosol
Deficient synthesis and reduced tissue levels of plasmalogens
Defective oxidation and abnormal accumulation of very-long-chain fatty acids
Deficient oxidation and age-dependent accumulation of phytanic acid
Defects in certain steps of bile acid formation and accumulation of bile acid intermediates
Defects in oxidation and accumulation of L -pipecolic acid
Increased urinary excretion of dicarboxylic acids

Mutations in 12 different *PEX* genes have been identified in PBDs. The pattern and severity of pathologic features vary with the nature of the import defects and the degree of import impairment. These gene defects lead to disorders that were named before their relationship to the peroxisome was recognized, namely, Zellweger syndrome, neonatal ALD, infantile Refsum disease, and rhizomelic chondrodysplasia punctata (**RCDP**). The first 3 disorders are considered to form a *clinical continuum* , with Zellweger syndrome the most severe, infantile Refsum disease the least severe, and neonatal ALD intermediate. They can be caused by mutations in any of the 11 genes involved in peroxisome assembly. The specific gene defects cannot be distinguished by clinical features. The clinical severity varies with the degree to which protein import is impaired. Mutations that abolish import completely are often associated with the Zellweger syndrome phenotype, whereas a missense mutation, in which some degree of import function is retained, leads to the somewhat milder phenotypes. A defect in *PEX7*, which involves the import of proteins that utilize PTS2, is associated with RCDP. *PEX7* defects that leave import partially intact are associated with milder phenotypes, some of which resemble classic (adult) Refsum disease.

The genetic disorders that involve single peroxisomal enzymes usually have clinical manifestations that are more restricted and relate to the single biochemical defect. The primary adrenal insufficiency of ALD is caused by accumulation of VLCFAs in the adrenal cortex, and the peripheral neuropathy in adult Refsum disease is caused by the accumulation of phytanic acid in Schwann cells and myelin.

Zellweger Spectrum Disorder

Newborn infants with **Zellweger syndrome** show striking and consistent recognizable abnormalities. Of central diagnostic importance are the typical facial appearance (high forehead, unslanting palpebral fissures, hypoplastic supraorbital ridges, and epicanthal folds; Fig. 104.3), severe weakness and hypotonia, neonatal seizures, and eye abnormalities. Because of the hypotonia and craniofacial appearance, Down syndrome may be suspected. Infants with Zellweger syndrome rarely live more than a few months. More than 90% show postnatal growth failure. Table 104.4 lists the main clinical abnormalities.

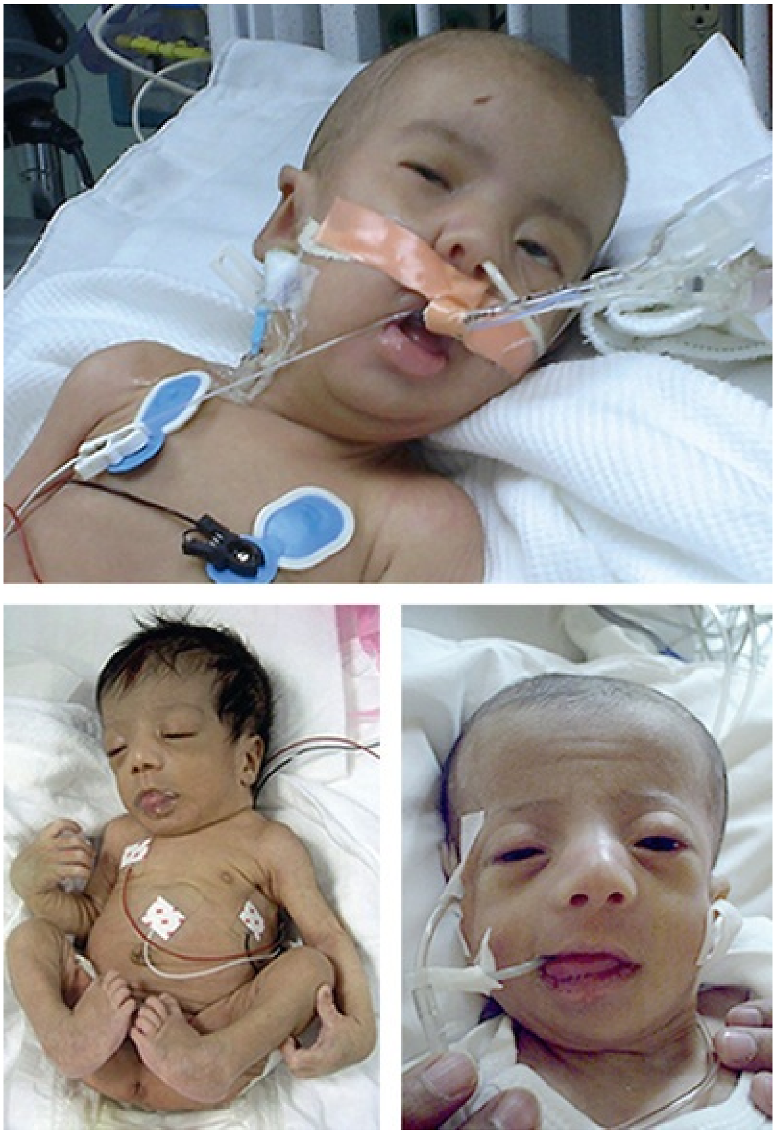

FIG. 104.3 Zellweger syndrome. Three affected neonates. Note the hypotonia, high forehead with shallow supraorbital ridges, anteverted nares, and mild micrognathia, as well as the talipes equinovarus and contractures at the knees. (From Shaheen R, Al-Dirbashi OY, Al-Hassnan ZN, et al: Clinical, biochemical and molecular characterization of peroxisomal diseases in Arabs, *Clin Genet* 79(1):60–70, 2011.)

Table 104.4

Main Clinical Abnormalities in Zellweger Syndrome

ABNORMAL FEATURE	PATIENTS IN WHOM THE FEATURE WAS PRESENT	
	Number	%
High forehead	58	97
Flat occiput	13	81
Large fontanelle(s), wide sutures	55	96

Shallow orbital ridges	33	100
Low/broad nasal bridge	23	100
Epicanthus	33	92
High-arched palate	35	95
External ear deformity	39	97
Micrognathia	18	100
Redundant skin fold of neck	13	100
Brushfield spots	5	83
Cataract/cloudy cornea	30	86
Glaucoma	7	58
Abnormal retinal pigmentation	6	40
Optic disc pallor	17	74
Severe hypotonia	94	99
Abnormal Moro response	26	100
Hyporeflexia or areflexia	56	98
Poor sucking	74	96
Gavage feeding	26	100
Epileptic seizures	56	92
Psychomotor retardation	45	100
Impaired hearing	9	40
Nystagmus	30	81

From Heymans HAS: Cerebro-hepato-renal (Zellweger) syndrome: clinical and biochemical consequences of peroxisomal dysfunctions, Thesis, University of Amsterdam, 1984.

Patients with **neonatal ALD** show fewer, less prominent craniofacial features. Neonatal seizures occur frequently. Some degree of psychomotor developmental delay is present; function remains in the range of severe intellectual disability, and development may regress after 3-5 yr of age, probably from a progressive leukodystrophy. Hepatomegaly, impaired liver function, pigmentary degeneration of the retina, and severely impaired hearing are invariably present. Adrenocortical function is usually impaired and may require adrenal hormone replacement. Chondrodysplasia punctata and renal cysts are absent.

Patients with **infantile Refsum disease** have survived to adulthood. They can walk, although gait may be ataxic and broad based. Cognitive function is generally impaired, but accurate assessment is limited, usually by the presence of both vision and hearing impairment. Almost all have some degree of sensorineural hearing loss and pigmentary degeneration of the retina. They have moderately dysmorphic features that may include epicanthal folds, a flat nose bridge, and low-set ears. Early hypotonia and hepatomegaly with impaired function are common. Levels of plasma cholesterol and high-density and low-density lipoprotein are often moderately reduced. Chondrodysplasia punctata and renal cortical cysts are absent. Postmortem study in infantile Refsum disease reveals micronodular liver cirrhosis and small, hypoplastic adrenals. The brain shows no malformations, except for severe hypoplasia of the cerebellar granule layer and ectopic locations of the Purkinje cells in the molecular layer. The mode of inheritance is autosomal recessive.

Some patients with PBDs have milder and atypical phenotypes. They may present with peripheral neuropathy or with retinopathy, impaired vision, or cataracts in childhood, adolescence, or adulthood and have been diagnosed to have **Charcot-Marie-Tooth disease** or **Usher syndrome** . Some patients have survived to the fifth decade. Defects in *PEX7*, which most frequently lead to the RCDP phenotype, may also lead to a milder phenotype with clinical manifestations similar to those of adult Refsum disease.

Rhizomelic Chondrodysplasia Punctata

RCDP is characterized by the presence of stippled foci of calcification within the hyaline cartilage and is associated with dwarfing, cataracts (72%), and multiple malformations caused by contractures. Vertebral bodies have a coronal cleft filled by cartilage that is a result of an embryonic arrest. Disproportionate short stature affects the proximal parts of the extremities (Fig. 104.4*A*). Radiologic abnormalities consist of shortening of the proximal limb bones, metaphyseal cupping, and disturbed ossification (Fig. 104.4*B*). Height, weight, and head circumference are less than the 3rd percentile, and these children have a severe intellectual disability. Skin changes such as those observed in **ichthyosiform erythroderma** are present in approximately 25% of patients.

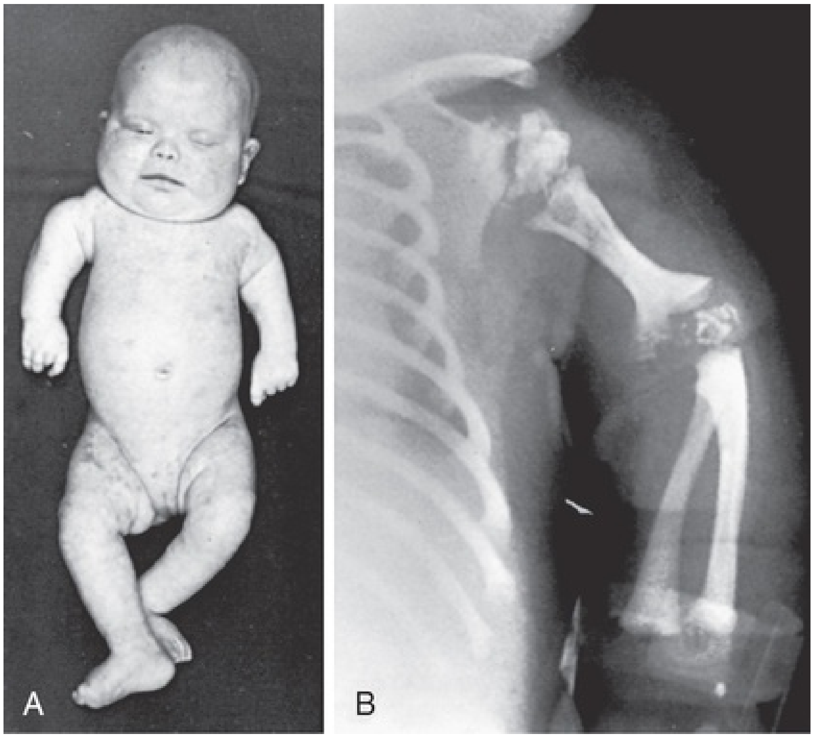

FIG. 104.4 **A,** Newborn infant with rhizomelic chondrodysplasia punctata. Note the severe shortening of the proximal limbs, the depressed bridge of the nose, hypertelorism, and widespread scaling skin lesions. **B,** Note the marked shortening of the humerus and epiphyseal stippling at the shoulder and elbow joints. (Courtesy of John P. Dorst, MD.)

Isolated Defects of Peroxisomal Fatty Acid Oxidation

In the group of single-enzyme defects, acyl-CoA oxidase and bifunctional enzyme deficiency involve a single enzymatic step in peroxisomal fatty acid oxidation. **Defects of bifunctional enzyme** are common and are found in approximately 15% of patients who are initially suspected of having Zellweger spectrum disorder. Patients with isolated **acyl-CoA oxidase deficiency** have a somewhat milder phenotype that resembles, and comes to attention because of the development of, an early childhood leukodystrophy.

Isolated Defects of Plasmalogen Synthesis

Plasmalogens are lipids in which the first carbon of glycerol is linked to an alcohol rather than a fatty acid. They are synthesized through a complex series of reactions, the first 2 steps of which are catalyzed by the peroxisomal enzymes dihydroxyacetone phosphate alkyl transferase (DHAPT) and synthase. Deficiency of either of these enzymes leads to a phenotype that is clinically indistinguishable from the peroxisomal import disorder RCDP. This latter disorder is caused by a defect in *PEX7*, the receptor for PTS2. RCDP shares the severe deficiency of plasmalogens with these single-enzyme disorders but also has defects of phytanic oxidation. The fact that these single genetic disorders are associated with the full phenotype of RCDP suggests that a deficiency of plasmalogens is sufficient to produce it.

Adult (Classic) Refsum Disease

The defective enzyme (phytanoyl-CoA hydroxylase) is localized to the peroxisome. The manifestation of Refsum disease includes impaired vision from retinitis pigmentosa, anosmia, ichthyosis, peripheral neuropathy, ataxia, and occasionally cardiac arrhythmias. In contrast to infantile Refsum disease, cognitive function is normal, and there are no congenital malformations. Refsum disease often does not manifest until young adulthood, but visual disturbances such as night blindness, ichthyosis, and peripheral neuropathy may already be present in childhood and adolescence. Early diagnosis is important because institution of a phytanic acid–restricted diet can reverse the peripheral neuropathy and prevent the progression of the visual and central nervous system (CNS) manifestations. The adult Refsum disease phenotype may also be caused by defects in *PEX7*.

2-Methylacyl-CoA Racemase Deficiency (AMACR)

This disorder is caused by an enzyme defect that leads to the accumulation of the branched-chain fatty acids (phytanic and pristanic acid) and bile acids. Individuals present with typically an adult-onset peripheral neuropathy and may also have pigmentary degeneration of the retina.

Laboratory Findings

Diagnosis of a peroxisomal disorder often follows from a biochemical determination of an abnormality and then is confirmed through further genetic testing.

The biochemical characterization of peroxisomal disorders uses the generally available testing listed in Table 104.5 . Measurement of plasma VLCFA levels is the most common assay. It must be emphasized that although plasma VLCFA levels are elevated in many patients with peroxisomal disorders, this is not always the case. The most important exception is RCDP, in which VLCFA levels are normal, but plasma phytanic acid levels are increased and red blood cell (RBC) plasmalogen levels are reduced. In other peroxisomal disorders, the biochemical abnormalities are still more restricted. Therefore, a panel of tests is recommended and includes plasma levels of VLCFAs and phytanic, pristanic, and pipecolic acids and RBC levels of plasmalogens. Tandem mass spectrometry techniques also permit convenient quantitation of bile acids in plasma and urine. This panel of tests can be performed on very small amounts of venous blood and permits detection of most peroxisomal disorders. Furthermore, normal results make the presence of the typical peroxisomal disorder unlikely. Biochemical findings combined with the clinical presentation are often sufficient to arrive at a clinical diagnosis. *Methods using dried blood spots of filter paper have been developed and are being incorporated into newborn screening assays.*

Table 104.5

Diagnostic Biochemical Abnormalities in Peroxisomal Disorders

DISORDER	VLCFA	PHYTANIC ACID	PRISTANIC ACID	PLASMALOGENS
ZSD	↑↑	↑[*]	↑[*]	↓
RCDP	Nl	↑	Nl	↓↓
ALD	↑	Nl	Nl	Nl
ACoX	↑	Nl	Nl	Nl
Bifunctional enzyme deficiency	↑	↑	↑	Nl
AMACR	Nl	↑	↑	Nl
Refsum disease	Nl	↑	↑	Nl

[*] Phytanic acid and pristanic acid accumulation is age dependent, and normal (Nl) levels may be seen in infants and young children.

VLCFA, Very-long-chain fatty acids; ZSD, Zellweger spectrum disorder; RCDP, rhizomelic chondroplasia punctata; ALD, adrenoleukodystrophy; ACoX, acyl-CoA oxidase deficiency; AMACR, 2-methylacyl-CoA racemase deficiency.

The next step in diagnosis is generally to proceed to molecular DNA diagnosis, and many clinical laboratories provide a peroxisomal panel using next-generation technology. In some circumstances the diagnosis has been revealed through whole exome sequencing and the pathogenic nature of the alteration then confirmed through biochemical means.

Definition of the molecular defect in the *proband* is essential for carrier detection and speeds **prenatal diagnosis** . Characterization of the mutation may be of prognostic value in patients with *PEX1* defects. This defect is present in approximately 60% of PBD patients, and about half the *PEX1* defects have the

G843D allele, which is associated with a significantly milder phenotype than found in other mutations.

Diagnosis

Several noninvasive laboratory tests permit precise and early diagnosis of peroxisomal disorders (see Table 104.5). The challenge in PBDs is to differentiate them from the large variety of other conditions that can cause hypotonia, seizures, failure to thrive, or dysmorphic features. Experienced clinicians readily recognize classic Zellweger syndrome by its clinical manifestations. However, more mildly affected PBD patients often do not show the full clinical spectrum of disease and may be identifiable only by laboratory assays. Clinical features that warrant diagnostic assay include intellectual disability; weakness and hypotonia; dysmorphic features; neonatal seizures; retinopathy, glaucoma, or cataracts; hearing deficits; enlarged liver and impaired liver function; and chondrodysplasia punctata. The presence of 1 or more of these abnormalities increases the likelihood of this diagnosis. Atypical milder forms presenting as peripheral neuropathy have also been described.

Some patients with the isolated defects of peroxisomal fatty acid oxidation resemble those with Zellweger spectrum disorder and can be detected by the demonstration of abnormally high levels of VLCFAs.

Patients with RCDP must be distinguished from patients with other causes of chondrodysplasia punctata. RCDP is suspected clinically because of the shortness of limbs, developmental delays, and ichthyosis. The most decisive laboratory test is the demonstration of abnormally low plasmalogen levels in RBCs and an alteration in *PEX7* .

Complications

Patients with Zellweger syndrome have multiple disabilities involving muscle tone, swallowing, cardiac abnormalities, liver disease, and seizures. These conditions are treated symptomatically, but the prognosis is poor, and most patients succumb in the 1st yr of life. Similarly, individuals with RCDP have multiple systemic and neurologic issues. In addition, they may develop quadriparesis from compression at the base of the brain.

Treatment

The most effective therapy is the dietary treatment of adult Refsum disease with a phytanic acid–restricted diet. However, this only applies to this specific condition.

For patients with the somewhat milder variants of the peroxisome import disorders, success has been achieved with multidisciplinary early intervention, including physical and occupational therapy, hearing aids or cochlear implants, augmentative and alternative communication, nutrition, and support for the families. Although most patients continue to function in the impaired range, some make significant gains in self-help skills, and several are in stable condition in their teens or even early 20s.

Attempts to mitigate some of the secondary biochemical abnormalities include the oral administration of docosahexaenoic acid (DHA). DHA level is greatly reduced in patients with disorders of peroxisome biogenesis, and this therapy normalizes DHA plasma levels. Although there were anecdotal reports of clinical improvement with DHA therapy, a randomized placebo-controlled study failed to find benefit.

Genetic Counseling

All the discussed peroxisomal disorders can be diagnosed prenatally. Prenatal testing using chorionic villi sampling or amniocentesis will usually rely on genetic testing when the alteration is known, but biochemical measurements may be made using the same tests as described for postnatal diagnosis (see Table 104.5). Because of the 25% recurrence risk, couples with an affected child should be advised about the availability of prenatal diagnosis.

Adrenoleukodystrophy

ALD is an X-linked disorder associated with the accumulation of saturated VLCFAs and a progressive dysfunction of the adrenal cortex and nervous system. It is the most common peroxisomal disorder.

Etiology

The key biochemical abnormality in ALD is the tissue accumulation of saturated VLCFAs, with a carbon chain length of 24 or more. Excess hexacosanoic acid ($C_{26:0}$) is the most striking and characteristic feature. This accumulation of fatty acids is caused by genetically deficient peroxisomal degradation of fatty acid. The defective gene *(ABCD1)* codes for a peroxisomal membrane protein (ALDP, the ALD protein). Many alterations in *ABCD1* have been determined to be pathogenic, with over half these being private or unique to the kindred. A curated database of mutations is maintained (www.x-ald.nl). The mechanism by which the ALDP defect leads to VLCFA accumulation appears to be a disruption of transport of saturated fatty acids into the peroxisome, with resultant continued elongation of progressively longer fatty acids.

Epidemiology

The minimum incidence of ALD in males is 1 in 21,000, and the combined incidence of ALD males and heterozygous females in the general population is estimated to be 1 in 17,000. All races are affected. The various phenotypes often occur in members of the same kindred. Increased implementation of newborn screening in the United States and other countries is expected to improve the accuracy of these incidence estimates.

Pathology

Characteristic lamellar cytoplasmic inclusions can be demonstrated on electron microscopy in adrenocortical cells, testicular Leydig cells, and nervous system macrophages. These inclusions probably consist of cholesterol esterified with VLCFA. They are most prominent in cells of the zona fasciculata of the adrenal cortex, which at first are distended with lipid and later atrophy.

The nervous system displays 2 types of ALD lesions. In the severe cerebral form, demyelination is associated with an inflammatory response manifested by the accumulation of perivascular lymphocytes that is most intense in the involved region. In the slowly progressive adult form, **adrenomyeloneuropathy** , the main finding is a distal axonopathy that affects the long tracts in the spinal cord. In this form the inflammatory response is mild or absent.

Pathogenesis

The adrenal dysfunction is probably a direct consequence of the accumulation of VLCFAs. The cells in the adrenal zona fasciculata are distended with abnormal lipids. Cholesterol esterified with VLCFA is relatively resistant to adrenocorticotropic hormone (ACTH)–stimulated cholesterol ester hydrolases, and this limits the capacity to convert cholesterol to active steroids. In addition, $C_{26:0}$ excess increases the viscosity of the plasma membrane, which may interfere with receptor and other cellular functions.

There is no correlation between the neurologic phenotype and the nature of the mutation or the severity of the biochemical defect as assessed by plasma VLCFA levels or between the degree of adrenal involvement and nervous system involvement. The severity of the illness and rate of progression correlate with the intensity of the **inflammatory response** . The inflammatory response may be partially cytokine mediated and may involve an autoimmune response triggered in an unknown way by the excess of VLCFAs. Mitochondrial damage and oxidative stress also appear to contribute. Approximately half the patients do not experience the inflammatory response; this difference is not understood.

Clinical Manifestations

There are 5 relatively distinct ALD phenotypes, 3 of which are present in childhood with symptoms and signs. In all the phenotypes, development is usually normal in the 1st 3-4 yr of life.

In the **childhood cerebral form** of ALD, symptoms most often are first noted between ages 4 and 8 yr. The most common initial manifestations are hyperactivity, inattention, and worsening school performance in a child who had previously been a good student. *Auditory discrimination* is often impaired, although tone perception is preserved. This may be evidenced by difficulty in using the telephone and greatly impaired performance on intelligence tests in items that are presented verbally. Spatial orientation is often impaired. Other initial symptoms are disturbances of vision, ataxia, poor handwriting, seizures, and strabismus. Visual disturbances are often caused by involvement of the parietooccipital cortex rather than eye or optic tract abnormalities, which leads to variable and seemingly inconsistent visual capacity. Seizures occur in nearly all patients and may represent the first manifestation of the disease. Some patients present with increased intracranial pressure. Impaired cortisol response to ACTH stimulation is present in 85% of patients, and mild hyperpigmentation is noted. In most patients with this phenotype, adrenal dysfunction is recognized only after the condition is diagnosed because of the cerebral symptoms. Cerebral childhood ALD tends to progress rapidly with increasing spasticity and paralysis, visual and hearing loss, and loss of ability to speak or swallow. The mean interval between the first neurologic symptom and an apparently vegetative state is 1.9 yr. Patients may continue in this apparently vegetative state for ≥10 yr.

Adolescent ALD designates patients who experience neurologic symptoms between ages 10 and 21 yr. The manifestations resemble those of childhood cerebral ALD except that progression is slower. Approximately 10% of patients present acutely with status epilepticus, adrenal crisis, acute encephalopathy, or coma.

Adrenomyeloneuropathy first manifests in late adolescence or adulthood as a progressive paraparesis caused by long tract degeneration in the spinal cord. Approximately half the affected men also have involvement of the cerebral white matter.

The **Addison-only** phenotype is an important condition. Of male patients with Addison disease, 25% may have the biochemical defect of ALD. Many of these patients have intact neurologic systems, whereas others have subtle neurologic signs. Many acquire adrenomyeloneuropathy in adulthood.

The term **asymptomatic ALD** is applied to persons who have the biochemical defect of ALD but are free of neurologic or endocrinal disturbances. Almost all persons with the gene defect eventually become neurologically symptomatic.

Approximately 50% of female heterozygotes acquire a syndrome that resembles adrenomyeloneuropathy but is milder and of later onset. Adrenal insufficiency and cerebral disease are rare.

Cases of typical ALD have occurred in relatives of those with adrenomyeloneuropathy. One of the most difficult problems in the management of ALD is the common observation that affected individuals in the same family may have quite different clinical courses. For example, in one family, an affected boy may have severe classic ALD culminating in death by age 10 yr, and another brother will have the later-onset adrenomyeloneuropathy.

Laboratory and Radiographic Findings

The most specific and important laboratory finding is the demonstration of abnormally high levels of VLCFAs in plasma, RBCs, or cultured skin fibroblasts. Positive results are obtained in all male patients with ALD and in approximately 85% of female carriers of ALD. Mutation analysis is the most reliable method for the identification of carriers. Simply finding a variation in *ABCD1* is not adequate for making the diagnosis of ALD. It must be shown to segregate with elevated VLCFA levels.

Neuroimaging

Patients with childhood cerebral or adolescent ALD have characteristic white matter lesions on MRI. In 80% of patients the lesions are symmetric and involve the splenium of the corpus callosum and periventricular white matter in the posterior parietal and occipital lobes. Many will show a garland of contrast enhancement adjacent and anterior to the posterior hypodense lesions (Fig. 104.5). This zone corresponds to the zones of intense perivascular lymphocytic infiltration where the blood-brain barrier breaks down. In 10–15% of patients, the initial lesions are frontal. Unilateral lesions that produce a mass effect suggestive of a brain tumor may occur rarely. MRI provides a clearer delineation of normal and abnormal white matter than does CT and is the preferred imaging modality.

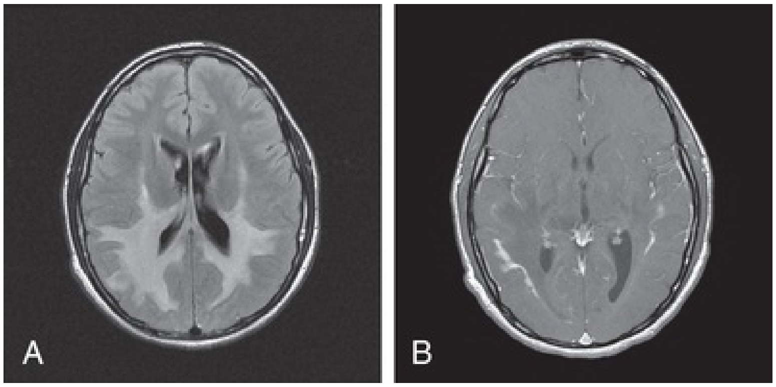

FIG. 104.5 **Characteristic MRI findings in cerebral adrenoleukodystrophy. A, Symmetric T2-weighted MRI abnormalities involve the posterior white matter, including the corpus callosum. B, Contrast administration reveals a garland of enhancement.**

Impaired Adrenal Function

More than 85% of patients with the childhood form of ALD have elevated levels of ACTH in plasma and a subnormal rise of cortisol levels in plasma after IV injection of 250 µg of ACTH (Cortrosyn).

Diagnosis and Differential Diagnosis

Diagnosis of asymptomatic males has become available by newborn screening that has been added to the recommended uniform screening panel. After diagnosis, confirmatory testing and genetic counseling should be provided. Males then enter a program of surveillance for adrenal insufficiency and early detection of potential cerebral disease. Females identified through these programs should also have confirmatory testing, genetic counseling for the family, and screening of other at-risk males. Females do not generally require any other monitoring in childhood.

The earliest manifestations of childhood cerebral ALD are difficult to distinguish from the more common attention-deficit disorders or learning disabilities of school-age children. Rapid progression, signs of dementia, or difficulty in auditory discrimination suggest ALD. Even in early stages, neuroimaging shows abnormal changes. Other leukodystrophies or multiple sclerosis may sometimes mimic these radiographic findings, although early ALD has more of a predilection for the posterior brain than its mimics. Definitive diagnosis depends on demonstration of VLCFA excess, which occurs only in ALD and the other peroxisomal disorders.

Cerebral forms of ALD, especially if asymmetric, may be misdiagnosed as gliomas or other mass lesion. Individuals have received brain biopsy and rarely other therapies before the correct diagnosis was made. Measurement of VLCFAs in plasma is the most reliable differentiating test.

Adolescent or adult cerebral ALD can be confused with psychiatric disorders, dementing disorders, multiple sclerosis, or epilepsy. The first clue to the diagnosis of ALD may be the demonstration of characteristic white matter lesions by neuroimaging; VLCFA assays are confirmatory.

ALD *cannot* be distinguished clinically from other forms of Addison disease; it is recommended that assays of VLCFA levels be performed in all male patients with Addison disease. ALD patients *do not* usually have antibodies to adrenal tissue in their plasma.

Complications

An avoidable complication is the occurrence of **adrenal insufficiency** . The most difficult neurologic problems are those related to bed rest, contracture, coma, and swallowing disturbances. Other complications involve behavioral disturbances and injuries associated with defects of spatial orientation, impaired vision and hearing, and seizures.

Treatment

Corticosteroid replacement for adrenal insufficiency or adrenocortical hypofunction is effective. It may be lifesaving and may increase general strength and well-being, but it does not alter the course of the neurologic disability.

Bone Marrow Transplantation

Bone marrow transplantation (BMT) or hematopoietic stem cell therapy benefits patients who show early evidence of the inflammatory demyelination characteristic of the rapidly progressive neurologic disability in boys and adolescents with the cerebral ALD phenotype. BMT carries risk, and patients must be evaluated and selected with care. The mechanism of the beneficial effect is incompletely understood. Bone marrow–derived cells do express ALDP, the protein that is deficient in ALD; approximately 50% of brain microglial cells are bone marrow derived. The favorable effect may be caused by modification of the brain inflammatory response. Follow-up of boys and adolescents who had early cerebral involvement has shown stabilization. On the other hand, BMT does not arrest the course in those who already had severe brain involvement and may accelerate disease progression under these circumstances. The ALD MRI score and the use of performance measures on IQ testing have shown some predictive ability for boys likely to benefit from this procedure. Transplant is not recommended in patients with performance IQ significantly <80. Unfortunately, in more than half the patients who are diagnosed because of neurologic symptoms, the illness is so advanced at diagnosis that they are not candidates for transplant.

Consideration of BMT is most relevant in neurologically asymptomatic or mildly involved patients. Screening at-risk relatives of symptomatic patients identifies these patients most frequently. Screening by measurement of plasma VLCFA levels in patients with Addison disease may also identify candidates for BMT. Because of its risk (10–20% mortality) and because up to 50% of untreated patients with ALD do not develop inflammatory brain demyelination, transplant is not recommended in patients who are free of demonstrable brain involvement on MRI. MRI is also of key importance for the crucial decision of whether transplant should be performed. MRI abnormalities precede clinically evident neurologic or neuropsychologic abnormalities. The brain MRI should be monitored at 6 mo intervals in neurologically asymptomatic boys and adolescents age 3-15 yr. If the MRI is normal, BMT is not indicated. If brain

MRI abnormalities develop, the boy should be evaluated by a center familiar with transplant for ALD. This should include MRI, neurologic, and neuropsychologic evaluations. It is not known whether BMT has a favorable effect on the noninflammatory spinal cord involvement in adults with the adrenomyeloneuropathy phenotype.

Lorenzo's Oil Therapy

Lorenzo's oil (4 : 1 mixture of glyceryl trioleate and glyceryl trierucate) combined with a dietary regimen has been under investigation to prevent the development of various aspects of ALD. The compound does lower plasma levels of VLCFAs, but despite early enthusiasm, clinical trials have been equivocal. Lorenzo's oil has not been shown to alter disease progression in males with cerebral disease. Whether it or another agent that lowers VLCFA levels has disease-modifying effects is as yet uncertain.

Supportive Therapy

The progressive behavioral and neurologic disturbances associated with the childhood form of ALD are extremely difficult for the family. ALD patients require the establishment of a comprehensive management program and partnership among the family, physician, visiting nursing staff, school authorities, and counselors. In addition, parent support groups (e.g., United Leukodystrophy Foundation) are often helpful. Communication with school authorities is important because under the provisions of Public Law 94-142, children with ALD qualify for special services as “other health impaired” or “multi-handicapped.” Depending on the rate of progression of the disease, special needs might range from relatively low-level resource services within a regular school program to home- and hospital-based teaching programs for children who are not mobile.

Management challenges vary with the stage of the illness. The early stages are characterized by subtle changes in affect, behavior, and attention span. Counseling and communication with school authorities are of prime importance. Changes in the sleep–wake cycle can be benefited by the judicious use of nighttime sleep medications.

As the leukodystrophy progresses, the modulation of muscle tone and support of bulbar muscular function are major concerns. **Baclofen** in gradually increasing doses (5 mg twice a day to 25 mg 4 times a day) is an effective pharmacologic agent for the treatment of acute episodic painful muscle spasms. Other agents may also be used, with care taken to monitor the occurrence of side effects and drug interactions. As the leukodystrophy progresses, bulbar muscular control is lost. Although initially this can be managed by changing the diet to soft and pureed foods, most patients eventually require a gastrostomy tube. At least 30% of patients have focal or generalized seizures that usually readily respond to standard anticonvulsant medications.

Genetic Counseling and Prevention

Genetic counseling and appropriate monitoring are of crucial importance. Extended-family screening should be offered to all at-risk relatives of symptomatic patients; one program led to the identification of >250 asymptomatic affected males and 1,200 women heterozygous for ALD. The plasma assay permits reliable identification of affected males in whom plasma VLCFA levels are increased already on the day of birth. Identification of asymptomatic males permits institution of steroid replacement therapy when appropriate and prevents adrenal crisis, which may be fatal. Monitoring of brain MRI also permits identification of patients who are candidates for BMT at a stage when this procedure has the greatest chance of success. Plasma VLCFA assay is recommended in all male patients with Addison disease. ALD has been shown to be the cause of adrenal insufficiency in >25% of boys with Addison disease of unknown cause. Identification of women heterozygous for ALD is more difficult than that of affected males. Plasma VLCFA levels are normal in 15–20% of heterozygous women, and failure to note this has led to serious errors in genetic counseling. DNA analysis permits accurate identification of carriers, provided that the mutation has been defined in a family member, and this is the procedure recommended for the identification of heterozygous women.

Prenatal diagnosis of affected male fetuses can be achieved by determination of the known mutation or by the measurement of VLCFA levels in cultured amniocytes or chorionic villus cells. Whenever a new patient with ALD is identified, a detailed pedigree should be constructed and efforts made to identify all at-risk female carriers and affected males. These investigations should be accompanied by careful and sympathetic attention to social, emotional, and ethical issues during counseling.

Epidemiology of Blood Lipids and Cardiovascular Disease

There is a strong association between average intake of saturated fats, plasma cholesterol, and mortality from coronary heart disease (CHD). Of all common chronic diseases, none is so clearly influenced by both environmental *and* genetic factors as CHD. This multifactorial disorder is strongly associated with increasing age and male gender, although it is increasingly apparent that heart disease is underrecognized in women. Tobacco use confers a 2-fold higher lifetime risk. Sedentary activity and high intake of processed sugars leading to adiposity increase risk through differences in the plasma levels of atherogenic lipoproteins. Family history reflects the combined influence of lifestyle and genetic predisposition to early heart disease. Risk of premature heart disease associated with positive family history is 1.7 times higher than in families with no such history.

Atherosclerosis begins during childhood. The Johns Hopkins Precursors Study demonstrated that white male medical students with blood cholesterol levels in the lowest quartile showed only a 10% incidence of CHD 3 decades later, whereas those in the highest quartile had a 40% incidence. The Pathobiological Determinants of Atherosclerosis in Youth Study demonstrated a significant relationship between the weight of the abdominal fat pad and the extent of atherosclerosis found at autopsy on individuals 15-34 yr of age. The Bogalusa Heart Study of more than 3,000 black and white children and adolescents has provided the most comprehensive longitudinal data relating the presence and severity of CHD risk factors with semiquantifiable severity of atherosclerosis. Coronary atherosclerosis was present in 8.5% of military autopsies performed following combat or unintentional injuries.

The *fetal origins hypothesis* is based on the observation that infants born with low birthweight have a higher incidence of heart disease as adults. Epidemiologic studies support the idea that prenatal and early postnatal conditions may affect adult health status. Children who are large for gestational age at birth and exposed to an intrauterine environment of either diabetes or maternal obesity are at increased risk of eventually developing the **metabolic syndrome** (insulin resistance, type II diabetes, obesity, CHD). Breastfeeding preterm infants confers a long-term cardioprotective benefit 13-16 yr later. Those adolescents who were breastfed as infants had lower C-reactive protein (CRP) concentrations and a 14% lower low-density lipoprotein (LDL)/high-density lipoprotein (HDL) ratio than formula-fed infants. The impact of early nutrition and other lifestyle variables on gene expression, *epigenetics* , is one mechanism by which adult metabolism and body composition may be determined.

Secondary causes of hyperlipidemia may be the result of drugs (cyclosporine, corticosteroids, isotretinoin, protease inhibitors, alcohol, thiazide diuretics, β-blocking agents, valproate); or various diseases (nephrotic syndrome, hypothyroidism, Cushing syndrome, anorexia nervosa, obstructive jaundice). Psychotropic medications, including second-generation antipsychotics such as olanzapine, are associated with dyslipidemia, obesity, and insulin resistance.

Blood Lipids and Atherogenesis

Numerous epidemiologic studies demonstrate the association of hypercholesterolemia, referring to elevated total and LDL blood cholesterol, with atherosclerotic disease. The ability to measure subcomponents within classes of lipid particles, as well as markers of inflammation, have further elucidated the process of atherogenesis and plaque rupture leading to acute coronary syndromes. Atherosclerosis affects primarily the coronary arteries but may also involve the aorta, arteries of the lower extremities, and carotid arteries.

The early stage of development of atherosclerosis is thought to begin with vascular endothelial dysfunction and intima-media thickness, which has been shown to occur in preadolescent children with risk factors such as obesity or familial hypercholesterolemia. The complex process of penetrating the intimal lining of the vessel may result from a variety of insults, including the presence of highly toxic oxidized LDL particles. Lymphocytes and monocytes penetrate the damaged endothelial lining, where they become macrophages laden with LDL lipids and then become foam cells. Such accumulation is counterbalanced by HDL particles capable of removing lipid deposits from the vessel wall. Fundamental to plaque formation is an inflammatory process (elevated CRP) involving macrophages and the arterial wall. The deposition of lipid within the subendothelial lining of the arterial wall appears macroscopically as fatty streaks, which may to some degree be reversible. A later stage of plaque development involves disruption of arterial smooth muscle cells stimulated by the release of tissue cytokines and growth factors. The *atheroma* is composed of a core of fatty substance separated from the lumen by collagen and smooth muscle (Fig. 104.6). Growth of the atherosclerotic plaque may result in ischemia of the tissue supplied by the artery. Chronic inflammation within the atheroma results in plaque instability and subsequent rupture. Platelet adherence leads to clot formation at the site of rupture, resulting in myocardial infarction (MI) or a cerebrovascular accident (CVA), depending on the site of thrombosis or thromboembolism.

FIG. 104.6 The early stage of development of atherosclerosis begins with penetration of the intimal lining of the vessel by inflammatory cells. Deposition of lipid within the subendothelial lining of the arterial wall eventually leads to disruption of smooth muscle cells to form an atheromatous lipid core that impinges on the lumen. Chronic inflammation leads to plaque instability, setting the stage for plaque rupture and complete occlusion of the vessel lumen by clot formation.

Plasma Lipoprotein Metabolism and Transport

Abnormalities of lipoprotein metabolism are associated with diabetes mellitus and premature atherosclerosis. *Lipoproteins* are soluble complexes of lipids and proteins that effect transport of fat absorbed from the diet, or synthesis by the liver and adipose tissues, for utilization and storage. Dietary fat is transported from the small intestine as chylomicrons. Lipids synthesized by the liver as very-low-density lipoproteins (VLDLs) are catabolized to intermediate-density lipoproteins (IDLs) and LDLs. HDL is fundamentally involved in VLDL and chylomicron metabolism and cholesterol transport. Nonesterified free fatty acids are metabolically active lipids derived from lipolysis of triglycerides stored in adipose tissue and bound to albumin for circulation in the plasma (Fig. 104.7).

FIG. 104.7 The exogenous, endogenous, and reverse cholesterol pathways. The exogenous pathway transports dietary fat from the small intestine as chylomicrons to the periphery and the liver. The endogenous pathway denotes the secretion of very-low-density lipoprotein (VLDL) from the liver and its catabolism to intermediate-density lipoprotein (IDL) and low-density lipoprotein (LDL). Triglycerides are hydrolyzed from the VLDL particle by the action of lipoprotein lipase (LPL) in the vascular bed, yielding free fatty acids (FFA) for utilization and storage in muscle and adipose tissue. High-density lipoprotein (HDL) metabolism is responsible for the transport of excess cholesterol from the peripheral tissues back to the liver for excretion in the bile. Nascent HDL-3 particles derived from the liver and small intestine are esterified to more mature HDL-2 particles by enzyme-mediated movement of chylomicron and VLDL into the HDL core, which is removed from the circulation by endocytosis.

Lipoproteins consist of a central core of triglycerides and cholesteryl esters surrounded by phospholipids, cholesterol, and proteins (Fig. 104.8). The density of the several classes of lipoproteins is inversely proportional to the ratio of lipid to protein, which is generally denser (Fig. 104.9). Lipoproteins consist of a central core of triglycerides and cholesteryl esters surrounded by phospholipids, cholesterol, and proteins.

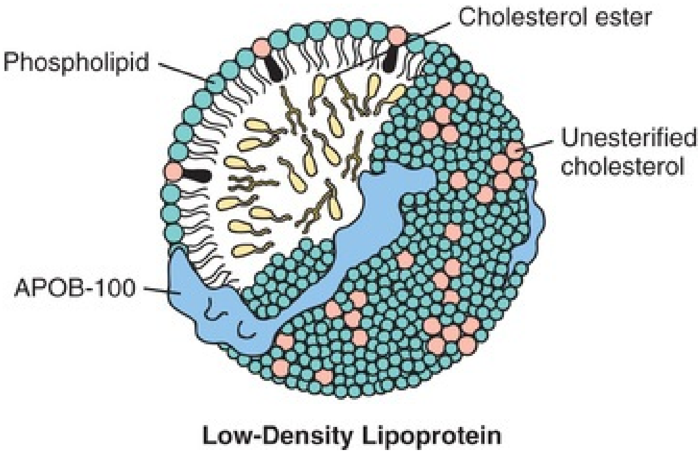

FIG. 104.8 **Schematic of low-density lipoprotein. Lipoprotein consists of a central core of cholesteryl esters, surrounded by phospholipids, cholesterol, and protein.**

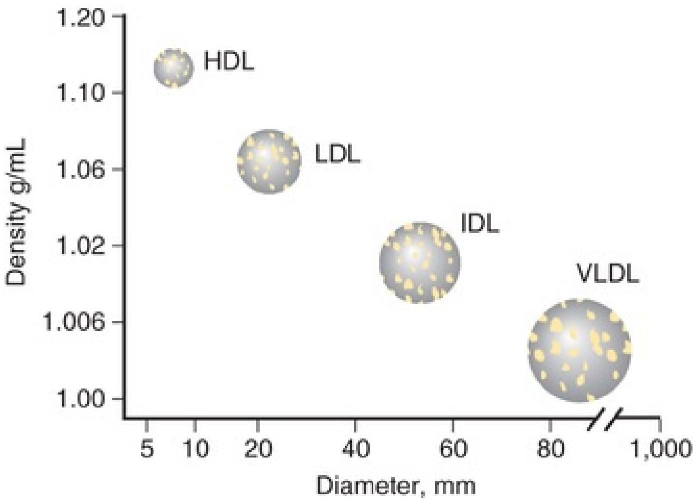

FIG. 104.9 The density of the several classes of lipoprotein is inversely proportional to the ratio of lipid to protein. As lipid is less dense than protein, the more lipid contained in the particle increases its size and decreases its density. HDL, High-density lipoprotein; LDL, low-density lipoprotein; IDL, intermediate-density lipoprotein; VLDL, very-low-density lipoprotein.

Constituent proteins known as *apolipoproteins* are responsible for a variety of metabolic functions in addition to their structural role, including as cofactors or inhibitors of enzymatic pathways and mediators of lipoprotein binding to cell surface receptors (Table 104.6). **ApoA** is the major apolipoprotein (Apo) of HDL. **ApoB** is present in LDL, VLDL, IDL, and chylomicrons. ApoB-100 is derived from the liver, whereas apoB-48 comes from the small intestine. ApoC-I, C-II, and C-III are small peptides important in triglyceride metabolism. Loss of function and disruptive mutations of the *APOC3* gene are associated with low levels of triglycerides and a reduced risk of ischemic CHD. Likewise, **apoE** , which is present in VLDL, HDL, chylomicrons, and chylomicron remnants, plays an important role in the clearance of triglycerides.

Table 104.6

Characteristics of the Major Lipoproteins

LIPOPROTEIN	SOURCE	SIZE (nm)	DENSITY (g/mL)	COMPOSITION		
				Protein (%)	Lipid (%)	Apolipoproteins
Chylomicrons	Intestine	80-1,200	<0.95	1-2	98-99	C-I, C-II, C-III, E, A-I, A-II, A-IV, B-48
Chylomicron remnants	Chylomicrons	40-150	<1.0006	6-8	92-94	B-48, E
VLDL	Liver, intestine	30-80	0.95-1.006	7-10	90-93	B-100, C-I, C-II, C-III
IDL	VLDL	25-35	1.006-1.019	11	89	B-100, E
LDL	VLDL	18-25	1.019-1.063	21	79	B-100
HDL	Liver, intestine VLDL, chylomicrons	5-20	1.125-1.210	32-57	43-68	A-I, A-II, A-IV C-I, C-II, C-III D, E

HDL, High-density lipoproteins; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; VLDL, very-low-density lipoproteins.

Transport of Exogenous (Dietary) Lipids

All dietary fat except medium-chain triglycerides is efficiently carried into the circulation by way of lymphatic drainage from the intestinal mucosa. Triglyceride and cholesteryl esters combine with apoA and apoB-48 in the intestinal mucosa to form chylomicrons, which are carried into the peripheral circulation via the lymphatic system. HDL particles contribute apoC-II to the chylomicrons, required for the activation of *lipoprotein lipase* (LPL) within the capillary endothelium of adipose, heart, and skeletal muscle tissue. Free fatty acids are oxidized, esterified for storage as triglycerides, or released into the circulation bound to albumin for transport to the liver. After hydrolysis of the triglyceride core from the chylomicron, apoC particles are recirculated back to HDL. The subsequent contribution of apoE from HDL to the remnant chylomicron facilitates binding of the particle to hepatic LDL receptor (LDL-R). Within the hepatocyte, the chylomicron remnant may be incorporated into membranes, resecreted as lipoprotein back into the circulation, or secreted as bile acids. Normally, all dietary fat is disposed of within 8 hr after the last meal, an exception being individuals with a disorder of chylomicron metabolism. **Postprandial hyperlipidemia** is a risk factor for atherosclerosis. Abnormal transport of chylomicrons and their remnants may result in their absorption into the blood vessel wall as foam cells, caused by the ingestion of cholesteryl esters by macrophages, the earliest stage in the development of fatty streaks.

Transport of Endogenous Lipids From the Liver

The formation and secretion of VLDL from the liver and its catabolism to IDL and LDL particles describe the endogenous lipoprotein pathway. Fatty acids used in the hepatic formation of VLDL are derived primarily by uptake from the circulation. VLDL appears to be transported from the liver as rapidly as it is synthesized, and it consists of triglycerides, cholesteryl esters, phospholipids, and apoB-100. Nascent particles of VLDL secreted into the circulation combine with apoC and apoE. The size of the VLDL particle is determined by the amount of triglyceride present, progressively shrinking in size as triglyceride is hydrolyzed by the action of LPL, yielding free fatty acids for utilization or storage in muscle and adipose tissue. Hydrolysis of approximately 80% of the triglyceride present in VLDL particles produces IDL particles containing an equal amount of cholesterol and triglyceride. The remaining remnant IDL is converted to LDL for delivery to peripheral tissues or to the liver. ApoE is attached to the remnant IDL particle to allow binding to the cell and subsequent incorporation into the lysosome. Individuals with deficiency of either apoE2 or hepatic triglyceride lipase accumulate IDL in the plasma.

LDL particles account for approximately 70% of the plasma cholesterol in normal individuals. LDL receptors are present on the surfaces of nearly all cells. Most LDL is taken up by the liver, and the rest is transported to peripheral tissues such as the adrenal glands and gonads for steroid synthesis. Dyslipidemia is greatly influenced by LDL-R activity. The efficiency with which VLDL is converted into LDL is also important in lipid homeostasis. The normal newborn LDL level of 50 mg/dL is probably adequate for steroid synthesis throughout the life cycle.

High-Density Lipoprotein and Reverse Cholesterol Transport

Because hepatic secretion of lipid particles into the bile is the only mechanism by which cholesterol can be removed from the body, transport of excess cholesterol from the peripheral cells is a vitally important function of HDL. HDL is heavily laden with apoA-I–containing lipoproteins, which is nonatherogenic, in contrast to B lipoproteins. Cholesterol-poor nascent HDL particles secreted by the liver and small intestine are esterified to more mature HDL-2 particles by the action of the enzyme lecithin-cholesterol acyltransferase (**LCAT**), which facilitates movement of chylomicrons and VLDL into the HDL core. HDL-2 may transfer cholesteryl esters back to apoB lipoproteins mediated by cholesteryl ester transfer protein (CETP), or the cholesterol-rich particle may be removed from the plasma by endocytosis, completing reverse cholesterol transport. Low HDL may be genetic (deficiency of apoA-I) or secondary to increased plasma triglyceride.

LCAT deficiency results in diminished maturation of HDL particles, affecting their ability to do reverse cholesterol transport. This reduces its protective effect on atherosclerosis. There are rare reports, however, of less-than-expected severity of atherosclerosis despite low HDL secondary to LCAT deficiency, suggesting that the relationship may, for unknown reasons, be variable.

Hyperlipoproteinemias

Hypercholesterolemia

See Table 104.7 .

Table 104.7

Hyperlipoproteinemias

DISORDER	LIPOPROTEINS ELEVATED	CLINICAL FINDINGS	GENETICS	ESTIMATED INCIDENCE
Familial hypercholesterolemia	LDL	Tendon xanthomas, CHD	AD	1 in 500
Familial defective ApoB-100	LDL	Tendon xanthomas, CHD	AD	1 in 1,000
Autosomal recessive hypercholesterolemia	LDL	Tendon xanthomas, CHD	AR	<1 in 1,000,000
Sitosterolemia	LDL	Tendon xanthomas, CHD	AR	<1 in 1,000,000
Polygenic hypercholesterolemia	LDL	CHD		1 in 30?
Familial combined hyperlipidemia	LDL, TG	CHD	AD	1 in 200

Familial dysbetalipoproteinemia	LDL, TG	Tuberoeruptive xanthomas, peripheral vascular disease	AD	1 in 10,000
Familial chylomicronemia (Frederickson type I)	TG ↑↑	Eruptive xanthomas, hepatosplenomegaly, pancreatitis	AR	1 in 1,000,000
Familial hypertriglyceridemia (Frederickson type IV)	TG ↑	±CHD	AD	1 in 500
Familial hypertriglyceridemia (Frederickson type V)	TG ↑↑	Xanthomas ± CHD	AD	—
Familial hepatic lipase deficiency	VLDL	CHD	AR	<1 in 1,000,000

AD, Autosomal dominant; AR, autosomal recessive; CHD, coronary heart disease; LDL, low-density lipoproteins, TG, triglycerides; VLDL, very-low-density lipoproteins.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is a monogenic autosomal co-dominant disorder characterized by strikingly elevated LDL cholesterol (LDL-C), premature cardiovascular disease (CVD), and tendon xanthomas. In the past, FH referred to defects of LDL-R activity. The etiology of this lipoprotein abnormality also includes defects in the genes for apoB (as well as PCSK-9). Of the almost 1200 mutations described, some result in failure of synthesis of the LDL-R (receptor negative), and others cause defective binding or release at the lipoprotein-receptor interface. Receptor-negative mutations result in more severe phenotypes than receptor-defective mutations.

Homozygous Familial Hypercholesterolemia

FH homozygotes inherit 2 abnormal LDL receptor genes, resulting in markedly elevated plasma cholesterol levels ranging between 500 and 1,200 mg/dL. Triglyceride levels are normal to mildly elevated, and HDL levels may be slightly decreased. The condition occurs in 1 in 500,000 persons. Receptor-negative patients have <2% normal LDL-R activity, whereas those who are receptor defective may have as much as 25% normal activity and a better prognosis.

The prognosis is poor regardless of the specific LDL-R aberration. Severe atherosclerosis involving the aortic root and coronary arteries is present by early to middle childhood. These children usually present with **xanthomas** , which may cause thickening of the Achilles tendon or extensor tendons of the hands, or cutaneous lesions on the hands, elbows, knees, or buttocks (Figs. 104.10 to 104.12). Corneal arcus may be present. Family history is informative because premature heart disease is strongly prevalent among relatives of both parents.

The diagnosis may be confirmed genetically or by measuring LDL-R activity in cultured skin fibroblasts. Phenotypic expression of the disease may also be assessed by measuring receptor activity on the surface of lymphocytes by using cell-sorting techniques.

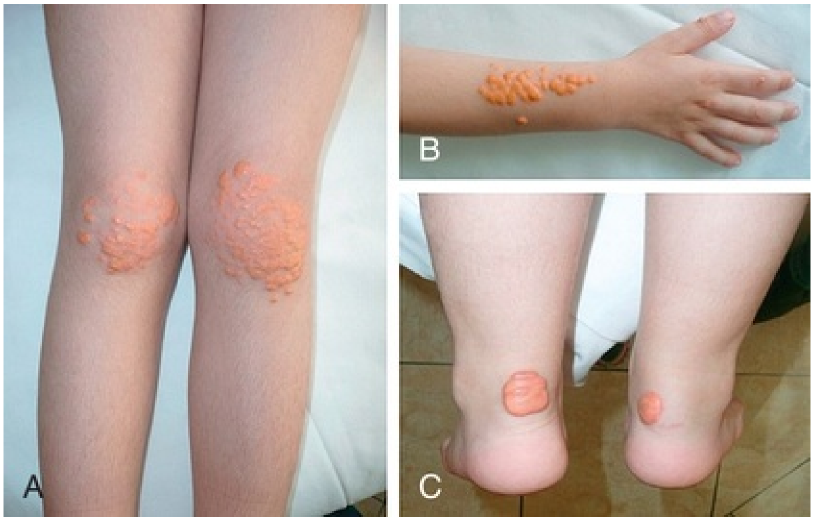

FIG. 104.10 **Homozygous familial hypercholesterolemia. Tendon xanthomas in a 5 yr old male with homozygous FH noted at the knee (A), wrist (B), and Achilles (C). (Modified from Macchiaiolo M, Gagliardi MG, Toscano A, et al: Homozygous familial hypercholesterolaemia, *Lancet* 379:1330, 2012.)**

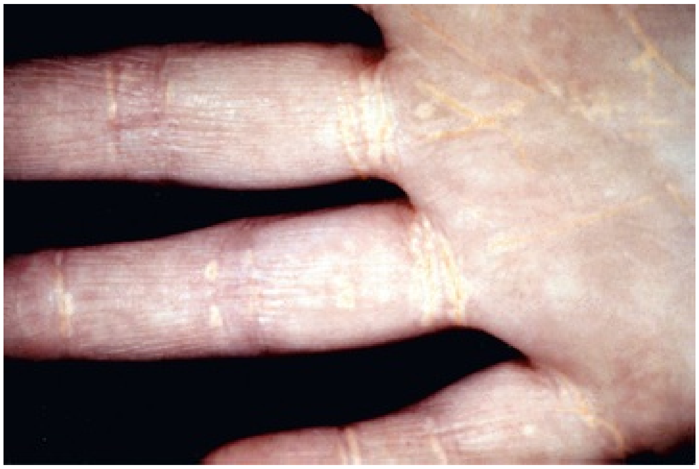

FIG. 104.11 Striate palmar xanthomata. (From Durrington P: Dyslipidaemia, *Lancet* 362:717–731, 2003.)

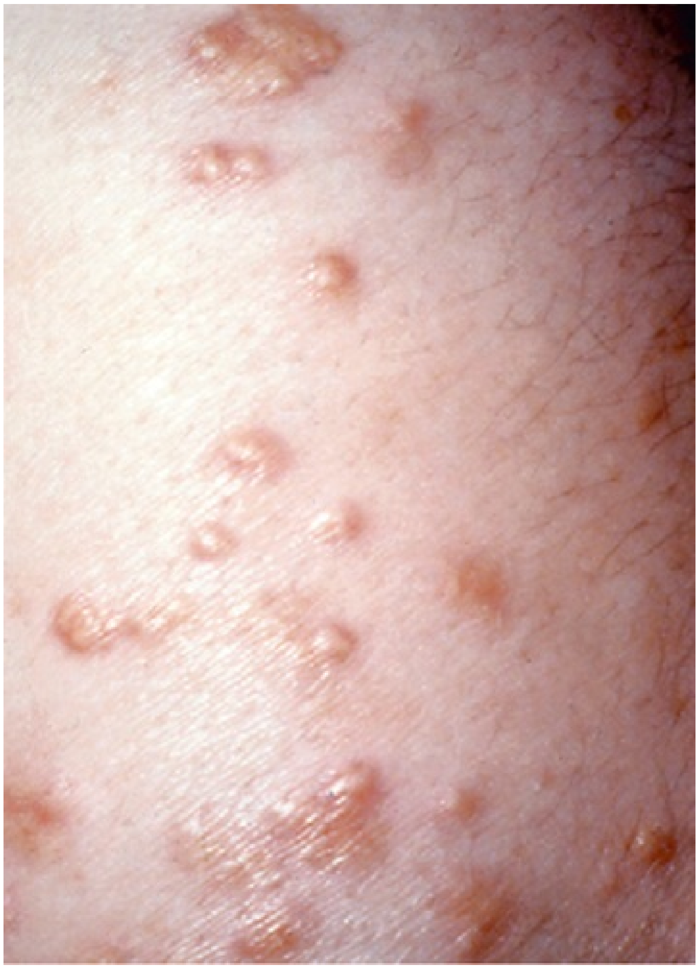

FIG. 104.12 Eruptive xanthomata on extensor surface of forearm. (From Durrington P: Dyslipidaemia, *Lancet* 362:717–731, 2003.)

Untreated homozygous patients rarely survive to adulthood. Symptoms of coronary insufficiency may occur; sudden death is common. LDL apheresis to remove LDL particles selectively from the circulation is recommended for many children because it slows the progression of atherosclerosis. Liver transplantation is also successful in decreasing LDL-C levels, but complications related to immunosuppression are common. HMG-CoA reductase inhibitors may be modestly effective depending on the specific class of LDL-R defect present. Combination therapy with *ezetimibe*, selectively blocking cholesterol adsorption in the gut, usually results in further decline in LDL levels; it has largely replaced the use of bile acid sequestrants. Early clinical trials using microsomal triglyceride transfer protein inhibition with *lomitapide* (oral agent) resulted in a significant reduction in all apoB lipoproteins, including LDL, but hepatic fat deposition as a side effect limits consideration of this pharmacologic approach.

Mipomersen (subcutaneous injection), an antisense oligonucleotide that binds to the sequence that encodes apolipoprotein B, reduces the synthesis of apoB and thus also VLDL and LDL; LDL cholesterol levels may decline approximately 25% with this treatment. Adverse effects include flulike symptoms, hepatic steatosis, and cirrhosis.

Heterozygous Familial Hypercholesterolemia

Heterozygous FH is the most common single-gene mutations associated with acute coronary syndromes and atherosclerotic CHD in adults. Its prevalence is approximately 1 in 250 individuals worldwide, but the frequency may be greater in select populations, such as French Canadians, Afrikaners, and Christian Lebanese, as a result of the founder effect of unique new mutations. The founder effect noted in Ashkenazi Jews can be traced through gene disequilibrium analysis to an initial mutation in Lithuania in the 1400s.

Heart disease accounts for more than half of all deaths in Western society. The pathogenesis of CHD is both environmental and genetic, and the complex interrelationship determines the phenotypic expression of disease.

Because heterozygous FH is a co-dominant condition with nearly full penetrance, 50% of first-degree relatives of affected individuals will have the disease, as will 25% of second-degree relatives. An estimated 20 million people have FH worldwide. Symptoms of CHD usually occur at the mean age of 45-48 yr in males and a decade later in females. Genetic testing of individuals who fulfill clinical criteria for the diagnosis of heterozygous FH is variably positive dependent on the population under investigation, including pediatric vs adult participants.

The World Health Organization (WHO) has targeted FH for individualized intervention strategies because of its large effect on morbidity and mortality. A relatively small percentage of the population accounts for a disproportionately high share of the burden of CVD. The clinical expression of the disease is straightforward, and treatment is effective.

One cannot overemphasize the importance of family history for suspecting the possibility of FH, especially given the 3% cholesterol screening rate for children in primary care offices. American Academy of Pediatrics (AAP) and National Heart, Lung, and Blood Institute (NHLBI) guidelines advocate for universal screening for cholesterol in childhood, but with poor acceptance and disagreement. There is an increased interest in genetic testing for persons with suspected FH because of variability in phenotype based on genotype. In fact, the risk of CHD in individuals with FH can be up to 20 times greater than in the general population.

Plasma levels of LDL-C do not allow unequivocal diagnosis of FH heterozygotes, but values are generally twice normal for age because of 1 absent or dysfunctional allele. The U.S. MED-PED *(Make Early Diagnosis–Prevent Early Death)* Program has formulated diagnostic criteria. Similar criteria with minor variations exist in the United Kingdom (Simon Broome criteria) and Holland (Dutch Lipid Clinic Network criteria). Within well-defined FH families, the diagnosis is reliably established according to LDL cutoff points. More stringent criteria are required to establish the diagnosis in previously undiagnosed families, requiring strong evidence of an autosomal inheritance pattern and higher LDL cutoff points. At a total cholesterol level of 310 mg/dL, only 4% of adults in the general population would have FH, whereas 95% of adults who were first-degree relatives of known cases would have the disease. The mathematical probability of FH in MED-PED, verified by molecular genetics, is derived from a U.S. population cohort and may not be applicable to other countries.

Very high cholesterol levels in children should prompt extensive screening of adult first- and second-degree relatives (“reverse cascade” cholesterol screening). In the general population, a child younger than age 18 yr with total plasma cholesterol of 270 mg/dL and/or LDL-C of 200 mg/dL has an 88% chance of having FH (Table 104.8). *Formal clinical diagnosis of FH is based on the presence of 2 or more family members having elevated LDL-C levels* (the 95th percentile LDL-C level cutoff points for children vary with age and are lower than for adults; see Table 104.9). Thus the criteria for probable FH in a child whose first-degree relative has known FH require only modest elevation of total cholesterol to 220 mg/dL (LDL-C 160 mg/dL; Table 104.8). The challenge of childhood FH diagnosis is heightened by the lack of clinical stigmata such as xanthomata that are employed in the Simon Broome and Dutch Lipid Clinic Network schema and highlights the shift toward genetic diagnosis.

Data for cord blood from Strong W: Atherosclerosis: its pediatric roots. In Kaplan N, Stamler J, editors: *Prevention of coronary heart disease* , Philadelphia, 1983, Saunders. Data for children 1-

4 yr from Tables 6, 7, 20, and 21, and all other data from Tables 24, 25, 32, 33, 36, and 37 in *Lipid research clinics population studies data book* , Vol 1, “The prevalence study,” NIH Pub No 80-1527, Washington, DC, 1980, National Institutes of Health.

Treatment of children with FH should begin with a rather rigorous low-fat diet. Diet alone is rarely sufficient for decreasing blood cholesterol levels to acceptable levels (LDL-C <130 mg/dL). Ezetimibe blocks cholesterol adsorption in the gastrointestinal (GI) tract and has a low risk of side effects. Data suggest that ezetimibe will lower total cholesterol by 20-30 mg/dL. *HMG-CoA reductase inhibitors (statins) are the drug of choice for treatment of FH because of their remarkable effectiveness and acceptable risk profile.* There is sufficient clinical experience with this class of drugs in children over age 10 yr to document that they are as effective in children as in adults, and the risks of elevated hepatic enzymes and myositis are no greater than in adults. Another class of drugs, the proprotein convertase subtilisin/kexin type 9 (**PCSK-9**) inhibitors, are monoclonal antibodies (mAbs) that block the action of PCSK-9 to downregulate the LDL-R. These agents boost LDL-R levels and result in a marked decrease in plasma LDL-C levels. PCSK-9 inhibitors have a role in adults intolerant of statins and those with subtherapeutic statin effect. Use in children is experimental.

Familial Defective ApoB-100

Familial defective apoB-100 is an autosomal dominant condition that is indistinguishable from heterozygous FH. LDL cholesterol levels are increased, triglycerides are normal, adults often develop tendon xanthomas, and premature CHD occurs. Familial defective apoB-100 is caused by mutation in the receptor-binding region of apoB-100, the ligand of the LDL receptor, with an estimated frequency of 1 in 700 people in Western cultures. It is usually caused by substitution of glutamine for arginine in position 3500 in apoB-100, which results in reduced ability of the LDL-R to bind LDL-C, thus impairing its removal from the circulation. Specialized laboratory testing can distinguish familial defective apoB-100 from FH, but this is not necessary, except in research settings, because treatment is the same.

Autosomal Recessive Hypercholesterolemia

This rare condition, caused by a defect in LDL-R–mediated endocytosis in the liver, clinically presents with severe hypercholesterolemia at levels intermediate between those found in homozygous and heterozygous FH. It is disproportionately present among Sardinians and is modestly responsive to treatment with HMG-CoA reductase inhibitors.

Sitosterolemia

A rare autosomal recessive condition characterized by excessive intestinal adsorption of plant sterols, sitosterolemia is caused by mutations in the adenosine triphosphate (ATP)–binding cassette transporter system (*ABCG5* or *ABCG8*), which is responsible for limiting adsorption of plant sterols in the small intestine and promotes biliary excretion of the small amounts adsorbed. Plasma cholesterol levels may be severely elevated, resulting in tendon xanthomas and premature atherosclerosis. Other features include hemolytic anemia, macrothrombocytopenia (large platelets, reduced number), and hemorrhage. Diagnosis can be confirmed by measuring elevated plasma sitosterol levels. Treatment with HMG-CoA reductase inhibitors is not effective, but cholesterol adsorption inhibitors, such as ezetimibe, and bile acid sequestrants are effective.

Polygenic Hypercholesterolemia

Primary elevation in LDL-C among children and adults is most often polygenic; the small effects of many genes are impacted by environmental influences (diet). Plasma cholesterol levels are modestly elevated; triglyceride levels are normal. Polygenic hypercholesterolemia aggregates in families sharing a common lifestyle but does not follow predictable hereditary patterns found in single-gene lipoprotein defects. Treatment of children with polygenic hypercholesterolemia is directed toward adoption of a healthy lifestyle: reduced total and saturated fat consumption and at least 1 hr of physical activity daily. Cholesterol-lowering medication is rarely necessary.

Hypercholesterolemia With Hypertriglyceridemia

Familial Combined Hyperlipidemia

This autosomal dominant condition is characterized by moderate elevation in plasma LDL-C and triglycerides and reduced plasma HDL-C. Familial combined hyperlipidemia (FCHL) is the most common primary lipid disorder, affecting approximately 1 in 200 people. Family history of premature heart disease is typically positive; the formal diagnosis requires that at least 2 first-degree relatives have evidence of 1 of 3 variants of dyslipidemia: (1) >90th percentile plasma LDL-C; (2) >90th percentile LDL-C and triglycerides; and (3) >90th percentile triglycerides. Individuals switch from one phenotype to another. Xanthomas are not a feature of FCHL. Elevated plasma apoB levels with increased small, dense LDL particles support the diagnosis.

Children and adults with FCHL have coexisting adiposity, hypertension, and hyperinsulinemia, suggesting the presence of the **metabolic syndrome** . Formal diagnosis in adults, as defined by the National Cholesterol Education Program (**NCEP**) Adult Treatment Panel III, identifies 6 major components: abdominal obesity, atherogenic dyslipidemia, hypertension, insulin resistance with or without impaired glucose tolerance, evidence of vascular inflammation, and prothrombotic state. An estimated 30% of overweight adults fulfill criteria for the diagnosis of metabolic syndrome, including 65% of those with FCHL. Hispanics and South Asians from the Indian subcontinent are especially susceptible. *There is no official definition of metabolic syndrome for children.* Absolute cutoffs for diagnosis in children do not account for continuous variables in aging, sexual maturation, and race/ethnicity.

FCHL and type 2 diabetes share many features of the metabolic syndrome, suggesting that they are less distinct entities than originally conceptualized. Genetic association studies reveal evidence for a common genetic background. The resultant metabolic overlap is associated with ectopic fat accumulation and insulin resistance. The mechanisms associating visceral adiposity with the metabolic syndrome and type 2 diabetes are not fully understood. A plausible unifying principle is that obesity causes endoplasmic reticulum stress, leading to suppression of insulin receptor signaling and thus insulin resistance and heightened inflammatory response. How this relates to atherogenesis is unclear. It is assumed that hypercholesterolemia and, with less certainty, hypertriglyceridemia confer risk for CVD in patients with FCHL. When features of the metabolic syndrome are included in logistic models, shared etiologic features such as increased visceral adiposity become apparent. Visceral adiposity increases with age, and its importance in children as a risk factor for heart disease and diabetes is limited by the relative paucity of data. Although longitudinal measurement of waist circumference and the presence of intraabdominal fat as determined by MRI is being conducted in the research setting, body mass index (BMI) remains the surrogate for adiposity in the pediatric clinical setting.

The metabolic syndrome is a dramatic illustration of the interaction of genetics and the environment. Genetic susceptibility is essential as an explanation for premature heart disease in individuals with FCHL. Unhealthy lifestyle, poor diet, and physical inactivity contribute to obesity and attendant features of the metabolic syndrome.

The cornerstone of management is lifestyle modification . This includes a diet low in saturated fats, *trans* fats, and cholesterol, as well as reduced consumption of processed sugars. Increased dietary intake of fruits and vegetables is important, as is 1 hr of moderate physical activity daily. Compliance among children and their parents is often a problem, but small incremental steps are more likely to succeed than aggressive weight loss strategies. It is very important that the child's caregivers participate in the process. Plasma triglyceride levels are usually quite responsive to dietary restriction, especially reduction in the amount of sweetened drinks consumed. Blood cholesterol levels may decrease by 10–15%, but if LDL-C remains >160 mg/dL, drug therapy should be considered.

Familial Dysbetalipoproteinemia (Type III Hyperlipoproteinemia)

Familial dysbetalipoproteinemia (FDBL) is caused by mutations in the gene for apoE, which when exposed to environmental influences (e.g., high-fat high-caloric diet, excessive alcohol intake) results in a mixed type of hyperlipidemia. Patients tend to have elevated plasma cholesterol and triglycerides to a relatively similar degree. HDL-C is typically normal, in contrast to other causes of hypertriglyceridemia associated with low HDL. This rare disorder affects approximately 1 in 10,000 persons. ApoE mediates removal of chylomicron and VLDL remnants from the circulation by binding to hepatic surface receptors. The polymorphic *APOE* gene expresses in 3 isoforms: *apoE3, apoE2,* and *apoE4. E4* is the “normal” allele present in the majority of the population. The *apoE2* isoform has lower affinity for the LDL receptor, and its frequency is approximately 7%. Approximately 1% of the population is homozygous for *apoE2/E2,* the most common mutation associated with FDBL, but only a minority expresses the disease. Expression requires precipitating illnesses such as diabetes, obesity, renal disease, or hypothyroidism. Individuals homozygous for *apoE4/E4* are at risk for late-onset Alzheimer disease and dementia from repeated sports-related head injuries.

Most patients with FDBL present in adulthood with distinctive xanthomas. Tuberoeruptive xanthomas resemble small, grapelike clusters on the knees, buttocks, and elbows. Prominent orange-yellow discoloration of the creases of the hands (palmar xanthomas) is also typically present. Atherosclerosis, often presenting with peripheral vascular disease, usually occurs in the 4th or 5th decade. Children may present with a less distinctive rash and generally have precipitating illnesses.

The diagnosis of FDBL is established by lipoprotein electrophoresis, which demonstrates a broad beta band containing remnant lipoproteins. Direct measurement of VLDL by ultracentrifugation can be performed in specialized lipid laboratories. A VLDL/total triglyceride ratio >0.30 supports the diagnosis. *APOE* genotyping for *apoE2* homozygosity can be performed, confirming the diagnosis in the presence of the distinctive physical findings. A negative result does not necessarily rule out the disease as other mutations in *APOE* may cause even more serious manifestations.

Pharmacologic treatment of FDBL is necessary to decrease the likelihood of symptomatic atherosclerosis in adults. HMG-CoA reductase inhibitors, nicotinic acid, and fibrates are all effective. FDBL is quite responsive to recommended dietary restriction.

Hypertriglyceridemias

The familial disorders of triglyceride-rich lipoproteins include both common and rare variants of the **Frederickson classification** system. These include familial chylomicronemia (type I), familial hypertriglyceridemia (type IV), and the more severe combined hypertriglyceridemia and chylomicronemia (type V). Hepatic lipase deficiency also results in a similar combined hyperlipidemia.

Familial Chylomicronemia (Type I Hyperlipidemia)

This rare single-gene defect, like FH, is caused by mutations affecting clearance of apoB-containing lipoproteins. Deficiency or absence of LPL or its cofactor apoC-II, which facilitates lipolysis by LPL, causes severe elevation of triglyceride-rich plasma chylomicrons. HDL-C levels are decreased. Clearance of these particles is greatly delayed, so the plasma is noted to have a turbid appearance even after prolonged fasting (Fig. 104.13). Chylomicronemia caused by LPL deficiency is associated with modest elevation in triglycerides, whereas this is not the case when the cause is deficient or absent apoC-II. Both are autosomal recessive conditions with a frequency of approximately 1 in 1 million population. The disease usually presents during childhood with acute pancreatitis. Eruptive xanthomas on the arms, knees, and buttocks may be present, and there may be hepatosplenomegaly. The diagnosis is established by assaying triglyceride lipolytic activity. **Treatment** of chylomicronemia is by vigorous dietary fat restriction supplemented by fat-soluble vitamins. Medium-chain triglycerides that are adsorbed into the portal venous system may augment total fat intake, and administration of fish oils may also be beneficial.

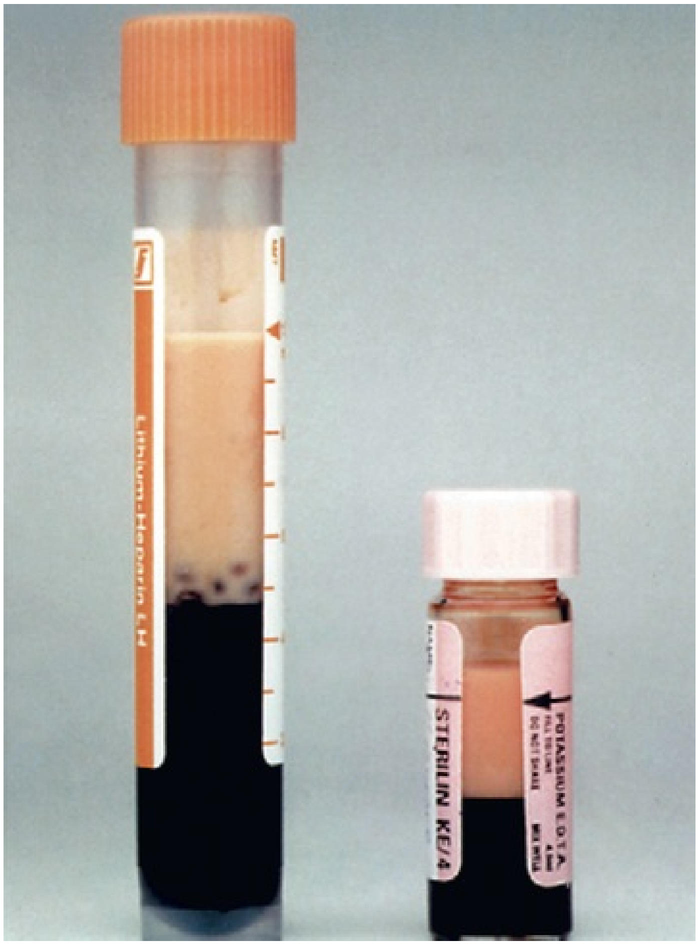

FIG. 104.13 Milky plasma from patient with acute abdominal pain. (From Durrington P: Dyslipidaemia, *Lancet* 362:717–731, 2003.)

Familial Hypertriglyceridemia (Type IV Hyperlipidemia)

Familial hypertriglyceridemia (FHTG) is an autosomal dominant disorder of unknown etiology that occurs in approximately 1 in 500 individuals. It is characterized by elevation of plasma triglycerides >90th percentile (250-1,000 mg/dL range), often accompanied by slight elevation in plasma cholesterol and low HDL. FHTG does not usually manifest until adulthood, although it is expressed in approximately 20% of affected children. In contrast to FCHL, FHTG is not thought to be highly atherogenic. It is most likely caused by defective breakdown of VLDL, or less often by overproduction of this class of lipoproteins.

The diagnosis should include the presence of at least 1 first-degree relative with hypertriglyceridemia. FHTG should be distinguished from FCHL and FDBL, which require more vigorous treatment to prevent coronary or peripheral vascular disease. The differentiation is usually possible on clinical grounds, in that lower LDL-C levels accompany FHTG, but measurement of normal apoB levels in FHTG may be helpful in ambiguous situations.

A more severe hypertriglyceridemia characterized by increased levels of chylomicrons as well as VLDL particles (Frederickson **type V**) may occasionally be encountered. Triglyceride levels are often >1,000 mg/dL. The disease is rarely seen in children. In contrast to chylomicronemia (Frederickson **type I**), LPL or apoC-II deficiency is not present. These patients often develop eruptive xanthomas in adulthood, whereas **type IV** hypertriglyceridemia individuals do not. Acute pancreatitis may be the presenting illness. As with other hypertriglyceridemias, excessive alcohol consumption and estrogen therapy can exacerbate the disease.

Secondary causes of *transient hypertriglyceridemia* should be ruled out before making a diagnosis of FHTG. A diet high in simple sugars and carbohydrates or excessive alcohol consumption, as well as estrogen therapy, may exacerbate hypertriglyceridemia. Adolescents and adults should be questioned about excessive consumption of soda and other sweetened drinks, as it is common to encounter people who drink supersized drinks or multiple 12 oz cans of sweetened drinks daily. Cessation of this practice often results in dramatic fall in triglyceride levels as well as weight among those who are obese. HDL-C levels will tend to rise as BMI stabilizes.

Pediatric diseases associated with hyperlipidemia include hypothyroidism, nephrotic syndrome, biliary atresia, glycogen storage disease, Niemann-Pick disease, Tay-Sachs disease, systemic lupus erythematosus, hepatitis, and anorexia nervosa (Table 104.10). Certain medications exacerbate hyperlipidemia, including isotretinoin (Accutane), thiazide diuretics, second-generation antipsychotic agents, oral contraceptives, corticosteroids, β blockers, immunosuppressants, and protease inhibitors used in HIV treatment.

Table 104.10

Secondary Causes of Hyperlipidemia

Hypercholesterolemia

Hypothyroidism
Nephrotic syndrome
Cholestasis
Anorexia nervosa
Drugs: progesterone, thiazides, carbamazepine (Tegretol), cyclosporine

Hypertriglyceridemia

Obesity
Type 2 diabetes
Alcohol
Renal failure
Sepsis
Stress
Cushing syndrome
Pregnancy
Hepatitis
AIDS, protease inhibitors
Drugs: anabolic steroids, β-blockers, estrogen, thiazides

Reduced High-Density Lipoprotein

Smoking
Obesity
Type 2 diabetes
Malnutrition
Drugs: β-blockers, anabolic steroids

Treatment of hypertriglyceridemia in children rarely requires medication unless levels >1,000 mg/dL persist after dietary restriction of fats, sugars, and carbohydrates, accompanied by increased physical activity. In such patients the aim is to prevent episodes of pancreatitis. The common use of fibrates (fenofibric acid) and niacin in adults with hypertriglyceridemia is not recommended in children. HMG-CoA reductase inhibitors are variably effective in lowering triglyceride levels, and there is considerably more experience documenting the safety and efficacy of this class of lipid-lowering medications in children. In adults, the U.S. Food and Drug Administration (FDA) has approved prescription (Lovaza, Vascepa) and nonprescription fish oils as adjuncts to diet in the treatment of severe hypertriglyceridemias.

Hepatic Lipase Deficiency

Hepatic lipase deficiency is a very rare autosomal recessive condition causing elevation in both plasma cholesterol and triglycerides. Hepatic lipase hydrolyzes triglycerides and phospholipids in VLDL remnants and IDL, preventing their conversion to LDL. HDL-C levels tend to be increased rather than decreased, suggesting the diagnosis. Laboratory confirmation is established by measuring hepatic lipase activity in heparinized plasma.

Disorders of High-Density Lipoprotein Metabolism

Primary Hypoalphalipoproteinemia

Isolated low HDL cholesterol is a familial condition that often follows a pattern suggestive of autosomal dominant inheritance but may occur independent of family history. It is the most common disorder of HDL metabolism. It is defined as HDL-C <10th percentile for gender and age with normal plasma triglycerides and LDL-C. Whether it is associated with more rapid atherosclerosis is uncertain. Primary hypoalphalipoproteinemia appears to be related to a reduction in apoA-I synthesis and increased catabolism of HDL. Secondary causes of low HDL-C, such as the metabolic syndrome, and rare diseases such as LCAT deficiency and Tangier disease must be ruled out.

Familial Hyperalphalipoproteinemia

This is an unusual condition conferring decreased risk for CHD among family members. Plasma levels of HDL-C exceed 80 mg/dL.

Familial Apolipoprotein A-I Deficiency

Mutations in the *apoA-I* gene may result in complete absence of plasma HDL. Nascent HDL is produced in the liver and small intestine. Free cholesterol from peripheral cells is esterified by LCAT, enabling formation of mature HDL particles. ApoA-I is required for normal enzymatic functioning of LCAT. The resultant accumulation of free cholesterol in the circulation eventually leads to corneal opacities, planar xanthomas, and premature atherosclerosis. Some patients, however, may have mutations of *apoA-I* that result in very rapid catabolism of the protein not associated with atherogenesis, despite HDL-C levels in the 15-30 mg/dL range.

Tangier Disease

This autosomal co-dominant disease is associated with HDL-C levels <5 mg/dL. It is caused by mutations in ABCA1, a protein that facilitates the binding of cellular cholesterol to apoA-I. This results in free cholesterol accumulation in the reticuloendothelial system, manifested by tonsillar hypertrophy of a distinctive orange color and hepatosplenomegaly. Intermittent peripheral neuropathy may occur from cholesterol accumulation in Schwann cells. Diagnosis should be suspected in children with enlarged orange tonsils and extremely low HDL-C levels.

Familial Lecithin–Cholesterol Acyltransferase (LCAT) Deficiency

Mutations affecting LCAT interfere with the esterification of cholesterol, thereby preventing formation of mature HDL particles. This is associated with rapid catabolism of apoA-I. Free circulating cholesterol in the plasma is greatly increased, which leads to corneal opacities and HDL-C levels <10 mg/dL. Partial LCAT deficiency is known as “fish-eye” disease. Complete deficiency causes hemolytic anemia and progressive renal insufficiency early in adulthood. This rare disease is not thought to cause premature atherosclerosis. Laboratory confirmation is based on demonstration of decreased cholesterol esterification in the plasma.

Cholesteryl Ester Transfer Protein Deficiency

Mutations involving the *CETP* gene are localized to chromosome 16y21. Cholesteryl ester transfer protein (CETP) facilitates the transfer of lipoproteins from mature HDL to and from VLDL and chylomicron particles, thus ultimately regulating the rate of cholesterol transport to the liver for excretion in the bile. About half of mature HDL-2 particles are directly removed from the circulation by HDL receptors on the surface of the liver. The other half of cholesteryl esters in the core of HDL exchange with triglycerides in the core of apoB lipoproteins (VLDL, IDL, LDL) for transport to the liver. Homozygous deficiency of CETP has been observed in subsets of the Japanese population with extremely high HDL-C levels (>150 mg/dL).

Conditions Associated With Low Cholesterol

Disorders of apoB-containing lipoproteins and intracellular cholesterol metabolism are associated with low plasma cholesterol.

Abetalipoproteinemia

This rare autosomal recessive disease is caused by mutations in the gene encoding microsomal triglyceride transfer protein necessary for the transfer of lipids to nascent chylomicrons in the small intestine and VLDL in the liver. This results in absence of chylomicrons, VLDL, LDL, and apoB and very low levels of plasma cholesterol and triglycerides. Fat malabsorption, diarrhea, and failure to thrive present in early childhood. Spinocerebellar degeneration, secondary to vitamin E deficiency, manifests in loss of deep tendon reflexes progressing to ataxia and lower-extremity spasticity by adulthood. Patients with abetalipoproteinemia also acquire a progressive pigmented retinopathy associated with decreased night and color vision and eventual blindness. The neurologic symptoms and retinopathy may be mistaken for **Friedreich ataxia** . Differentiation from Friedreich ataxia is suggested by the presence of malabsorption and acanthocytosis on peripheral blood smear in abetalipoproteinemia. Many of the clinical manifestations of the disease are a result of malabsorption of fat-soluble vitamins, such as vitamins E, A, and K. *Early treatment with supplemental vitamins, especially E, may significantly slow the development of neurologic sequelae.* Vitamin E is normally transported from the small intestine to the liver by chylomicrons, where it is dependent on the endogenous VLDL pathway for delivery into the circulation and peripheral tissues. Parents of children with abetalipoproteinemia have normal blood lipid and apoB levels.

Familial Hypobetalipoproteinemia

Familial homozygous hypobetalipoproteinemia is associated with symptoms very similar to those of abetalipoproteinemia, but the inheritance pattern is autosomal co-dominant. The disease is caused by mutations in the gene encoding apoB-100 synthesis. It is distinguishable from abetalipoproteinemia in that heterozygous parents of probands have plasma LDL-C and apoB levels less than half normal. There are no symptoms or sequelae associated with the heterozygous condition.

The selective inability to secrete apoB-48 from the small intestine results in a condition resembling abetalipoproteinemia or homozygous hypobetalipoproteinemia. Sometimes referred to as **Anderson disease** , the failure of chylomicron absorption causes steatorrhea and fat-soluble vitamin deficiency. The blood level of apoB-100, derived from normal hepatocyte secretion, is normal in this condition.

Smith-Lemli-Opitz Syndrome

Patients with Smith-Lemli-Opitz syndrome (**SLOS**) often have multiple congenital anomalies and developmental delay caused by low plasma cholesterol and accumulated precursors (Tables 104.11 and 104.12) (see Chapter 606.2). Family pedigree analysis has revealed its autosomal recessive inheritance pattern. Mutations in the *DHCR7* (7-dehydrocholesterol-Δ7 reductase) gene result in deficiency of the microsomal enzyme DHCR7, which is necessary to complete the final step in cholesterol synthesis. It is not known why defects in cholesterol synthesis result in congenital malformations, but since cholesterol is a major component of myelin and a contributor to signal transduction in the developing nervous system, neurodevelopment is severely impaired. The incidence of SLOS is estimated to be 1 in 20,000-60,000 births among whites, with a somewhat higher frequency in Hispanics and lower incidence in individuals of African descent.

Table 104.11

Major Clinical Characteristics of Smith-Lemli-Opitz Syndrome: Frequent Anomalies (>50% of Patients)

Craniofacial

Microcephaly
Blepharoptosis
Anteverted nares
Retromicrognathia
Low-set, posteriorly rotated ears
Midline cleft palate
Broad maxillary alveolar ridges
Cataracts (<50%)

Skeletal Anomalies

Syndactyly of toes II/III
Postaxial polydactyly (<50%)
Equinovarus deformity (<50%)

Genital Anomalies

Hypospadias
Cryptorchidism
Sexual ambiguity (<50%)

Development

Prenatal and postnatal growth retardation
Feeding problems
Mental impairment
Behavioral abnormalities

Table 104.12

Characteristic Malformations of Internal Organs in Severely Affected Smith-Lemli-Opitz Patients

Central Nervous System

Frontal lobe hypoplasia
Enlarged ventricles
Agenesis of corpus callosum
Cerebellar hypoplasia
Holoprosencephaly

Cardiovascular

Atrioventricular canal
Secundum atrial septal defect
Patent ductus arteriosus
Membranous ventricular septal defect

Urinary Tract

Renal hypoplasia or aplasia
Renal cortical cysts
Hydronephrosis
Ureteral duplication

Gastrointestinal

Hirschsprung disease
Pyloric stenosis
Refractory dysmotility
Cholestatic and noncholestatic progressive liver disease

Pulmonary

Pulmonary hypoplasia
Abnormal lobation

Endocrine	
	Adrenal insufficiency

From Haas D, Kelley RI, Hoffmann GF: Inherited disorders of cholesterol biosynthesis, *Neuropediatrics* 32:113–122, 2001.

Spontaneous abortion of SLOS fetuses may occur. **Type II** SLOS often leads to death by the end of the neonatal period. Survival is unlikely when the plasma cholesterol level is <20 mg/dL. Laboratory measurement should be performed by gas chromatography, because standard techniques for lipoprotein assay include measurement of cholesterol precursors, which may yield a false-positive result. Milder cases may not present until late childhood. Phenotypic variance ranges from microcephaly, cardiac and brain malformation, and multiorgan system failure to only subtle dysmorphic features and mild developmental delay. **Treatment** includes supplemental dietary cholesterol (egg yolk) and HMG-CoA reductase inhibition to prevent the synthesis of toxic precursors proximal to the enzymatic block.

Disorders of Intracellular Cholesterol Metabolism

Cerebrotendinous Xanthomatosis

This autosomal recessive disorder presents clinically in late adolescence with tendon xanthomas, cataracts, and progressive neurodegeneration. It is caused by tissue accumulation of bile acid intermediates shunted into cholestanol, resulting from mutations in the gene for sterol 27-hydroxylase. This enzyme is necessary for normal mitochondrial synthesis of bile acids in the liver. Early treatment with chenodeoxycholic acid reduces cholesterol levels and prevents the development of symptoms.

Wolman Disease and Cholesterol Ester Storage Disease

These autosomal recessive disorders are caused by lack of lysosomal acid lipase. After LDL cholesterol is incorporated into the cell by endocytosis, it is delivered to lysosomes, where it is hydrolyzed by lysosomal lipase. Failure of hydrolysis because of complete absence of the enzyme causes accumulation of cholesteryl esters within the cells. Hepatosplenomegaly, steatorrhea, and failure to thrive occur during early infancy, leading to death by age 1 yr. In cholesterol ester storage disease, a less severe form than Wolman disease, there is low but detectable acid lipase activity (see Chapter 104.4).

Niemann-Pick Disease Type C

This disorder of intracellular cholesterol transport is characterized by accumulation of cholesterol and sphingomyelin in the CNS and reticuloendothelial system. Death from this autosomal recessive neurologic disease usually occurs by adolescence (see Chapter 104.4).

Lipoprotein Patterns in Children and Adolescents

Derived primarily from the Lipid Research Clinics Population Studies, Table 104.9 shows the distribution of lipoprotein levels in American youth at various ages. Total plasma cholesterol rises rapidly from a mean of 68 mg/dL at birth to a level approximately twice that by the end of the neonatal period. A very gradual rise in total cholesterol level occurs until puberty, when the mean level reaches 160 mg/dL. Total cholesterol falls transiently during puberty, in males because of a small decrease in HDL-C, and in females secondary to a slight fall in LDL-C. Blood cholesterol levels track reasonably well as individuals age.

High blood cholesterol tends to aggregate in families, a reflection of genetic and environmental influences.

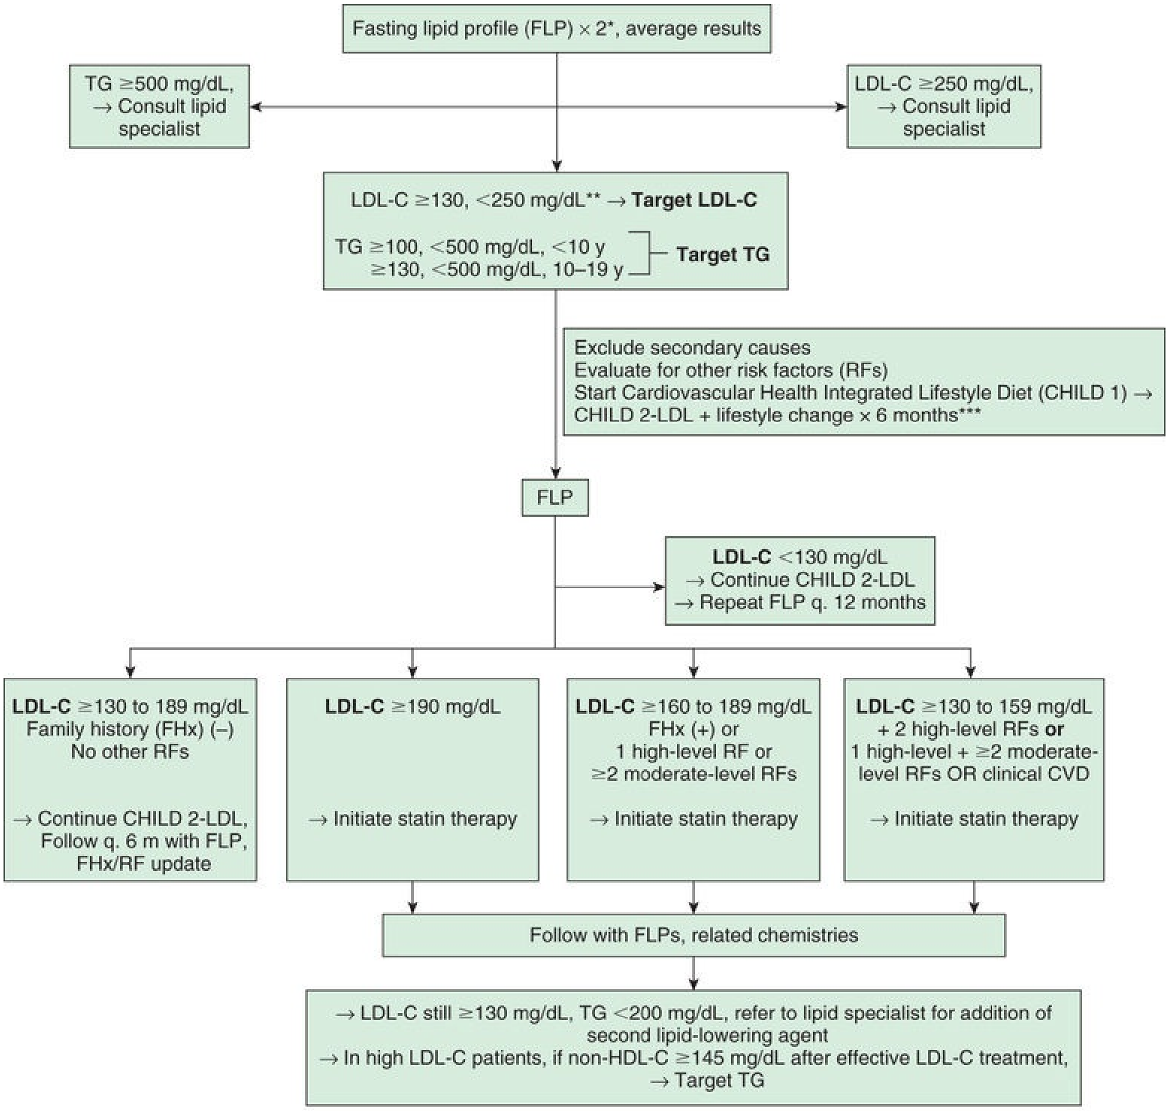
Acceptable total cholesterol among children and adolescents is <170 mg/dL; borderline is 170-199 mg/dL; and high >200 mg/dL. Acceptable LDL-C is <110 mg/dL; borderline 110-129 mg/dL; and high >130 mg/dL. HDL-C should be >40 mg/dL.

Blood Cholesterol Screening

The AAP began recommending a universal approach for cholesterol screening to all children in 2011. *A lipid profile should be checked for all children between ages 9 and 11 yr and then another between ages 17 and 21 yr*, because cholesterol levels may vary after puberty. However, if a child would have met the selective criteria from the previous risk-based guidelines (premature coronary artery disease in parent or grandparent, parent with cholesterol >240 mg/dL), screening can occur as early as age 2 yr. Data also suggest that obtaining a *nonfasting* lipid profile can be just as useful in detecting severe genetic dyslipidemias as a fasting lipid profile, and thus can be used as first-line screening in children. Fasting lipid profiles may also be used depending on parental, child, and clinician preference, especially if there is concern for hypertriglyceridemia, since triglycerides are affected more by fasting status. Abnormal lipid panels should be repeated, and especially when the concern is the triglycerides, the 2nd panel should be obtained ≥2 wk later in the fasted state. Treatment other than lifestyle modification is not initiated based on a single lipid panel determination.

Risk Assessment and Treatment of Hyperlipidemia

The NCEP recommends a population-based approach toward healthy lifestyle applicable to all children, and an individualized approach directed at those children at high risk (Fig. 104.14). The important focus on maintenance of a healthy lifestyle rather than aggressive weight reduction is recommended by the AAP.



Fasting lipid profile (FLP) × 2*, average results
TG ≥500 mg/dL, → Consult lipid specialist
LDL-C ≥250 mg/dL, → Consult lipid specialist
LDL-C ≥130, <250 mg/dL** → Target LDL-C
TG ≥100, <500 mg/dL, <10 y
≥130, <500 mg/dL, 10–19 y
Target TG
Exclude secondary causes
Evaluate for other risk factors (RFs)
Start Cardiovascular Health Integrated Lifestyle Diet (CHILD 1) → CHILD 2-LDL + lifestyle change × 6 months***
FLP
LDL-C <130 mg/dL → Continue CHILD 2-LDL → Repeat FLP q. 12 months
LDL-C ≥130 to 189 mg/dL Family history (FHx) (–) No other RFs → Continue CHILD 2-LDL, Follow q. 6 m with FLP, FHx/RF update
LDL-C ≥190 mg/dL → Initiate statin therapy
LDL-C ≥160 to 189 mg/dL FHx (+) or 1 high-level RF or ≥2 moderate-level RFs → Initiate statin therapy
LDL-C ≥130 to 159 mg/dL + 2 high-level RFs or 1 high-level + ≥2 moderate-level RFs OR clinical CVD → Initiate statin therapy
Follow with FLPs, related chemistries
→ LDL-C still ≥130 mg/dL, TG <200 mg/dL, refer to lipid specialist for addition of second lipid-lowering agent
→ In high LDL-C patients, if non-HDL-C ≥145 mg/dL after effective LDL-C treatment, → Target TG

* Obtain FLPs at least 2 weeks but no more than 3 months apart.

** Use of drug therapy is limited to children ≥10 y with defined risk profiles.

*** In a child with LDL-C >190 mg/dL and other RFs, trial of CHILD 2-LDL may be abbreviated.

FIG. 104.14 Dyslipidemia treatment algorithm: Target LDL-C (low-density lipoprotein cholesterol). Note: Values given are in mg/dL. To convert to SI units, divide results for total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C), and non-HDL-C by 38.6; for triglycerides (TG), divide by 88.6. (From US Department of Health and Human Services, National Institutes of Health, National Heart, Lung, and Blood Institute: Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents. NIH Publication No. 12-7486A, Oct 2012, Fig 9-1.)

All children with dyslipidemias are stratified according to the presence of high-level or moderate-level risk factors to determine their ultimate treatment. **High-level risk factors** are defined as hypertension requiring drug therapy (blood pressure ≥99th percentile + 5 mm Hg), current cigarette smoker, BMI at the ≥97th percentile, presence of type 1 or type 2 diabetes mellitus, chronic kidney disease, postorthoptic heart transplant, and/or Kawasaki disease with current aneurysms. **Moderate-level risk factors** are defined as hypertension that does not require drug therapy, BMI at the ≥95th percentile but <97th percentile, HDL-C <40 mg/dL, Kawasaki disease with regressed coronary aneurysms, chronic inflammatory disease, HIV infection, and/or presence of nephrotic syndrome.

The initial treatment for dyslipidemia in a child always begins with a 6-mo trial of lifestyle modification, namely, improvements in dietary and physical activity patterns. Being overweight confers special risk of CVD because of the strong association with the insulin resistance syndrome (metabolic syndrome). Although there is no standardized definition of metabolic syndrome defined for youth, it is likely that half of all severely obese children are insulin resistant. Data from the CARDIAC project noted that 49% of 5th grade children with the hyperpigmented rash, acanthosis nigricans, had 3 or more factors for the insulin resistance syndrome when using the definition classically used for adults, including evidence of insulin resistance, hypertension, HDL-C <40 mg/dL, and triglycerides >150 mg/dL, in addition to obesity.

The Cardiovascular Health Integrated Lifestyle Diet-1 (**CHILD-1**) diet is the first level of dietary change to be recommended for all children with dyslipidemias. The CHILD-1 diet is specially designed for children with risk factors for coronary artery disease and focuses on limiting dietary cholesterol to 300 mg/day, limiting sugary drink consumption, using reduced-fat/skim milk, avoiding foods high in *trans* -type fats, limiting foods high in sodium, and encouraging consumption of foods high in fiber. Specific recommendations depend on the child's age.

The use of the Cardiovascular Health Integrated Lifestyle Diet-2 (**CHILD-2**) diet is recommended if the CHILD-1 diet alone is unsuccessful. Although similar in many aspects to the CHILD-1 diet, the CHILD-2 diet is geared toward a specific dyslipidemia type; the **CHILD-2 LDL** diet is recommended for children with elevated LDL levels and the **CHILD-2 TG** diet for those presenting with elevated triglycerides. The basic recommendations of calorie consumption for the CHILD-2 diet are as follows: only 25–30% of calories from fat, ≤7% of calories from saturated fat, 10% of calories from monounsaturated fat, and <200 mg/day of cholesterol. If the CHILD-2 LDL diet is recommended, the use of plant sterols and water-soluble fiber is emphasized. If the CHILD-2 TG diet is recommended, the increasing consumption of omega-3 fatty acids and complex rather than simple carbohydrates is emphasized.

If followed, these dietary recommendations will provide adequate calories for optimal growth and development without promoting obesity. Compliance on the part of children and their caregivers is challenging. Children learn eating habits from their parents. Successful adoption of a healthier lifestyle is much more likely to occur if meals and snacks in the home are applicable to the entire family rather than an individual child. A regular time for meals together as a family is desirable. Grandparents and other nonparental caregivers sometimes need to be reminded not to indulge the child who is on a restricted diet. Additionally, the rise in obesity is prompting some school districts to restrict sweetened drink availability and offer more nutritious cafeteria selections.

Changes in physical activity habits are also an important part of the initial lifestyle modification. The National Association for Sport and Physical Education recommends that children should accumulate at least 60 min of age-appropriate physical activity on most days of the week. Extended periods (≥2 hr) of daytime inactivity are discouraged, as is >2 hr of television and other forms of screen time.

Pharmacologic Therapy.

See Tables 104.13 and 104.14 .

Table 104.13

Drugs Used for the Treatment of Hyperlipidemia

DRUG	MECHANISM OF ACTION	INDICATION	STARTING DOSE
HMG-CoA reductase inhibitors (statins)	↓ Cholesterol and VLDL synthesis	Elevated LDL	5-80 mg every night at bedtime
	↑ Hepatic LDL receptors		
Bile acid sequestrants:	↑ Bile and excretion	Elevated LDL	
Cholestyramine			4-32 g daily
Colestipol			5-40 g daily
Nicotinic acid	↓ Hepatic VLDL synthesis	Elevated LDL	100-2,000 mg 3 times daily
		Elevated TG	
Fibric acid derivatives:	↑ LPL	Elevated TG	600 mg twice daily
Gemfibrozil	↓ VLDL		
Fish oils	↓ VLDL production	Elevated TG	3-10 g daily
Cholesterol absorption inhibitors:			
Ezetimibe	↓ Intestinal absorption cholesterol	Elevated LDL	10 mg daily

LDL, Low-density lipoprotein(s); LPL, lipoprotein lipase; TG, triglycerides; VLDL, very-low-density lipoprotein.

Table 104.14

Adverse Effects of Cholesterol-Lowering Drugs

Statins

Myalgia, myositis, transaminase elevations, hepatic dysfunction, increased risk of diabetes mellitus
Rare: Rhabdomyolysis, hemorrhagic stroke

Ezetimibe

Diarrhea, arthralgia, rhabdomyolysis, hepatitis, pancreatitis, thrombocytopenia

Pcsk9 Inhibitors

Nasopharyngitis, upper respiratory tract infection, influenza, back pain, injection site reactions, rash, allergic skin reactions, cognitive effects, antidrug antibodies

Bile Acid Sequestrants

Constipation, heartburn, nausea, eructation, bloating
Adverse effects are more common with colestipol and cholestyramine and may diminish over time.

Fibric Acid Derivatives

Gastrointestinal (GI) disturbances, cholelithiasis, hepatitis, myositis

Niacin

Skin flushing, pruritus, GI disturbances, blurred vision, fatigue, glucose intolerance, hyperuricemia, hepatic toxicity, exacerbation of peptic ulcers
Adverse effects, especially flushing, occur more frequently with immediate-release products.
Rare: Dry eyes, hyperpigmentation

Fish Oil

Eructation, dyspepsia, unpleasant aftertaste

From *The Medical Letter:* Lipid-lowering drugs, *Med Lett* 58:133-140, 2016 (Table 2, p 136).

Pharmacologic therapy with cholesterol-lowering medication is the cornerstone of therapy for children who fail to respond to 6 mo of rigorous lifestyle modification. Drug therapy should be considered when 1 of the following conditions are met (also shown in Fig. 104.14):

- LDL cholesterol remains >190 mg/dL
- LDL cholesterol remains >160 mg/dL with presence of 1 high-level risk factor *and/or* at least 2 moderate-level risk factors
- LDL cholesterol remains >130 mg/dL with presence of at least 2 high-level risk factors, 1 high-level risk factor, *and* at least 2 moderate-level risk factors, *or* evidence of coronary artery disease (CAD)

HMG-CoA reductase inhibitors, also known as “statins” are remarkably effective in lowering LDL cholesterol levels and reducing plaque inflammation, thereby reducing the likelihood of a sudden coronary event in an at-risk adult within weeks of starting the medication. As a class, they work by blocking the intrahepatic biosynthesis of cholesterol, thereby stimulating the production of more LDL receptors on the cell surface and facilitating the uptake of LDL-C from the bloodstream. The NCEP Adult Treatment Panel advocates aggressive lowering of LDL to <70 mg/dL in individuals with known CAD. This information is relevant because a child who fulfills criteria for consideration of cholesterol-lowering medication will almost always have inherited the condition from one of the child's parents. Not infrequently, when providing care for the child, questions arise about screening and treatment of parents or grandparents. Statins are equally effective in children, capable of lowering LDL-C levels by 50% when necessary. They are considered first-line therapy for children who meet criteria for pharmacologic therapy. They also will affect a modest reduction in triglycerides and an inconsistent increase in HDL-C. Their side effect profile, mainly liver dysfunction and rarely rhabdomyolysis with secondary renal failure, should be taken into consideration before prescribing the drug. However, there has been no evidence that complications are any more frequent in children than adults, and skeletal muscle discomfort seems to be somewhat less of a problem. Drug interactions may occur as well, so careful attention should be paid to a child's active prescriptions to avoid potentiation of the side effects. Children should have liver enzymes monitored regularly, and creatine phosphokinase measured if muscle aches or weakness occurs. Liver (muscle) enzymes may be allowed to rise 3-fold before discontinuing the drug. There is a suggested link between the use of statins and increased risk of developing type 2 diabetes mellitus in adults, but these results have not been replicated in children. Sex hormones have been measured in children receiving statins and are unchanged. It should be reemphasized that children with modest elevations in cholesterol, such as that seen in polygenic hypercholesterolemia, are not, as a rule, candidates for statins because of their side effect profile and the childhood response to lifestyle modifications. Statins should be started at the lowest effective dose and allowed at least 8 wk to achieve their peak effect. If LDL levels are not at goal, which in children who are treated is generally established to be <130 mg, the medication may be titrated upward with careful monitoring of side effects.

Other cholesterol-lowering medications, such as nicotinic acid and fibrates, have been used far less often in children than bile acid sequestrants and statins. Nicotinic acid and fibrates have been used selectively in children with marked hypertriglyceridemia (>500 mg/dL) at risk for acute pancreatitis, though dietary restriction of complex sugars (stressing elimination of sugar-sweetened beverages) and carbohydrates will usually result in significant lowering of triglyceride levels. Current guidelines recommend treatment of LDL-C as the initial priority and after LDL levels are at goal, then if triglycerides remain between 200 and 499 mg/dL and non-HDL cholesterol ≥145 mg/dL, pharmacologic treatment to reduce triglyceride levels is indicated. Omega-3 fatty acid supplementation, available in both over-the-counter and prescription form, is a safe and useful treatment thought to reduce triglyceride levels by decreasing the hepatic synthesis of triglycerides. LDL-C levels in adults of about 70 mg/dL were recently associated with coronary artery atheromatous plaque reduction and reversal of CAD. Knowledge in this area will continue to evolve.

Ezetimibe has proved to be useful in the pediatric population because of its efficacy and low side effect profile. Ezetimibe reduces plasma LDL-C by blocking sterol absorption in enterocytes. The drug is marketed as an adjunct to statins when adults are not achieving sufficient blood lipid lowering with statins alone. Sufficient reports documenting its effectiveness without side effects support recommending ezetimibe instead of a statin when moderate hypercholesterolemia is encountered, or apprehension from parents makes using a statin difficult.

Farber disease
Wolman disease

Multiple sulfatase deficiency
Krabbe disease

The lysosomal lipid storage diseases are diverse disorders, each caused by an inherited deficiency of a specific lysosomal hydrolase leading to the intralysosomal accumulation of the enzyme's particular substrate (Tables 104.15 and 104.16). Except for Wolman disease and cholesterol ester storage disease, the lipid substrates share a common structure that includes a ceramide backbone (2-*N* -acylsphingosine) from which the various sphingolipids are derived by substitution of hexoses, phosphorylcholine, or 1 or more sialic acid residues on the terminal hydroxyl group of the ceramide molecule. The pathway of sphingolipid metabolism in nervous tissue (Fig. 104.15) and in visceral organs (Fig. 104.16) is known; each catabolic step, with the exception of the catabolism of lactosylceramide, has a genetically determined metabolic defect and a resultant disease. Because **sphingolipids** are essential components of all cell membranes, the inability to degrade these substances and their subsequent accumulation results in the physiologic and morphologic alterations and characteristic clinical manifestations of the lipid storage disorders (Table 104.15). Progressive lysosomal accumulation of glycosphingolipids in the CNS leads to neurodegeneration, whereas storage in visceral cells can lead to organomegaly, skeletal abnormalities, pulmonary infiltration, and other manifestations. The storage of a substrate in a specific tissue depends on its normal distribution in the body.

Table 104.16

Lysosomal Storage Disorders in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation

DISORDER	ONSET	FACIES	NEUROLOGIC FINDINGS	DISTINCTIVE FEATURES	EYE FINDINGS	DEFECT

Niemann–Pick A disease	Early infancy	Frontal bossing	Difficulty feeding, apathy, deafness, blindness, hypotonia	Brownish-yellow skin, xanthomas	Cherry-red spot (50%)	Sphingomye deficiency
Niemann–Pick C disease	Birth–3 months	Normal	Developmental delay, vertical gaze paralysis, hypotonia, later spasticity	–	–	Abnormal cholesterol esterification
Gaucher disease type 2	In utero–6 months	Normal	Poor suck and swallow, weak cry, squint, trismus, strabismus, opsoclonus, hypertonic, later flaccidity	Congenital ichthyosis, collodion skin	–	Glucocerebr deficiency
Krabbe disease	3–6 months	Normal	Irritability, tonic spasms with light or noise stimulation, seizures, hypertonia, later flaccidity	Increased CSF protein level	Optic atrophy	Galactocereb deficiency
GM1 gangliosidosis	Birth	Coarse	Poor suck, weak cry, lethargy, exaggerated startle, blindness, hypotonia, later spasticity	Gingival hypertrophy, edema, rashes	Cherry-red spot (50%)	β-Galactosid deficiency
Farber disease type I	2 weeks–4 months	Normal	Progressive psychomotor impairment, seizures, decreased reflexes, hypotonia	Joint swelling with nodules, hoarseness, lung disease, contractures, fever, granulomas, dysphagia, vomiting, increased CSF protein level	Grayish opacification surrounding retina in some patients, subtle cherry-red spot	Lysosomal a ceramidase
Farber disease types II and III	Birth–9 months (≤20 months)	Normal	—	Joint swelling with nodules, hoarseness	Normal macula, corneal opacities	—
Farber disease type IV (neonatal)	Birth	Normal	Nodules not consistent findings	Corneal opacities (1/3)	—	—
Congenital sialidosis	In utero–birth	Cognitive, edema	Intellectual impairment, hypotonia	Neonatal ascites, inguinal hernias, renal disease	Corneal clouding	Neuraminida deficiency

Galactosialidosis	In utero–birth	Coarse	Intellectual impairment, occasional deafness, hypotonia	Ascites, edema, inguinal hernias, renal disease, telangiectasias	Cherry-red spot, corneal clouding	Absence of a protective pr that safeguar neuraminidas β-galactosida premature degradation
Wolman disease	First weeks of life	Normal	Cognitive deterioration	Vomiting, diarrhea, steatorrhea, abdominal distention, failure to thrive, anemia, adrenal calcifications	—	Lysosomal a lipase deficie
Infantile sialic acid storage disease	In utero–birth	Coarse, dysmorphic	Intellectual impairment, hypotonia	Ascites, anemia, diarrhea, failure to thrive	—	Defective tra of sialic acid the lysosome
I-cell disease	In utero–birth	Coarse	Intellectual impairment, deafness	Gingival hyperplasia, restricted joint mobility, hernias	Corneal clouding	Lysosomal e lack mannos phosphate recognition r and fail to er lysosome (phosphotrar deficiency, 3 complex [α2
Mucolipidosis type IV	Birth–3 months	Normal	Intellectual impairment, hypotonia	—	Severe corneal clouding, retinal degeneration, blindness	Unknown; sc patients with deficiency of ganglioside s
Mucopolysaccharidosis type VII	In utero–childhood	Variable coarseness	Mild to severe intellectual impairment	Hernias	Variable corneal clouding	β-Glucuronic deficiency

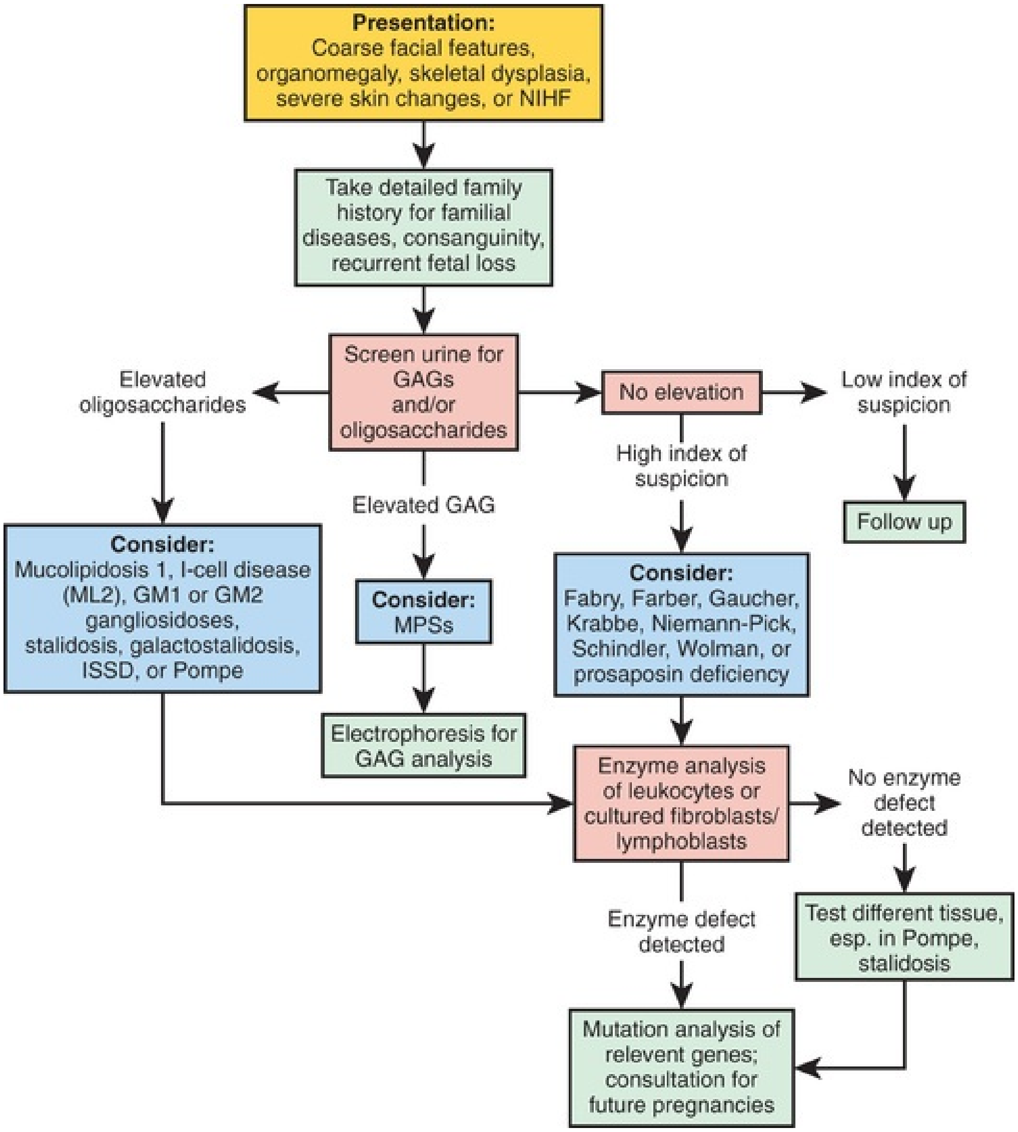
Diagnostic assays for the identification of affected individuals rely on the measurement of the specific enzymatic activity, typically in isolated leukocytes. Fig. 104.17 shows an approach to differentiating these disorders. For most, carrier identification and prenatal diagnosis are available; a specific diagnosis is essential to permit genetic counseling. Neonatal screening using dried blood spots and performing enzyme assays and mutational analysis for Gaucher, Pompe, Fabry, and Niemann-Pick diseases are undergoing pilot studies, and the FDA has approved the *Seeker System* for detection of Gaucher and Fabry diseases. The characterization of the genes that encode the specific enzymes required for sphingolipid metabolism permit the development of therapeutic options, such as recombinant enzyme replacement therapy, as well as the potential of cell or gene therapy. Identification of specific disease-causing mutations improves diagnosis, prenatal detection, and carrier identification. For several disorders (Gaucher, Fabry, Niemann-Pick types A and B), it has been possible to make genotype-phenotype correlations that predict disease severity and allow more precise genetic counseling. Inheritance is autosomal recessive except for X-linked Fabry disease.



Presentation:
Coarse facial features, organomegaly, skeletal dysplasia, severe skin changes, or NIHF
Take detailed family history for familial diseases, consanguinity, recurrent fetal loss
Screen urine for GAGs and/or oligosaccharides
Elevated oligosaccharides
No elevation
Low index of suspicion
High index of suspicion
Follow up
Elevated GAG
Consider:
Mucolipidosis 1, I-cell disease (ML2), GM1 or GM2 gangliosidoses, stalidosis, galactostalidosis, ISSD, or Pompe
Consider:
MPSs
Consider:
Fabry, Farber, Gaucher, Krabbe, Niemann-Pick, Schindler, Wolman, or prosaposin deficiency
Electrophoresis for GAG analysis
Enzyme analysis of leukocytes or cultured fibroblasts/ lymphoblasts
No enzyme defect detected
Test different tissue, esp. in Pompe, stalidosis
Enzyme defect detected
Mutation analysis of relevent genes; consultation for future pregnancies

storage disorders in the newborn, *Pediatrics* 123:1191–1207, 2009.)

GM_1 Gangliosidosis

GM_1 gangliosidosis most frequently presents in early infancy but has been described in patients with juvenile- and adult-onset subtypes. Inherited as an autosomal recessive trait, each subtype results from a different gene mutation that leads to the deficient activity of β-galactosidase, a lysosomal enzyme encoded by a gene on chromosome 3 (3p21.33). Although the disorder is characterized by the pathologic accumulation of GM_1 gangliosides in the lysosomes of both neural and visceral cells, GM_1 ganglioside accumulation is most marked in the brain. In addition, keratin sulfate, a mucopolysaccharide, accumulates in liver and is excreted in the urine of patients with GM_1 gangliosidosis. The β-galactosidase gene has been isolated and sequenced; mutations causing the disease subtypes have been identified.

The clinical manifestations of the **infantile** form of GM_1 gangliosidosis may be evident in the newborn as hepatosplenomegaly, edema, and skin eruptions (**angiokeratoma**). It most frequently presents in the 1st 6 mo of life with developmental delay followed by progressive psychomotor retardation and the onset of tonic-clonic seizures. Typical facies is characterized by low-set ears, frontal bossing, a depressed nasal bridge, and an abnormally long philtrum. Up to 50% of patients have a macular cherry-red spot. Hepatosplenomegaly and skeletal abnormalities are present, such as those of the mucopolysaccharidoses, including anterior beaking of the vertebrae, enlargement of the sella turcica, and thickening of the calvarium. By the end of the 1st yr of life, most patients are blind and deaf, with severe neurologic impairment characterized by decerebrate rigidity. Death usually occurs by 3-4 yr of age. The **juvenile-onset** form of GM_1 gangliosidosis is clinically distinct, with a variable age at onset. Affected patients present primarily with neurologic symptoms, including ataxia, dysarthria, intellectual disability, and spasticity. Deterioration is slow; patients may survive through the 4th decade of life. These patients lack the visceral involvement, facial abnormalities, and skeletal features seen in type 1 disease. Adult-onset patients have been described who present with gait and speech abnormalities, dystonia and mild skeletal abnormalities. *There is no specific treatment* for either form of GM_1 gangliosidosis.

The diagnosis of GM_1 gangliosidosis should be suspected in infants with typical clinical features and is confirmed by the demonstration of the deficiency of β-galactosidase activity in peripheral leukocytes. Other disorders that share some of the features of the GM_1 gangliosidoses include Hurler disease (mucopolysaccharidosis type I), I-cell disease, and Niemann-Pick disease type A, each of which can be distinguished by the demonstration of their specific enzymatic deficiencies. Carriers of the disorder are detected by the measurement of the enzymatic activity in peripheral leukocytes or by identifying the specific gene mutations; prenatal diagnosis is accomplished by determination of the enzymatic activity in cultured amniocytes or chorionic villi or identification of the specific disease-causing mutations. Only supportive therapy is available for patients with GM_1 gangliosidosis. However, studies in mice with GM_1 gangliosidosis have demonstrated that oral *N* -octyl-4-epi-β-valienamine (NOEV), which stabilizes the mutant enzyme protein produced by the affected animals, crossed the brain and improved neurologic deterioration, suggesting that this approach may be useful in human study.

The GM_2 Gangliosidoses

The GM_2 gangliosidoses include Tay-Sachs disease and Sandhoff disease; each results from deficiency of β-hexosaminidase activity and lysosomal accumulation of GM_2 gangliosides, particularly in the CNS. Both disorders have been classified into infantile-, juvenile-, and adult-onset forms based on the age at onset and clinical features. β-Hexosaminidase occurs as 2 isozymes: β-hexosaminidase A, which is composed of 1 α and 1 β subunit, and β-hexosaminidase B, which has 2 β subunits. B-Hexosaminidase A deficiency results from mutations in the α subunit and causes Tay-Sachs disease, whereas mutations in the β subunit result in the deficiency of both β-hexosaminidases A and B and cause Sandhoff disease. Both are autosomal recessive traits, with Tay-Sachs disease being more common in the Ashkenazi Jewish population, in whom the carrier frequency is approximately 1 in 25.

More than 50 mutations have been identified; most are associated with the infantile forms of disease. Three mutations account for >98% of mutant alleles among Ashkenazi Jewish carriers of Tay-Sachs disease, including one allele associated with the adult-onset form. Mutations that cause the subacute or adult-onset forms result in enzyme proteins with residual enzymatic activities, the levels of which correlate with the severity of the disease.

Patients with the infantile form of **Tay-Sachs disease** have clinical manifestations in infancy such as loss of motor skills, increased startle reaction, and macular pallor and retinal cherry-red spots (see Table 104.15). Affected infants usually develop normally until 4-5 mo of age, when decreased eye contact and an exaggerated startle response to noise (**hyperacusis**) are noted. **Macrocephaly** , not associated with hydrocephalus, may develop. In the 2nd yr of life, seizures develop, which may be refractory to anticonvulsant therapy. Neurodegeneration is relentless, with death occurring by age 4 or 5 yr. The juvenile- and later-onset forms initially present with ataxia and dysarthria and may not be associated with a macular cherry-red spot.

The clinical manifestations of **Sandhoff disease** are similar to those of Tay-Sachs disease. Infants with Sandhoff disease have hepatosplenomegaly, cardiac involvement, and mild bony abnormalities. The **juvenile** form of this disorder presents as ataxia, dysarthria, and mental deterioration, but without visceral enlargement or a macular cherry-red spot. *No treatment is available* for Tay-Sachs disease or Sandhoff disease, although experimental approaches are being evaluated.

The diagnosis of **infantile** Tay-Sachs disease and Sandhoff disease is usually suspected in an infant with neurologic features and a cherry-red spot. Definitive diagnosis is made by determination of β-hexosaminidase A and B activities in peripheral leukocytes. The 2 disorders are distinguished by the enzymatic assay, because in Tay-Sachs disease only the β-hexosaminidase A isozyme is deficient, whereas in Sandhoff disease both the β-hexosaminidase A and B isozymes are deficient. At-risk pregnancies for both disorders can be prenatally diagnosed by determining the enzyme levels in fetal cells obtained by amniocentesis or chorionic villus sampling. Identification of carriers in families is also possible by β-hexosaminidases A and B determination. Indeed, for Tay-Sachs disease, carrier screening of all couples in which at least 1 member is of Ashkenazi Jewish descent is recommended before the initiation of pregnancy to identify couples at risk. These studies can be conducted by the determination of the level of β-hexosaminidase A activity in peripheral leukocytes or plasma. Molecular studies to identify the exact molecular defect in enzymatically identified carriers should also be performed to permit more specific identification of carriers in the family and to allow prenatal diagnosis in at-risk couples by both enzymatic and genotype determinations. The incidence of Tay-Sachs disease has been greatly reduced since the introduction of carrier screening programs in the Ashkenazi

Jewish population. Newborn screening may be possible by measuring specific glycosphingolipid markers or the relevant enzymatic activities in dried blood spots.

Gaucher Disease

Gaucher disease is a multisystemic lipidosis characterized by hematologic abnormalities, organomegaly, and skeletal involvement, the latter usually manifesting as bone pain and pathologic fractures (see Table 104.15). It is one of the most common lysosomal storage diseases and the most prevalent genetic defect among Ashkenazi Jews. There are 3 clinical subtypes, delineated by the absence or presence and progression of neurologic manifestations: **type 1** , or the adult, nonneuronopathic form; **type 2** , the infantile or acute neuronopathic form; and **type 3** , the juvenile or subacute neuronopathic form. All are autosomal recessive traits. Type 1, which accounts for 99% of cases, has a striking predilection for Ashkenazi Jews, with an incidence of approximately 1 in 1,000 live births and a carrier frequency of approximately 1 in 18 adults.

Gaucher disease results from the deficient activity of the lysosomal hydrolase, acid β-glucosidase, which is encoded by a gene located on chromosome 1q21-q31. The enzymatic defect results in the accumulation of undegraded glycolipid substrates, particularly glucosylceramide, in cells of the reticuloendothelial system (RES). This progressive deposition results in infiltration of the bone marrow, progressive hepatosplenomegaly, and skeletal complications. Four mutations—N370S, L444P, 84insG, and IVS2+2—account for approximately 95% of mutant alleles among Ashkenazi Jewish patients, permitting screening for this disorder in this population. Genotype-phenotype correlations have been noted, providing the molecular basis for the clinical heterogeneity seen in Gaucher disease type 1. Patients who are homozygous for the N370S mutation tend to have a later onset of clinical manifestations, with a more indolent course than patients with 1 copy of N370S and another common allele.

Clinical manifestations of **type 1 Gaucher disease** have a variable age at onset, from early childhood to late adulthood, with most symptomatic patients presenting by adolescence. At presentation, patients may have bruising from thrombocytopenia, chronic fatigue secondary to anemia, hepatomegaly with or without elevated LFT results, splenomegaly, and bone pain. Occasional patients have pulmonary involvement at presentation. Patients presenting in the 1st decade frequently are not Jewish and have growth retardation and a more malignant course. Other patients may be discovered fortuitously during evaluation for other conditions or as part of routine examinations; these patients may have a milder or even a benign course. In symptomatic patients, splenomegaly is progressive and can become massive. Most patients develop radiologic evidence of skeletal involvement, including an Erlenmeyer flask deformity of the distal femur. Clinically apparent bony involvement, which occurs in most patients, can present as bone pain, a pseudoosteomyelitis pattern, or pathologic fractures. Lytic lesions can develop in the long bones, including the femur, ribs, and pelvis; osteosclerosis may be evident at an early age. Bone crises with severe pain and swelling can occur. Bleeding secondary to thrombocytopenia may manifest as epistaxis or bruising and is frequently overlooked until other symptoms become apparent. With the exception of the severely growth-retarded child, who may experience developmental delay secondary to the effects of chronic disease, development and intelligence are normal.

The pathologic hallmark of Gaucher disease is the Gaucher cell in the RES, particularly in the bone marrow (Fig. 104.18). These cells, which are 20-100 µm in diameter, have a characteristic wrinkled-paper appearance resulting from the presence of intracytoplasmic substrate inclusions. The cytoplasm of the Gaucher cell reacts strongly positive with the periodic acid–Schiff (PAS) stain. The presence of this cell in bone marrow and tissue specimens is highly suggestive of Gaucher disease, although it also may be found in patients with granulocytic leukemia and myeloma.

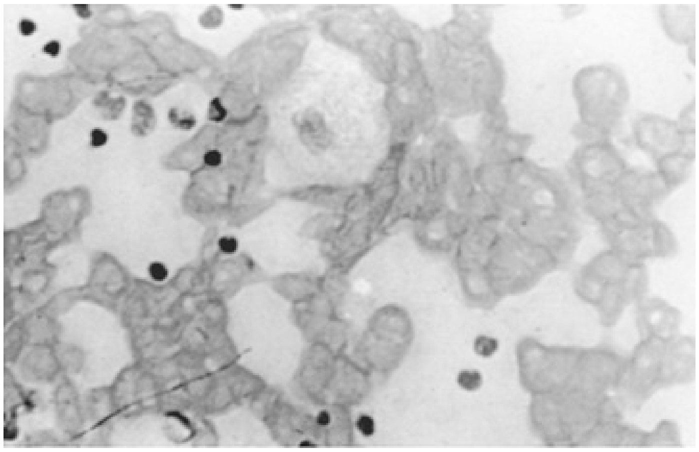

FIG. 104.18 Cells from the spleen of a patient with Gaucher disease. A characteristic spleen cell is shown engorged with glucocerebroside.

Gaucher disease type 2 is a rare form and does not have an ethnic predilection. It is characterized by a rapid neurodegenerative course with extensive visceral involvement and death early in life. It presents in infancy with increased tone, strabismus, and organomegaly. Failure to thrive and stridor caused by laryngospasm are typical. After a several-year period of psychomotor regression, death typically occurs secondary to respiratory compromise. **Gaucher disease type 3** presents with clinical manifestations that are intermediate to those seen in types 1 and 2, with presentation in childhood and death by age 10-15 yr. It has a predilection for the Swedish Norrbottnian population, in whom the incidence is approximately 1 in 50,000. Neurologic involvement is present. Type 3 disease is further classified as types 3a and 3b based on the extent of neurologic involvement and whether there is progressive myotonia and dementia (**type 3a**) or isolated supranuclear gaze palsy (**type 3b**).

Gaucher disease should be considered in the differential diagnosis of patients with unexplained organomegaly, who bruise easily, who have bone pain, or who have a combination of these conditions. Bone marrow examination usually reveals the presence of Gaucher cells. All suspected diagnoses should be confirmed by determination of the acid β-glucosidase activity in isolated leukocytes or cultured fibroblasts, as well as by identification of their specific acid β-glucosidase gene mutations. In Ashkenazi Jewish individuals the identification of carriers can be achieved best by molecular testing for the common Ashkenazi mutations. Testing should be offered to all family members, keeping in mind that heterogeneity, even among members of the same kindred, can be so great that nonsymptomatic affected individuals may be diagnosed. **Prenatal diagnosis** is available by determination of enzyme activity and/or the specific family mutations in chorionic villi or cultured amniotic fluid cells.

Treatment of patients with Gaucher disease type 1 includes enzyme replacement therapy (ERT). The efficacy of ERT with mannose-terminated recombinant human acid β-glucosidase (*imiglucerase* [Cerezyme, Genzyme]), *velaglucerase alfa* [VPRIV, Shire HGT]), or *taliglucerase alfa* (Uplyso, Protalix Biotherapeutics) is the standard of care for the treatment of patients with type 1 disease. Most symptoms (organomegaly, hematologic indices, bone pain) are reversed by ERT (60 IU/kg) administered by IV infusion every other week, and the bone involvement can be stabilized or improved. Although ERT does not alter the neurologic progression of patients with Gaucher disease types 2 and 3, it has been used in selected patients as a palliative measure, particularly in type 3 patients with severe visceral involvement. Alternative treatment with oral substrate reduction agents designed to decrease the synthesis of glucosylceramide by chemical inhibition of glucosylceramide synthase include *miglustat* (Zavesca, Actelion), although its efficacy on hematologic parameters is not as great as ERT. A 2nd, more effective substrate inhibitor, *eliglustat* (Cerdelga, Sanofi-Genzyme), has demonstrated significant efficacy versus placebo and is not inferior to imiglucerase making this an alternative first-line oral treatment for patients with type 1 disease. A small number of patients have undergone bone marrow transplantation (BMT), which is curative but is associated with significant morbidity and mortality from the procedure, limiting the selection of appropriate candidates.

Niemann-Pick Disease

The original description of Niemann-Pick disease (NPD) was what is now known as **type A** NPD, a fatal disorder of infancy characterized by failure to thrive, hepatosplenomegaly, and a rapidly progressive neurodegenerative course that leads to death by 2-3 yr of age. **Type B** disease is a nonneuronopathic form observed in children and adults. **Type C** disease is a neuronopathic form that results from defective cholesterol transport. All subtypes are inherited as autosomal recessive traits and display variable clinical features (see Table 104.15).

NPD types A and B result from the deficient activity of **acid sphingomyelinase (ASM)** , a lysosomal enzyme encoded by a gene on chromosome 11 (11p15.1-p15.4). The enzymatic defect results in the pathologic accumulation of *sphingomyelin*, a ceramide phospholipid, and other lipids in the monocyte-macrophage system, the primary pathologic site. The progressive deposition of sphingomyelin in the CNS results in the neurodegenerative course seen in type A and in nonneural tissue in the systemic disease manifestations of type B, including progressive lung disease in some patients. A variety of mutations in the acid sphingomyelinase gene that cause types A and B NPD have been identified.

The **clinical manifestations** and course of type A NPD are uniform and characterized by a normal appearance at birth followed by hepatosplenomegaly, moderate lymphadenopathy, and psychomotor retardation evident by 6 mo of age. Over time, the loss of motor function and the deterioration of intellectual capabilities are progressively debilitating; spasticity and rigidity develop; and death occurs by 3 yr of age. In contrast to the stereotyped type A phenotype, the clinical presentation and course of patients with type B disease are more variable. Most are diagnosed in infancy or childhood when enlargement of the liver or spleen, or both, is detected during a routine physical examination. At diagnosis, type B NPD patients usually have evidence of mild pulmonary involvement, usually detected as a diffuse reticular or finely nodular infiltration on the chest radiograph. Pulmonary symptoms may present in adults. In most patients, hepatosplenomegaly is particularly prominent in childhood, but with increasing linear growth, the abdominal protuberance decreases and becomes less conspicuous. In mildly affected patients the splenomegaly may not be noted until adulthood, and disease manifestations may be minimal.

Severely affected patients may have liver involvement leading to life-threatening cirrhosis, portal hypertension, and ascites. Clinically significant pancytopenia caused by secondary hypersplenism may require partial or complete splenectomy; this should be avoided if possible because splenectomy frequently causes progression of pulmonary disease, which can be life threatening. In general, type B patients do not have neurologic involvement and have a normal IQ. Some patients with type B disease have cherry-red maculae or haloes and subtle neurologic symptoms (peripheral neuropathy). In some type B patients, decreased pulmonary diffusion caused by alveolar infiltration becomes evident in late childhood or early adulthood and progresses with age. Severely affected individuals may experience significant pulmonary compromise by 15-20 yr of age. Such patients have low oxygen tension (Po_2) values and dyspnea on exertion. Life-threatening bronchopneumonia may occur, and cor pulmonale has been described.

Type C NPD patients often present with prolonged neonatal jaundice, appear normal for 1-2 yr, and then experience a slowly progressive and variable neurodegenerative course. Their hepatosplenomegaly is less severe than that of patients with types A or B NPD, and they may survive into adulthood. The underlying biochemical defect in type C patients is an abnormality in cholesterol transport, leading to the accumulation of sphingomyelin and cholesterol in their lysosomes and a secondary partial reduction in ASM activity (see Chapter 104.3).

In type B NPD patients, splenomegaly is usually the first manifestation detected. The splenic enlargement is noted in early childhood; in very mild disease the enlargement may be subtle and detection delayed until adolescence or adulthood. The presence of the characteristic NPD cells in bone marrow aspirates supports the diagnosis of type B NPD. Patients with type C NPD, however, also have extensive infiltration of NPD cells in the bone marrow, and thus all suspected cases should be evaluated enzymatically to confirm the clinical diagnosis by measuring the ASM activity level in peripheral leukocytes. Patients with types A and B NPD have greatly decreased ASM levels (1–10%), whereas patients with type C NPD have normal or somewhat decreased ASM activities. The enzymatic identification of NPD carriers is problematic. For families in whom the specific molecular lesion has been identified, however, family members can be accurately tested for heterozygote status by DNA analysis. **Prenatal diagnosis** of types A and B NPD can be made reliably by the measurement of ASM activity in cultured amniocytes or chorionic villi; molecular analysis of fetal cells to identify the specific *ASM* mutations can provide the specific diagnosis or serve as a confirmatory test. The clinical diagnosis of type C NPD can be supported by filipin stain positivity in cultured fibroblasts and identification of a specific mutation in the *NPC1* or *NPC2* gene.

There is no specific treatment for NPD. Orthotopic liver transplantation in an infant with type A disease and cord blood transplantation in several type B NPD patients have been attempted with little or no success. BMT in a small number of type B NPD patients has been successful in reducing the spleen and liver volumes, the sphingomyelin content of the liver, the number of Niemann-Pick cells in the marrow, and radiologically detected infiltration of the lungs. In one patient, liver biopsies taken up to 33 mo after transplant showed only a moderate reduction in stored sphingomyelin. ERT with recombinant human ASM is currently in clinical trials for the treatment of type B patients. A 26-wk phase 1b study in adult patients with NPD type B established initial proof of concept in this patient group, and a phase 1/2 clinical trial in pediatric patients and a phase 2/3 trial in adult patients with ASM deficiency are ongoing. Clinical trials of miglustat have been performed, and the drug has been approved in Europe for the treatment of type C disease. Treatment of type A disease by BMT has not been successful, presumably because of the severe neurologic involvement.

Fabry Disease

Fabry disease is an X-linked inborn error of glycosphingolipid metabolism caused by the absent or extremely deficient activity of α-galactosidase A (α-gal A). There are 2 major phenotypes. Affected males with the **classic** phenotype present in childhood with angiokeratomas (telangiectatic skin lesions), hypohidrosis, corneal and lenticular opacities, and painful acroparesthesias. With advancing age, they develop kidney failure, heart disease, and stroke (see Table 104.15). This classic phenotype is caused by the absent activity of the α-gal A and has an estimated prevalence of approximately 1 in 40,000 males. The **later-onset** phenotype occurs in affected males with residual α-gal A activity and presents in the 4th to 8th decades with cardiac disease and renal failure. This phenotype is more prevalent than the classic phenotype. Heterozygous females for the classic phenotype can be asymptomatic or as severely affected as the males, the variability a result of random X-chromosomal inactivation. The enzyme deficiency results from mutations in the α-gal A gene located on the long arm of the X chromosome (Xq22). The enzymatic defect leads to the systemic accumulation of neutral glycosphingolipids, primarily globotriaosylceramide, particularly in the plasma and lysosomes of vascular endothelial and smooth muscle cells, cardiac myocytes, and renal podocytes. The progressive vascular glycosphingolipid deposition in classically affected males results in small-vessel occlusion and ischemia, leading to the major disease manifestations. The complementary DNA (cDNA) and genomic sequences encoding α-gal A have been characterized, and >900 different mutations in the α-gal A gene are responsible for this lysosomal storage disease.

The **angiokeratomas** usually occur in childhood and may lead to early diagnosis (Fig. 104.19). They increase in size and number with age and range from barely visible to several millimeters in diameter. The lesions are punctate, dark red to blue-black, and flat or slightly raised. They do not blanch with pressure, and the larger ones may show a slight hyperkeratosis. Characteristically, the lesions are densest between the umbilicus and knees, in the “bathing trunk area,” but may occur anywhere, including the oral mucosa. The hips, thighs, buttocks, umbilicus, lower abdomen, scrotum, and glans penis are common sites, and there is a tendency toward symmetry. Variants without skin lesions have been described. Sweating is usually decreased or absent. Corneal opacities and characteristic lenticular lesions, observed under slit-lamp examination, are present in affected males, as well as in approximately 90% of heterozygotes from families with the classic phenotype. Conjunctival and retinal vascular tortuosity is common and results from the systemic vascular involvement.

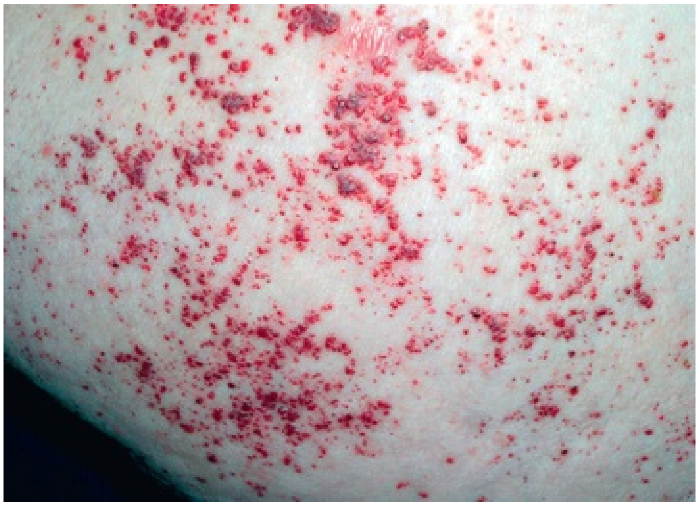

FIG. 104.19 Typical angiokeratomas. Angiokeratomas are quite large and easily recognizable, but if only a few lesions exist or they are restricted only to the genitalia or umbilical regions, they can be easily missed. (From Zarate VA, Hopkin RJ: Fabry's disease, *Lancet* 372:1427, 2008.)

Pain is the most debilitating symptom in childhood and adolescence. **Fabry crises,** lasting from hours to several days, consist of agonizing, burning pain in the hands, feet, and proximal extremities and are usually associated with exercise, fatigue, fever, or a combination of these factors. These painful acroparesthesias usually become less frequent in the 3rd and 4th decades, although in some men these may become more frequent and severe. Attacks of abdominal or flank pain may simulate appendicitis or renal colic. Pain may suggest other diagnoses (Table 104.17).

Table 104.17

Common Misdiagnoses for Fabry Disease

Growing pains Chronic overlapping pain syndrome Irritable bowel syndrome Malingering Systemic lupus erythematous Rheumatic fever Fibromyalgia Dermatomyositis Raynaud phenomenon Raynaud syndrome	Polyphyria Guillain-Barre syndrome Hereditary neuropathy Uremic neuropathy Diabetic neuropathy Polyneuropathy C1 esterase deficiency TNF receptor-associated periodic syndrome (TRAPS) Joint and recurrent fever syndromes (juvenile idiopathic arthritis, familial Mediterranean fever)	Erythromelalgia Meniere disease Coronary heart disease Complex regional pain syndromes Multiple sclerosis Osler disease Appendicitis Metabolic bone disease (rickets, uremia, scurvy)

Adapted from Sivley MD: Fabry disease: a review of ophthalmic and systemic manifestations. Optometry Vision Sci 90(2)e63-e78, 2013 (Table 2, p e71).

The major morbid symptoms in classically affected males result from the progressive involvement of the vascular system. Early in the course of the classic phenotype, casts, RBCs, and lipid inclusions with characteristic birefringent “Maltese crosses” appear in the urinary sediment. Proteinuria, isosthenuria, and gradual deterioration of renal function and development of azotemia occur in the 2nd to 4th decades in the classic phenotype and in the 4th to 8th decades in the later-onset form. Cardiovascular findings may include arrhythmias, hypertrophic cardiomyopathy, and heart failure. Mitral insufficiency is the most common valvular lesion. Cerebrovascular manifestations, including transient ischemic attack (TIA) and stroke (CVA), result secondary to cardiac arrhythmias as well as multifocal small-vessel involvement, other features may include chronic bronchitis and dyspnea, lymphedema of the legs without hypoproteinemia, episodic diarrhea, osteoporosis, impaired growth, and delayed puberty. Death most often results from renal failure, cardiac disease, or stroke. Before hemodialysis or renal transplantation, the mean age at death for affected men was about 40 yr. Patients with the later-onset phenotype with residual α-gal A activity have cardiac and/or renal disease. The cardiac manifestations include hypertrophy of the left ventricular wall and interventricular septum, and electrocardiographic abnormalities consistent with cardiomyopathy. Hypertrophic cardiomyopathy may lead to ventricular tachycardia as a cause of death.

The **diagnosis** of Fabry disease in classically affected males is most readily made from the history of painful acroparesthesias, hypohidrosis, the presence of the characteristic skin lesions, and the observation of the corneal opacities and lenticular lesions. The disorder is often misdiagnosed as rheumatic fever, erythromelalgia, or neurosis. The skin lesions must be differentiated from the benign angiokeratomas of the scrotum (**Fordyce disease**) or from angiokeratoma circumscriptum. Angiokeratomas identical to those of Fabry disease have been reported in fucosidosis, aspartylglycosaminuria, late-onset GM_1 gangliosidosis, galactosialidosis, α-*N* -acetylgalactosaminidase deficiency, and sialidosis. Later-onset patients have been identified among patients on hemodialysis and patients with hypertrophic cardiomyopathy or who had cryptogenic strokes. Later-onset patients lack the early classic manifestations previously described. The diagnosis of classic and later-onset Fabry disease is confirmed biochemically by the demonstration of greatly decreased α-gal A activity in plasma, isolated leukocytes, or cultured fibroblasts or lymphoblasts. The specific α-gal A mutation can be determined by gene sequencing.

Heterozygous females from classic families may have corneal opacities, isolated skin lesions, and intermediate activities of α-gal A in plasma or cells. Rare female heterozygotes may have manifestations as severe as those in affected males. Asymptomatic at-risk females in classic and later-onset families affected by Fabry disease, however, should be optimally diagnosed by the direct analysis of their family's specific mutation. Prenatal detection of affected males can be accomplished by demonstrating deficient α-gal A activity and the family's specific gene mutation in chorionic villi obtained in the 1st trimester or in cultured amniocytes obtained by amniocentesis in the 2nd trimester of pregnancy. Fabry disease can be detected by newborn screening, and pilot studies have been conducted in Europe, Asia, and North America.

Treatment for Fabry disease may include the use of phenytoin and carbamazepine to decrease the frequency and severity of the chronic acroparesthesias and the periodic crises of excruciating pain. Renal transplantation and long-term hemodialysis are lifesaving procedures for patients with renal failure.

Enzyme replacement therapy (ERT) for Fabry patients using recombinant human α-gal A preparations produced in Chinese hamster ovary cells (*agalsidase beta*, Fabrazyme, Genzyme) and in human fibrosarcoma cells (*agalsidase alfa*, Replagal, Shire HGT) is available. Both Fabrazyme and Replagal were approved by the European Medicines Agency in the European Union, but only Fabrazyme is approved by the U.S. FDA. The effectiveness of ERT with Fabrazyme has been demonstrated in stabilization of renal disease, regression of hypertrophic cardiomyopathy, reduction of pain, and improvement in quality of life. Because most classically affected males produce no enzyme protein, these patients can produce immunoglobulin G (IgG) antibodies in response to the infused enzyme, which does not reduce the effectiveness of substrate clearance unless the antibody titer is very high. Treatment of classically affected males should begin in childhood.

Fucosidosis

Fucosidosis is a rare autosomal recessive disorder caused by the deficient activity of α-fucosidase and the accumulation of fucose-containing glycosphingolipids, glycoproteins, and oligosaccharides in the lysosomes of the liver, brain, and other organs (see Table 104.15). The α-fucosidase gene is on chromosome 1 (1p24), and specific mutations are known. Although the disorder is panethnic, most reported patients are from Italy and the United States. There is wide variability in the clinical phenotype, with the most severely affected patients presenting in the 1st yr of life with developmental delay and somatic features similar to those of the mucopolysaccharidoses. These features include frontal bossing, hepatosplenomegaly, coarse facial features, and macroglossia. The CNS storage results in a relentless neurodegenerative course, with death in childhood. Patients with milder disease have angiokeratomas and longer survival. *No specific therapy exists for fucosidosis.* The disorder can be diagnosed by the demonstration of deficient α-fucosidase activity in peripheral leukocytes or cultured fibroblasts. Carrier identification and prenatal diagnosis are possible by determination of the enzymatic activity or the specific family mutations.

Schindler Disease

This autosomal recessive neurodegenerative disorder results from the deficient activity of α-*N* -acetylgalactosaminidase and the accumulation of asialoglycopeptides and sialyloligosaccharides (see Table 104.15). The gene for the enzyme is located on chromosome 22 (22q11). Schindler disease is clinically heterogeneous, and 2 major phenotypes have been identified. **Type I** disease is an infantile-onset neuroaxonal dystrophy. Affected infants have normal development for the 1st 9-15 mo of life followed by a rapid neurodegenerative course that results in severe psychomotor retardation, cortical blindness, and frequent myoclonic seizures. **Type II** disease is characterized by a variable age at onset, mild intellectual disability, and angiokeratomas. *There is no specific therapy* for either form of the disorder. The diagnosis is by demonstration of the enzymatic deficiency in leukocytes or cultured skin fibroblasts or specific gene mutations.

Metachromatic Leukodystrophy

This autosomal recessive white matter disease is caused by a deficiency of **arylsulfatase A (ASA)** , which is required for the hydrolysis of sulfated glycosphingolipids. Another form of metachromatic leukodystrophy (**MLD**) is caused by a deficiency of a sphingolipid activator protein (SAP1), which is required for the formation of the substrate-enzyme complex. The deficiency of this enzymatic activity results in the white matter storage of sulfated glycosphingolipids, which leads to demyelination and a neurodegenerative course. The *ASA* gene is on chromosome 22 (22q13.31qter); specific mutations tend to fall into 2 groups that correlate with disease severity.

The **clinical manifestations** of the **late-infantile** form of MLD, which is most common, usually present between 12 and 18 mo of age as irritability, inability to walk, and hyperextension of the knee, causing genu recurvatum. The clinical progression of the disease relates to the pathologic involvement of both central and peripheral nervous systems, giving a mixture of upper and lower motor neuron and cognitive and psychiatric signs. Deep tendon reflexes are diminished or absent. Gradual muscle wasting, weakness, and hypotonia become evident and lead to a debilitated state. As the disease progresses, nystagmus, myoclonic seizures, optic atrophy, and quadriparesis appear, with death in the 1st decade of life (see Table 104.15). The **juvenile** form of MLD has a more indolent course, with onset that may occur as late as 20 yr of age. This form of the disease presents with gait disturbances, mental deterioration, urinary incontinence, and emotional difficulties. The **adult** form, which presents after the 2nd decade, is similar to the juvenile form in its clinical manifestations, although emotional difficulties and psychosis are more prominent features. Dementia, seizures, diminished reflexes, and optic atrophy also occur in both juvenile and adult forms. The pathologic hallmark of MLD is the *deposition of metachromatic bodies,* which stain strongly positive with PAS and Alcian blue, in the white matter of the brain. Neuronal inclusions may be seen in the midbrain, pons, medulla, retina, and spinal cord; demyelination occurs in the peripheral nervous system. The **diagnosis** of MLD should be suspected in patients with the clinical features of leukodystrophy. Decreased nerve conduction velocities, increased cerebrospinal fluid protein, metachromatic deposits in sampled segments of sural nerve, and metachromatic granules in urinary sediment are all suggestive of MLD. Confirmation of the diagnosis is based on the demonstration of the reduced activity of ASA in leukocytes or cultured skin fibroblasts. SAP deficiency is diagnosed by measuring the concentration of SAP1 in cultured fibroblasts using a specific antibody to the protein. The diagnosis, identification of carriers, and prenatal diagnosis are available for both forms of MLD by detection of the causative mutations in the *ASA* or *SAP* genes.

Unrelated-donor umbilical cord blood transplantation has been undertaken in some pediatric patients with MLD. A longitudinal study of 6 patients with late-infantile onset and 14 with juvenile onset revealed that motor deficits present at the time of transplant did not improve, and that neurologic symptoms continued to progress in those with late-infantile presentation. In contrast, in juvenile patients the brainstem auditory evoked responses, visual evoked potentials, electroencephalogram, and/or peripheral nerve conduction velocities stabilized or improved. Therefore, consideration of umbilical cord blood transplantation for children with presymptomatic late-infantile MLD or minimally symptomatic juvenile MLD may be indicated. Clinical trials of a recombinant human arylsulfatase A (rhARSA) enzyme (Metazym, Shire HGT) demonstrated its safety in children with late-infantile MLD, but a lack of efficacy. A multicenter phase I/II clinical trial to evaluate the safety and efficacy of rhARSA administered intrathecally is ongoing.

Multiple-Sulfatase Deficiency

This autosomal recessive disorder results from the enzymatic deficiency of at least 9 sulfatases, including arylsulfatases A, B, and C and iduronate-2-sulfatase. The specific defect is an enzyme in the C-α-formylglycine–generating system (the gene for which is located at 3p26), which introduces a common posttranslational modification in all the affected sulfatases and explains the occurrence of these multiple enzyme defects. Because of the deficiency of these enzymes, sulfatides, mucopolysaccharides, steroid sulfates, and gangliosides accumulate in the cerebral cortex and visceral tissues, resulting in a clinical phenotype with features of a **leukodystrophy** as well as those of the **mucopolysaccharidoses** . Severe ichthyosis may also occur. Carrier testing and prenatal diagnosis can be done by measurement of the enzymatic activities or the specific gene defects. *There is no specific treatment for multiple sulfatase deficiency* other than supportive care.

Krabbe Disease

Also called *globoid cell leukodystrophy,* Krabbe disease is an autosomal recessive fatal disorder of infancy. It results from the deficient activity of **galactocerebrosidase** and the white matter accumulation of **galactosylceramide**

, which is normally found almost exclusively in the myelin sheath. Both peripheral and central myelin is affected, resulting in spasticity and cognitive impairment coupled with deceptively normal or even absent deep tendon reflexes. The galactocerebrosidase gene is on chromosome 14 (14q31), and specific disease-causing mutations are known. The **infantile** form of Krabbe disease is rapidly progressive, and patients present in early infancy with irritability, seizures, and hypertonia (see Table 104.15). Optic atrophy is evident in the 1st yr of life, and mental development is severely impaired. As the disease progresses, optic atrophy and severe developmental delay become apparent; affected children exhibit opisthotonos and die before 3 yr of age. A **late-infantile** form of Krabbe presents after age 2 yr. Affected individuals have a course similar to that of the early-infantile form.

The **diagnosis** of Krabbe disease relies on the demonstration of the specific enzymatic deficiency in white blood cells or cultured skin fibroblasts. Causative gene mutations have been identified. Carrier identification and prenatal diagnosis are available. The development of methods to measure galactocerebrosidase activity on dried blood spots has led to the inclusion of Krabbe disease in the newborn screening programs of some states. **Treatment** of infants with Krabbe disease with umbilical cord blood transplantation has been reported in prenatally identified asymptomatic newborns and symptomatic infants. Transplanted infants appear to develop neurologic manifestations at a slower rate but succumb to a neurologic demise.

Farber Disease

This rare autosomal recessive disorder results from the deficiency of the lysosomal enzyme acid ceramidase and the accumulation of ceramide in various tissues, especially the joints. Symptoms can begin in the 1st yr of life with painful joint swelling and nodule formation (Fig. 104.20), which is sometimes diagnosed as **rheumatoid arthritis** . As the disease progresses, nodule or granulomatous formation on the vocal cords can lead to hoarseness and breathing difficulties; failure to thrive is common. In some patients, moderate CNS dysfunction is present (see Table 104.15). Patients may die of recurrent pneumonias in their teens. *There is currently no specific therapy.* The **diagnosis** of Farber disease should be suspected in patients who have nodule formation over the joints but no other findings of rheumatoid arthritis. In such patients, acid ceramidase activity should be determined in cultured skin fibroblasts or peripheral leukocytes. Various disease-causing mutations have been identified in the acid ceramidase gene. Carrier detection and prenatal diagnosis are available.

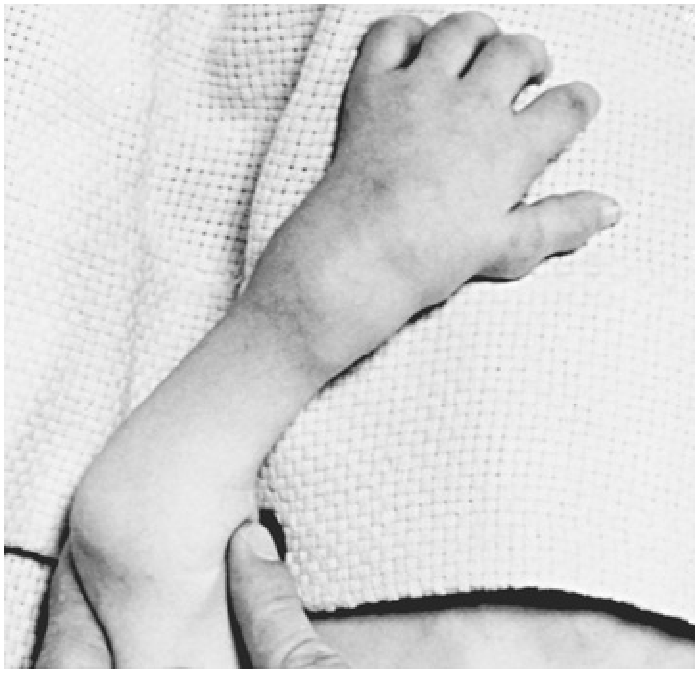

FIG. 104.20 Forearm of an 18 mo old girl with Farber disease. Note the painful joint swelling and the nodule formation. The infant was suspected of having rheumatoid arthritis.

Wolman Disease and Cholesterol Ester Storage Disease

These autosomal recessive lysosomal storage diseases result from deficiency of **lysosomal acid lipase (LAL)** and accumulation of cholesterol esters and triglycerides in histiocytic foam cells of most visceral organs. The *LAL* gene is on chromosome 10 (10q24-q25). **Wolman disease** is the more severe clinical phenotype and is a fatal disorder of infancy. Clinical features become apparent in the 1st weeks of life and include failure to thrive, relentless vomiting, abdominal distention, steatorrhea, and hepatosplenomegaly (see Table 104.15). There usually is hyperlipidemia. Hepatic dysfunction and fibrosis may occur. **Calcification of the adrenal glands** occurs in about 50% of patients. Death usually occurs within the 1st 6 mo of life.

Cholesterol ester storage disease is less severe than Wolman disease and may not be diagnosed until adulthood. Hepatomegaly can be the only detectable abnormality, but affected individuals are at significant risk for premature cirrhosis and atherosclerosis. Adrenal calcification can occur in patients with severe early onset.

Diagnosis and carrier identification are based on measuring LAL activity in peripheral leukocytes or cultured skin fibroblasts. Disease-causing mutations have been identified in the *LAL* gene. Prenatal diagnosis depends on measuring decreased enzyme levels or identifying specific mutations in cultured chorionic villi or amniocytes. Pharmacologic agents to suppress cholesterol synthesis, in combination with cholestyramine and diet modification, have been used in patients, but with little to no clinical benefit. *Sebelipase alfa* (Kanuma, Alexion) is a recombinant form of LAL approved by the FDA in 2015. In a clinical study, 67% of infants with LAL deficiency survived beyond 12 mo of age, compared with 0% of untreated infants in a historical cohort, all of whom died by 8 mo. In a study of 66 pediatric and adult patients with cholesteryl ester storage disease, those treated with Kanuma had demonstrated significant reductions in serum alanine transaminase (ALT) levels and liver fat and improvements in LDL-C, triglycerides, and HDL-C, compared to placebo-treated patients (see Chapter 104.3).

Mucolipidoses

Margaret M. McGovern, Robert J. Desnick

Keywords

I cell disease
mucolipidosis

I-cell disease (mucolipidosis II [ML-II]) and **pseudo-Hurler polydystrophy (mucolipidosis III [ML-III])** are rare autosomal recessive disorders that share some clinical features with Hurler syndrome (see Chapter 107). These diseases result from the abnormal targeting of newly synthesized lysosomal enzymes that normally have phosphorylated mannose residues for binding to the mannose-6-phosphate receptors that transport the enzymes to the lysosomes. These mannose-6-phosphate residues are synthesized in a 2-step reaction that occurs in the Golgi apparatus and is mediated by 2 enzymatic activities. The enzyme that catalyzes the first step, the lysosomal enzyme *N* -acetylglucosamine-1-phosphotransferase, is defective in both ML-II and ML-III, which are allelic disorders resulting from mutations in the GlcNAc-phosphotransferase α/β-subunits precursor gene *(GNPTAB).* This enzyme deficiency results in abnormal targeting of the lysosomal enzymes, which are consequently secreted into the extracellular matrix. Because the lysosomal enzymes require the acidic environment of the lysosome to function, patients with this defect accumulate a variety of different substrates because of the intracellular deficiency of most lysosomal enzymes. The **diagnosis** of ML-II and ML-III can be made by the determination of the serum lysosomal enzymatic activities, which are markedly elevated, or by the demonstration of their reduced enzymatic activity levels in cultured skin fibroblasts. Direct measurement of the phosphotransferase activity is possible as well. **Prenatal diagnosis** is available for both disorders by measurement of lysosomal enzymatic activities in amniocytes or chorionic villus cells. Carrier identification is available for both disorders by measurement of enzymatic activities using cultured skin fibroblasts or by mutation analysis of the causative gene. Neonatal screening by tandem mass spectroscopy may detect I-cell disease.

I-Cell Disease

I-cell disease, or ML-II, shares many of the clinical manifestations of Hurler syndrome (see Chapter 107), although there is no mucopolysacchariduria, and the presentation is earlier (see Table 104.15). Some patients have clinical features evident at birth, including coarse facial features, craniofacial abnormalities, restricted joint movement, and hypotonia. Nonimmune hydrops may be present in the fetus. The remainder of patients present in the 1st yr with severe psychomotor retardation, coarse facial features, and skeletal manifestations that include kyphoscoliosis and a lumbar gibbus. Patients may also have congenital dislocation of the hips, inguinal hernias, and gingival hypertrophy. Progressive, severe psychomotor impairment leads to death in early childhood. *No treatment is available for I-cell disease.*

Pseudo-Hurler Polydystrophy

Pseudo-Hurler polydystrophy, or ML-III, is a less severe disorder than I-cell disease, with later onset and survival to adulthood reported. Affected children may present around age 4 or 5 yr with joint stiffness and short stature. Progressive destruction of the hip joints and moderate dysostosis multiplex are evident. Radiographic evidence of low iliac wings, flattening of the proximal femoral epiphyses with valgus deformity of the femoral head, and hypoplasia of the anterior third of the lumbar vertebrae are characteristic findings. Ophthalmic findings include corneal clouding, retinopathy, and astigmatism; visual complaints are uncommon (see Table 104.15). Some patients have learning disabilities or intellectual disability. **Treatment** , which should include orthopedic care, is symptomatic.

CHAPTER 105

Defects in Metabolism of Carbohydrates

Priya S. Kishnani, Yuan-Tsong Chen

Carbohydrate synthesis and degradation provide the energy required for most metabolic processes. The important carbohydrates include 3 monosaccharides—glucose, galactose, and fructose—and a polysaccharide, glycogen. Fig. 105.1 shows the relevant biochemical pathways of these carbohydrates. **Glucose** is the principal substrate of energy metabolism, continuously available through dietary intake, gluconeogenesis (glucose made de novo from amino acids, primarily alanine), and glycogenolysis (breakdown of glycogen). Metabolism of glucose generates adenosine triphosphate (ATP) via glycolysis (conversion of glucose or glycogen to pyruvate), mitochondrial oxidative phosphorylation (conversion of pyruvate to carbon dioxide and water), or both. Dietary sources of glucose come from polysaccharides, primarily starch, and the disaccharides lactose, maltose, and sucrose. However, oral intake of glucose is intermittent and unreliable. Gluconeogenesis contributes to maintaining euglycemia (normal levels of glucose in the blood), but this process requires time. Hepatic glycogenolysis provides the rapid release of glucose, and is the most significant factor in maintaining euglycemia. **Glycogen** is also the primary stored energy source in muscle, providing glucose for muscle activity during exercise. Galactose and fructose are monosaccharides that provide fuel for cellular metabolism, though their role is less significant than that of glucose. **Galactose** is derived from lactose (galactose + glucose), which is found in milk and milk products. Galactose is an important energy source in infants, but it is first metabolized to glucose. Galactose (exogenous or endogenously synthesized from glucose) is also an important component of certain glycolipids, glycoproteins, and glycosaminoglycans. The dietary sources of **fructose** are sucrose (fructose + glucose, sorbitol) and fructose itself, which is found in fruits, vegetables, and honey.

In Harrison TR, Isselbacher KJ, editors: *Harrison's principles of internal medicine,* ed 13, New York, 1994, McGraw-Hill. Reproduced with permission of The McGraw-Hill Companies.)

Defects in glycogen metabolism typically cause an accumulation of glycogen in the tissues, thus the name **glycogen storage disease** (Table 105.1). Defects in gluconeogenesis or the glycolytic pathway, including galactose and fructose metabolism, do not result in an accumulation of glycogen (Table 105.1). The defects in pyruvate metabolism in the pathway of the conversion of pyruvate to carbon dioxide and water via mitochondrial oxidative phosphorylation are more often associated with **lactic acidosis** and some tissue glycogen accumulation.

Table 105.1

Features of the Disorders of Carbohydrate Metabolism

DISORDERS	BASIC DEFECTS	CLINICAL PRESENTATION	COMMENTS
LIVER GLYCOGENOSES			
Type/Common Name			
Ia/Von Gierke	Glucose-6-phosphatase	Growth retardation, hepatomegaly, hypoglycemia; elevated blood lactate, cholesterol, triglyceride, and uric acid levels	Common, severe hypoglycemia Adulthood: hepatic adenomas and carcinoma, osteoporosis, pulmonary hypertension, and renal failure
Ib	Glucose-6-phosphate translocase	Same as type Ia, with additional findings of neutropenia, periodontal disease, inflammatory bowel disease	10% of type Ia
IIIa/Cori or Forbes	Liver and muscle debrancher deficiency (amylo-1,6-glucosidase)	Childhood: hepatomegaly, growth retardation, muscle weakness, hypoglycemia, hyperlipidemia, elevated transaminase levels Adult form: muscle atrophy and weakness, peripheral neuropathy, liver cirrhosis and failure, risk for hepatocellular carcinoma	Common, intermediate severity of hypoglycemia Muscle weakness may progress to need for ambulation assistance such as wheelchair.
IIIb	Liver debrancher deficiency; normal muscle enzyme activity	Liver symptoms same as in type IIIa; no muscle symptoms	15% of type III
IV/Andersen	Branching enzyme	Childhood: failure to thrive, hypotonia, hepatomegaly, splenomegaly, progressive cirrhosis (death usually before	Rare neuromuscular variants exist

		5th yr), elevated transaminase levels; a subset does not have progression of liver disease Adult form: isolated myopathy, central and peripheral nervous system involvement	
VI/Hers	Liver phosphorylase	Hepatomegaly, typically mild hypoglycemia, hyperlipidemia, and ketosis	Often underdiagnosed, severe presentation also known
IX/phosphorylase kinase (PhK) deficiency			Common, X-linked, typically less severe than autosomal forms; clinical variability within and between subtypes; severe cases being recognized across different subtypes
IX (*PHKA2* variant)	Liver PhK	Hypoglycemia, hyperketosis hepatomegaly, chronic liver disease, hyperlipidemia, elevated liver enzymes, growth retardation	X-linked
IX (*PHKB* variant)	Liver and muscle PhK	Hepatomegaly, growth retardation	Autosomal recessive
IX (*PHKG2* variant)	Liver PhK	More severe than IXa; marked hepatomegaly, recurrent hypoglycemia, liver cirrhosis	Autosomal recessive
Glycogen synthase deficiency	Glycogen synthase	Early morning drowsiness and fatigue, fasting hypoglycemia, and ketosis, no hepatomegaly	Decreased liver glycogen store
XI/Fanconi-Bickel syndrome	Glucose transporter 2 (GLUT-2)	Failure to thrive, rickets, hepatorenomegaly, proximal renal tubular dysfunction, impaired glucose and galactose utilization	GLUT-2 expressed in liver, kidney, pancreas, and intestine
MUSCLE GLYCOGENOSES			
Type/Common Name			
IX (*PHKA1* variant)	Muscle PhK	Exercise intolerance, cramps, myalgia, myoglobinuria; no hepatomegaly	X-linked or autosomal recessive
II/Pompe infantile	Acid α-glucosidase (acid maltase)	Cardiomegaly, hypotonia, hepatomegaly; onset: birth to 6 mo	Common, cardiorespiratory failure leading to death by age 1-2 yr; minimal to no residual enzyme activity
II/Late-onset Pompe (juvenile and adult)	Acid α-glucosidase (acid maltase)	Myopathy, variable cardiomyopathy, respiratory insufficiency; onset: childhood to adulthood	Residual enzyme activity
Danon disease	Lysosome-associated membrane protein 2 (LAMP2)	Hypertrophic cardiomyopathy, heart failure	Rare, X-linked
PRKAG2 deficiency	Adenosine monophosphate (AMP)–activated protein kinase γ	Hypertrophic cardiomyopathy. Congenital fetal form is rapidly fatal; myopathy, myalgia, seizures	Autosomal dominant
V/McArdle	Myophosphorylase	Exercise intolerance, muscle cramps, myoglobinuria, “second	Common, male predominance

		wind" phenomenon	
VII/Tarui	Phosphofructokinase	Exercise intolerance, muscle cramps, compensatory hemolytic anemia, myoglobinuria	Prevalent in Japanese and Ashkenazi Jews
Late-onset polyglucosan body myopathy	Glycogenin-1	Adult-onset proximal muscle weakness, nervous system involvement uncommon	Autosomal recessive, rare
Phosphoglycerate kinase deficiency	Phosphoglycerate kinase	As with type V	Rare, X-linked
Phosphoglycerate mutase deficiency	M subunit of phosphoglycerate mutase	As with type V	Rare, majority of patients are African American
Lactate dehydrogenase deficiency	M subunit of lactate dehydrogenase	As with type V	Rare
GALACTOSE DISORDERS			
Galactosemia with transferase deficiency	Galactose-1-phosphate uridyltransferase	Vomiting, hepatomegaly, cataracts, aminoaciduria, failure to thrive	Black patients tend to have milder symptoms
Galactokinase deficiency	Galactokinase	Cataracts	Benign
Generalized uridine diphosphate galactose-4-epimerase deficiency	Uridine diphosphate galactose-4-epimerase	Similar to transferase deficiency with additional findings of hypotonia and nerve deafness	A benign variant also exists
FRUCTOSE DISORDERS			
Essential fructosuria	Fructokinase	Urine reducing substance	Benign
	Fructose-1-phosphate aldolase	Acute: vomiting, sweating, lethargy	
Hereditary fructose intolerance		Chronic: failure to thrive, hepatic failure	Prognosis good with fructose restriction
DISORDERS OF GLUCONEOGENESIS			
Fructose-1,6-diphosphatase deficiency	Fructose-1,6-diphosphatase	Episodic hypoglycemia, apnea, acidosis	Good prognosis, avoid fasting
Phosphoenolpyruvate carboxykinase deficiency	Phosphoenolpyruvate carboxykinase	Hypoglycemia, hepatomegaly, hypotonia, failure to thrive	Rare
DISORDERS OF PYRUVATE METABOLISM			
Pyruvate dehydrogenase complex defect	Pyruvate dehydrogenase	Severe fatal neonatal to mild late onset, lactic acidosis, psychomotor retardation, failure to thrive	Most commonly caused by $E_{1\alpha}$ subunit, defect X-linked
Pyruvate carboxylase deficiency	Pyruvate carboxylase	Same as above	Rare, autosomal recessive
Respiratory chain defects (oxidative phosphorylation disease)	Complexes I-V, many mitochondrial DNA mutations	Heterogeneous with multisystem involvement	Mitochondrial inheritance
DISORDERS IN PENTOSE METABOLISM			
Pentosuria	L-Xylulose reductase	Urine-reducing substance	Benign
Transaldolase deficiency	Transaldolase	Liver cirrhosis and failure, cardiomyopathy	Autosomal recessive
Ribose-5-phosphate	Ribose-5-phosphate	Progressive leukoencephalopathy	

isomerase deficiency	isomerase	and peripheral neuropathy	

105.1

Glycogen Storage Diseases

enzyme replacement therapy

The disorders of glycogen metabolism, the glycogen storage diseases (**GSDs**), result from deficiencies of various enzymes or transport proteins in the pathways of glycogen metabolism (see Fig. 105.1). Glycogen found in these disorders is abnormal in quantity, quality, or both. GSDs are categorized by numerical type in accordance with the chronological order in which these enzymatic defects were identified. This numerical classification is still widely used, at least up to number VII. The GSDs can also be classified by organ involvement into liver and muscle glycogenoses (see Table 105.1).

There are more than 12 forms of GSDs. Glucose-6-phosphatase deficiency (type I), lysosomal acid α-glucosidase deficiency (type II), debrancher deficiency (type III), and liver phosphorylase kinase deficiency (type IX) are the most common of those that typically present in early childhood; myophosphorylase deficiency (type V, McArdle disease) is the most common in adolescents and adults. The cumulative frequency of all forms of GSD is approximately 1 in 20,000 live births.

Liver Glycogenoses

The GSDs that principally affect the liver include glucose-6-phosphatase deficiency (**type I**), debranching enzyme deficiency (**type III**), branching enzyme deficiency (**type IV**), liver phosphorylase deficiency (**type VI**), phosphorylase kinase deficiency (**type IX** , formerly GSD VIa), glycogen synthase deficiency (**type 0**), and glucose transporter-2 defect. Because hepatic carbohydrate metabolism is responsible for plasma glucose homeostasis, this group of disorders typically causes fasting hypoglycemia and hepatomegaly. Some (types III, IV, IX) can be associated with liver cirrhosis. Other organs can also be involved and may manifest as renal dysfunction in type I, myopathy (skeletal and/or cardiomyopathy) in types III and IV, as well as in some rare forms of phosphorylase kinase deficiency, and neurologic involvement in types III (peripheral nerves) and IV (diffuse central and peripheral nervous system dysfunction).

Type I Glycogen Storage Disease (Glucose-6-Phosphatase or Translocase Deficiency, Von Gierke Disease)

Type I GSD is caused by the absence or deficiency of **glucose-6-phosphatase** activity in the liver, kidney, and intestinal mucosa. It has 2 subtypes: **type Ia** , in which the defective enzyme is glucose-6-phosphatase, and **type Ib** , in which the defective enzyme is a **translocase** that transports glucose-6-phosphate across the microsomal membrane. Deficiency of the enzymes in both type Ia and type Ib lead to inadequate hepatic conversion of glucose-6-phosphate to glucose through normal glycogenolysis and gluconeogenesis, resulting in fasting hypoglycemia.

Type I GSD is an autosomal recessive disorder. The gene for glucose-6-phosphatase *(G6PC)* is located on chromosome 17q21; the gene for translocase *(SLC37A4)* is on chromosome 11q23. Common pathogenic variants have been identified. Carrier detection and prenatal diagnosis are possible with DNA-based methodologies.

Clinical Manifestations

Patients with type I GSD may present in the neonatal period with hypoglycemia and lactic acidosis but more often present at 3-4 mo of age with hepatomegaly, hypoglycemic seizures, or both. Affected children often have a **doll-like face** with fat cheeks, relatively thin extremities, short stature, and a protuberant abdomen that is a consequence of massive hepatomegaly. The kidneys are also enlarged, whereas the spleen and heart are not involved.

The biochemical characteristics of type I GSD are *hypoglycemia, lactic acidosis, hyperuricemia,* and *hyperlipidemia*. Hypoglycemia and lactic acidosis can develop after a short fast. Hyperuricemia is present in young children; it rarely progresses to symptomatic gout before puberty. Despite marked hepatomegaly, the liver transaminase levels are usually normal or only slightly elevated. Intermittent diarrhea may occur in GSD I. In patients with GSD Ib, the loss of mucosal barrier function as a result of inflammation, which is likely related to the disturbed neutrophil function, seems to be the main cause of diarrhea. Easy bruising and epistaxis are common and are associated with a **prolonged bleeding time** as a result of impaired platelet aggregation and adhesion.

The plasma may be “milky” in appearance due to strikingly elevated triglyceride levels. Cholesterol and phospholipids are also elevated, but less prominently. The lipid abnormality resembles type IV hyperlipidemia and is characterized by increased levels of very-low-density lipoprotein, low-density lipoprotein, and a unique apolipoprotein profile consisting of increased levels of apolipoproteins B, C, and E, with relatively normal or reduced levels of apolipoproteins A and D. The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and fat. The lipid vacuoles are particularly large and prominent. There is no associated liver fibrosis.

Although type I GSD affects mainly the liver, multiple organ systems are involved. **Delayed puberty** is often seen. Females can have ultrasound findings consistent with **polycystic ovaries** even though other features of polycystic ovary syndrome (acne, hirsutism) are not seen. Nonetheless, fertility appears to be normal, as evidenced in several reports of successful pregnancy in women with GSD I. Increased bleeding during menstrual cycles, including life-threatening menorrhagia, has been reported and could be related to the impaired platelet aggregation. Symptoms of gout usually start around puberty from long-term hyperuricemia. There is an increased risk of **pancreatitis,** secondary to the lipid abnormalities. The dyslipidemia, together with elevated erythrocyte aggregation, could predispose these patients to atherosclerosis, but premature atherosclerosis has not yet been clearly documented except for rare cases. Impaired platelet aggregation and increased antioxidative defense to prevent lipid peroxidation may function as a protective mechanism to help reduce the risk of atherosclerosis. Frequent fractures and radiographic evidence of **osteopenia** are common; bone mineral content is reduced, even in prepubertal patients.

By the 2nd or 3rd decade of life, some patients with type I GSD develop **hepatic adenomas** that can hemorrhage and turn malignant in some cases. **Pulmonary hypertension** has been seen in some long-term survivors of the disease. Iron-refractory anemia and an increased prevalence of thyroid autoimmunity are also being recognized.

Renal disease is another late complication, and most patients with type I GSD >20 yr of age have proteinuria. Many also have hypertension, renal stones, nephrocalcinosis, and altered creatinine clearance. Glomerular hyperfiltration, increased renal plasma flow, and microalbuminuria are often found in the early stages of renal dysfunction and can occur before the onset of proteinuria. In younger patients, hyperfiltration and hyperperfusion may be the only signs of renal abnormalities. With the advancement of renal disease, focal segmental glomerulosclerosis and interstitial fibrosis become evident. In some patients, renal function has deteriorated and progressed to failure, requiring dialysis and transplantation. Other renal abnormalities include amyloidosis, a Fanconi-like syndrome, hypocitraturia, hypercalciuria, and a distal renal tubular acidification defect.

Patients with GSD Ib can have additional features of recurrent bacterial infections from **neutropenia** and impaired neutrophil function. Oral involvement including recurrent mucosal ulceration, gingivitis, and rapidly progressive periodontal disease may occur in type Ib. Intestinal mucosa ulceration culminating in GSD enterocolitis is also common. Type 1b is also associated with a chronic inflammatory bowel disease (IBD)–like picture involving the colon that may be associated with neutropenia and/or neutrophil dysfunction; it may resemble ulcerative colitis or Crohn disease.

Diagnosis

The clinical presentation and laboratory findings of hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia lead to a suspected diagnosis of type I GSD. Neutropenia is noted in GSD Ib patients, typically before 1 yr of age. Neutropenia has also been noted in some patients with GSD Ia, especially those with the p.G188A variant. Administration of glucagon or epinephrine leads to a negligible increase, if any, in blood glucose levels, but the lactate level rises significantly. Before the availability of genetic testing, a definitive diagnosis required a liver biopsy. Gene-based variant analysis by single-gene sequencing or gene panels provides a noninvasive way to diagnose most patients with GSD types Ia and Ib.

Treatment

Treatment focuses on maintaining normal blood glucose levels and is achieved by continuous nasogastric (NG) infusion of glucose or oral administration of uncooked cornstarch. In infancy, overnight NG drip feeding may be needed to maintain normoglycemia. NG feedings can consist of an elemental enteral formula or only glucose or a glucose polymer to provide sufficient glucose to maintain euglycemia. During the day, frequent feedings with high-carbohydrate content are typically sufficient.

Uncooked cornstarch acts as a slow-release form of glucose and can be introduced at a dose of 1.6 g/kg every 4 hr for children <2 yr of age. The response of young children is variable. For older children, the cornstarch regimen can be changed to every 6 hr at a dose of 1.6-2.5 g/kg body weight and can be given orally as a liquid. Newer starch products, such as extended-release waxy maize starch, are thought to be longer acting, better tolerated, and more palatable. Medium-chain triglyceride (MCT) supplementation improves metabolic control, leading to improved growth in children. Since fructose and galactose cannot be converted directly to glucose in GSD type I, these sugars should be restricted in the diet. Sucrose (table sugar, cane sugar, other ingredients), fructose (fruit, juice, high-fructose corn syrup), lactose (dairy foods), and sorbitol should be avoided or limited. As a result of these dietary restrictions, vitamins and minerals such as calcium and vitamin D may be deficient, and supplementation is required to prevent nutritional deficiencies.

Dietary therapy improves hyperuricemia, hyperlipidemia, and renal function, slowing the development of renal failure. This therapy fails, however, to normalize blood uric acid and lipid levels completely in some individuals, despite good metabolic control, especially after puberty. The control of hyperuricemia can be further augmented by the use of allopurinol, a xanthine oxidase inhibitor. The hyperlipidemia can be reduced with lipid-lowering drugs such as β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors and fibrate (see Chapter 104). **Microalbuminuria** , an early indicator of renal dysfunction in type I disease, is treated with angiotensin-converting enzyme (ACE) inhibitors. Citrate supplements can be beneficial for patients with hypocitraturia by preventing or ameliorating nephrocalcinosis and development of urinary calculi. Thiazide diuretics increase renal reabsorption of filtered calcium and decrease urinary calcium excretion, thereby preventing hypercalciuria and nephrocalcinosis. Growth hormone (GH) should be used with extreme caution and limited to only those with a documented GH deficiency. Even in those patients, there should be close monitoring of metabolic parameters and for the presence of adenomas.

In patients with type Ib GSD, granulocyte and granulocyte-macrophage colony-stimulating factors are successful in correcting the neutropenia, decreasing the number and severity of bacterial infections, and improving the chronic IBD. The minimum effective dose should be used because side effects are noted on these agents, including splenomegaly, hypersplenism, and bone pain. Bone marrow transplantation has been reported to correct the neutropenia of type Ib GSD.

Orthotopic liver transplantation is a potential cure of type I GSD, especially for patients with liver malignancy, multiple liver adenomas, metabolic derangements refractory to medical management, and liver failure. However, this should be considered as a last resort because of the inherent short- and long-term complications. Large adenomas (>2 cm) that are rapidly increasing in size and/or number may necessitate partial hepatic resection. Smaller adenomas (<2 cm) may be treated with percutaneous ethanol injection or transcatheter arterial embolization. Recurrence of liver adenomas is a challenge and may potentiate malignant transformation in these patients, ultimately requiring a liver transplant.

Before any surgical procedure, the bleeding status must be evaluated and good metabolic control established. Prolonged bleeding times can be normalized by the use of intensive intravenous (IV) glucose infusion for 24-48 hr before surgery. DDAVP (1-deamino-8-D -arginine vasopressin) can reduce bleeding complications, but it should be used with caution because of the risk of fluid overload and hyponatremia when administered as an IV infusion. Lactated Ringer solution should be avoided because it contains lactate and no glucose. Glucose levels should be maintained in the normal range throughout surgery with the use of 10% dextrose. Overall, metabolic control is assessed by growth, improvement, and correction of the metabolic abnormalities, such as elevated lactate, glucose, triglyceride, cholesterol, and uric acid levels.

Prognosis

Previously, type I GSD was associated with a high mortality at a young age, and even for those who survived, the prognosis was guarded. Inadequate metabolic control during childhood can lead to long-term complications in adults. Clinical outcomes have improved dramatically with early diagnosis and effective treatment. However, serious complications such as renal disease and formation of hepatic adenomas with potential risk for malignant transformation persist. The ability to identify transformation to hepatocellular carcinoma in the liver adenomas remains a challenge: α-fetoprotein (AFP) and carcinoembryonic antigen (CEA) levels often remain normal in the setting of hepatocellular carcinoma.

Type III Glycogen Storage Disease (Debrancher Deficiency, Limit Dextrinosis)

Type III GSD is caused by deficient activity of the **glycogen debranching enzyme** . Debranching enzyme, together with phosphorylase, is responsible for complete degradation of glycogen. When debranching enzyme is defective, glycogen breakdown is incomplete, resulting in the accumulation of an abnormal glycogen with short outer-branch chains, which resemble *limit dextrin.* Symptoms of glycogen debranching enzyme deficiency include hepatomegaly, hypoglycemia, short stature, variable skeletal myopathy, and variable cardiomyopathy. GSD **type IIIa** usually involves both liver and muscle, whereas in **type IIIb** , seen in approximately 15% of patients, the disease appears to involve only liver.

Type III GSD is an autosomal recessive disease that has been reported in many different ethnic groups. The frequency is relatively high in Sephardic Jews from North Africa, inhabitants of the Faroe Islands, and in Inuits. The gene for debranching enzyme *(AGL)* is located on chromosome 1p21. More than 130 different pathogenic variants have been identified; 2 pathogenic variants in exon 3, c.18_19delGA (previously described as c.17_18delAG) and p.Gln6X, are specifically associated with glycogenosis IIIb. Carrier detection and prenatal diagnosis are possible using DNA-based methodologies.

Clinical Manifestations

In infancy and childhood, GSD type III may be indistinguishable from type I

GSD because of overlapping features such as hepatomegaly, hypoglycemia, hyperlipidemia, and growth retardation (Fig. 105.2). Splenomegaly may be present, but the kidneys are typically not affected. Hepatomegaly in most patients with type III GSD improves with age; however, liver fibrosis, cirrhosis progressing to liver failure, and hepatocellular carcinoma (HCC) are noted in many in late adulthood. Hepatic adenomas occur less often in individuals with GSD III than those with GSD I. The relationship between hepatic adenomas and malignancy in GSD III remains unclear. AFP and CEA levels are not good predictors of the presence of hepatocellular adenomas or malignant transformation. A single case of malignant transformation at the site of adenomas has been noted.

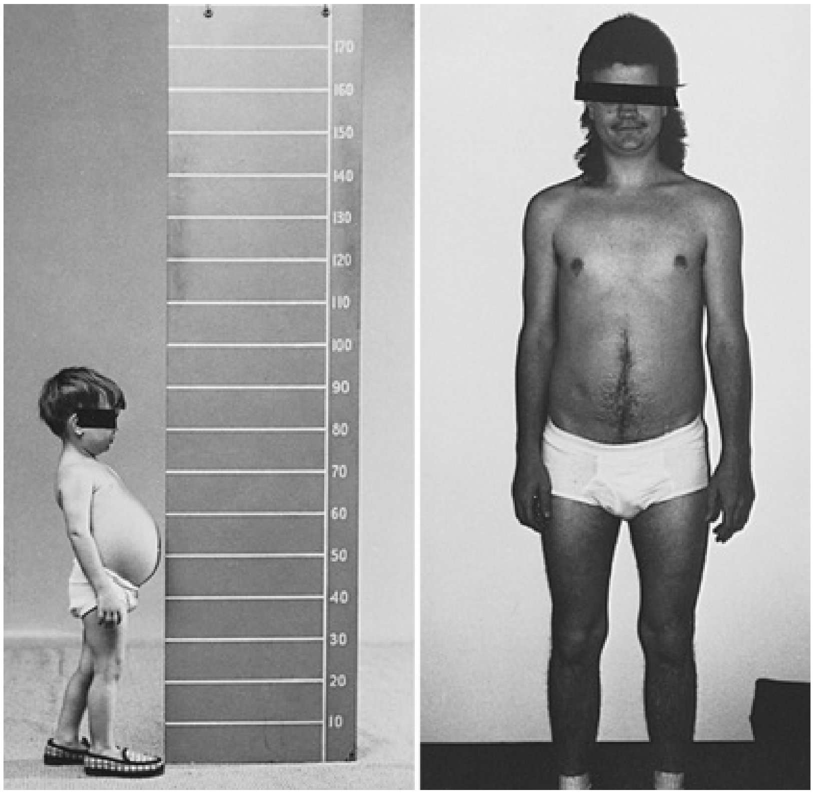

FIG. 105.2 **Growth and development in a patient with type IIIb glycogen storage disease. The patient has debrancher deficiency in the liver but normal activity in muscle. As a child, he had hepatomegaly, hypoglycemia, and growth retardation. After puberty, he no longer had hepatomegaly or hypoglycemia, and his final adult height is normal. He had no muscle weakness or atrophy; this is in contrast to type IIIa patients, in whom a progressive myopathy is seen in adulthood.**

In patients with GSD type IIIa, the **muscle weakness** is slowly progressive and associated with wasting. The weakness is less remarkable in childhood but can become severe after the 3rd or 4th decade of life. Low bone mineral density in patients with GSD III put them at an increased risk of potential fractures. Myopathy does not follow any particular pattern of involvement; both proximal and distal muscles are involved. Electromyography reveals a widespread myopathy; nerve conduction studies are often abnormal.

Although overt cardiac dysfunction is rare, ventricular hypertrophy is a frequent finding. **Cardiac pathology** has shown diffuse involvement of various cardiac structures, including vacuolation of myocytes, atrioventricular conduction, and hyperplasia of smooth muscles. Life-threatening arrhythmia and the need for heart transplant have been reported in some GSD III patients. Hepatic symptoms in some patients may be so mild that the diagnosis is not made until adulthood, when the patients show symptoms and signs of neuromuscular disease.

The initial diagnosis has been confused with Charcot-Marie-Tooth disease (see Chapter 631.1). Polycystic ovaries are noted; some patients can develop hirsutism, irregular menstrual cycles, and other features of polycystic ovarian syndrome. Fertility does not appear to be affected; successful pregnancies have been reported.

Hypoglycemia and hyperlipidemia are common. In contrast to type I GSD, elevation of liver transaminase levels and fasting ketosis are prominent, but blood lactate and uric acid concentrations are usually normal. Glucagon administration 2 hr after a carbohydrate meal provokes a normal increase in blood glucose; after an overnight fast, however, glucagon may provoke no change in blood glucose level. Serum creatine kinase levels can be useful to identify patients with muscle involvement, although normal levels do not rule out muscle enzyme deficiency.

Diagnosis

The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and the presence of fibrous septa. The fibrosis and the paucity of fat distinguish type III glycogenosis from type I. The fibrosis, which ranges from minimal periportal fibrosis to micronodular cirrhosis, appears in most cases to be nonprogressive. Overt cirrhosis has been seen in some patients with GSD III.

Patients with myopathy and liver symptoms have a generalized enzyme defect (type IIIa). The deficient enzyme activity can be demonstrated not only in liver and muscle, but also in other tissues such as heart, erythrocytes, and cultured fibroblasts. Patients with hepatic symptoms without clinical or laboratory evidence of myopathy have debranching enzyme deficiency only in the liver, with enzyme activity retained in the muscle (type IIIb). Before the availability of genetic testing, a definitive diagnosis required enzyme assay in liver, muscle, or both. Gene sequencing now allows for diagnosis and subtype assignment in the majority of patients.

Treatment

The mainstay of treatment of GSD III is dietary management, as in GSD I, although it is less demanding. Patients do not need to restrict dietary intake of fructose and galactose, although simple sugars should be avoided to prevent sudden spikes in blood glucose levels. Hypoglycemia is treated with small, frequent meals high in complex carbohydrates, such as cornstarch supplements or nocturnal gastric drip feedings. Additionally, a high-protein diet during the daytime as well as overnight protein enteral infusion is effective in preventing hypoglycemia. The exogenous protein can be used as a substrate for gluconeogenesis which helps to meet energy needs and prevent endogenous protein breakdown. Protein in the diet also reduces the overall starch requirement. Overtreatment with cornstarch should be avoided as it can result in excessive glycogen buildup, which is detrimental and can lead to excessive weight gain. MCT supplementation is being considered as an alternative source of energy. There is no satisfactory treatment for the progressive myopathy other than recommending a high-protein diet and a submaximal exercise program. Close monitoring with abdominal MRI is needed to detect progression of liver fibrosis to cirrhosis and further to HCC. Liver transplantation has been performed in GSD III patients with progressive cirrhosis and/or HCC. There are reports of cardiac transplant in GSD III patients with end stage cardiac disease.

Type IV Glycogen Storage Disease (Branching Enzyme Deficiency, Amylopectinosis, Polyglucosan Disease, or Andersen Disease)

Type IV GSD is caused by the deficiency of **branching enzyme** activity, which results in the accumulation of an abnormal glycogen with poor solubility. The disease is also known as *amylopectinosis* because the abnormal glycogen has fewer branch points, more α 1-4 linked glucose units, and longer outer chains, resulting in a structure resembling amylopectin. Accumulation of polyglucosan, which is positive on periodic acid–Schiff (PAS) and partially resistant to diastase digestion, is seen in all tissues of patients, but to different degrees.

Type IV GSD is an autosomal recessive disorder. The glycogen branching enzyme *(GBE)* gene is located on chromosome 3p21. More than 20 pathogenic variants responsible for type IV GSD have been identified, and their characterization in individual patients can be useful in predicting clinical outcome. The nearly complete absence of GBE activity with null variants has been associated with perinatal death and fatal neonatal hypotonia. Residual GBE enzyme activity >5% and presence of at least 1 missense variant are associated with a nonlethal hepatic cirrhosis phenotype and, in some situations, a lack of progressive liver disease.

Clinical Manifestations

There is a high degree of clinical variability associated with type IV GSD. The most common and classic form is characterized by progressive cirrhosis of the liver and manifests in the 1st 18 mo of life as hepatosplenomegaly and failure to thrive. Cirrhosis may present with portal hypertension, ascites, and esophageal varices and may progress to liver failure, usually leading to death by 5 yr of age. Rare patients survive without progression of liver disease; they have a milder hepatic form and do not require a liver transplant. Extrahepatic involvement in some patients with GSD IV consists of musculoskeletal involvement, particularly cardiac and skeletal muscles, as well as central nervous system (CNS) involvement.

A **neuromuscular** form of type IV GSD has been reported, with 4 main variants recognized based on age at presentation. The **perinatal** form is characterized by a *fetal akinesia deformation sequence* (FADS) and death in the perinatal period. The **congenital** form presents at birth with severe hypotonia, muscle atrophy, and neuronal involvement, with death in the neonatal period; some patients have cardiomyopathy. The **childhood** form presents primarily with myopathy or cardiomyopathy. The **adult** form, *adult polyglucosan body disease* (APBD), presents as an isolated myopathy or with diffuse CNS and peripheral nervous system dysfunction, accompanied by accumulation of polyglucosan material in the nervous system. Symptoms of neuronal involvement include peripheral neuropathy, neurogenic bladder, and leukodystrophy, as well as mild cognitive decline in some patients. For APBD, a leukocyte or nerve biopsy is needed to establish the diagnosis because branching enzyme deficiency is limited to those tissues.

Diagnosis

Deposition of amylopectin-like materials can be demonstrated in liver, heart, muscle, skin, intestine, brain, spinal cord, and peripheral nerve in type IV GSD. Liver histology shows micronodular cirrhosis and faintly stained basophilic inclusions in the hepatocytes. The inclusions are composed of coarsely clumped, stored material that is PAS positive and partially resistant to diastase digestion. Electron microscopy (EM) shows, in addition to the conventional α and β glycogen particles, accumulation of the fibrillar aggregations that are typical of amylopectin. The distinct staining properties of the cytoplasmic inclusions, as well as EM findings, could be diagnostic. However, polysaccharides with histologic features reminiscent of type IV disease, but without enzymatic correlation, have been observed. The definitive diagnosis rests on the demonstration of the deficient branching enzyme activity in liver, muscle, cultured skin fibroblasts, or leukocytes, or on the identification of pathogenic variants in the *GBE* gene. Prenatal diagnosis is possible by measuring enzyme activity in cultured amniocytes, chorionic villi, or DNA-based methodologies.

Treatment

There is no specific treatment for type IV GSD. Nervous system involvement, such as gait problems and bladder involvement, requires supportive, symptomatic management. Unlike patients with the other liver GSDs (I, III, VI, IX), those with GSD IV do not have hypoglycemia, which is only seen when there is overt liver cirrhosis. Liver transplantation has been performed for patients with progressive liver disease, but patients must be carefully selected as this is a multisystem disease, and in some patients, extrahepatic involvement may manifest after transplant. The long-term success of liver transplantation is unknown. Individuals with significant diffuse reticuloendothelial involvement may have greater risk for morbidity and mortality, which may impact the success rate for liver transplant.

Type VI Glycogen Storage Disease (Liver Phosphorylase Deficiency, Hers Disease)

Type VI GSD is caused by deficiency of **liver glycogen phosphorylase** .

Relatively few patients are documented, likely because of underreporting of this disease. Patients usually present with hepatomegaly and growth retardation in early childhood. Hypoglycemia, hyperlipidemia, and hyperketosis are of variable severity. Ketotic hypoglycemia may present after overnight or prolonged fasting. Lactic acid and uric acid levels are normal. Type VI GSD presents within a broad spectrum of involvement, some with a more severe clinical presentation. Patients with severe hepatomegaly, recurrent severe hypoglycemia, hyperketosis, and postprandial lactic acidosis have been reported. Focal nodular hyperplasia of liver and hepatocellular adenoma with malignant transformation into carcinoma is reported in some patients. While cardiac muscle was thought to be unaffected, recently mild cardiomyopathy has been reported in a patient with GSD VI.

Treatment is symptomatic and aims to prevent hypoglycemia while ensuring adequate nutrition. A high-carbohydrate, high-protein diet and frequent feeding are effective in preventing hypoglycemia. Blood glucose and ketones should be monitored routinely, especially during periods of increased activity/illness. Long-term follow-up of these patients is needed to expand the understanding of the natural history of this disorder.

GSD VI is an autosomal recessive disease. **Diagnosis** can be confirmed through molecular testing of the liver phosphorylase gene *(PYGL),* which is found on chromosome 14q21-22 and has 20 exons. Many pathogenic variants are known in this gene; a splice-site variant in intron 13 has been identified in the Mennonite population. A liver biopsy showing elevated glycogen content and decreased hepatic phosphorylase enzyme activity can also be used to make a diagnosis. However, with the availability of DNA analysis and next-generation sequencing panels, liver biopsies are considered unnecessary.

Type IX Glycogen Storage Disease (Phosphorylase Kinase Deficiency)

Type IX GSD represents a heterogeneous group of glycogenoses. It results from deficiency of the enzyme **phosphorylase kinase** (PhK), which is involved in the rate-limiting step of glycogenolysis. This enzyme has 4 subunits (α, β, γ, δ), each encoded by different genes on different chromosomes and differentially expressed in various tissues. Pathogenic variants in the *PHKA1* gene cause muscle PhK deficiency; pathogenic variants in the *PHKA2* and *PHKG2* genes cause liver PhK deficiency; pathogenic variants in the *PHKB* gene cause PhK deficiency in liver and muscle. Pathogenic variants in the *PHKG1* gene have not been identified. Defects in subunits α, β, and γ are responsible for liver presentation.

Clinical manifestations of liver PhK deficiency are usually recognizable within the 1st 2 yr of life and include short stature and abdominal distention from moderate to marked hepatomegaly. The clinical severity of liver PhK deficiency varies considerably. Hyperketotic hypoglycemia, if present, can be mild but may be severe in some cases. Ketosis may occur even when glucose levels are normal. Some children may have mild delays in gross motor development and hypotonia. It is becoming increasingly clear that GSD IX is not a benign condition. Severe phenotypes are reported, with liver fibrosis progressing to cirrhosis and HCC, particularly in patients with *PHKG2* variants. Progressive splenomegaly and portal hypertension are reported secondary to cirrhosis. Mild cardiomyopathy has been reported in a patient with GSD IX *(PHKB variant).* Cognitive and speech delays have been reported in a few individuals, but it is not clear whether these delays are caused by PhK deficiency or coincidental. Renal tubular acidosis has been reported in rare cases. Unlike in GSD I, lactic acidosis, bleeding tendency, and loose bowel movements are not characteristic. Although growth is retarded during childhood, normal height and complete sexual development are eventually achieved. As with debrancher deficiency, abdominal distention and hepatomegaly usually decrease with age and may disappear by adolescence. Most adults with liver PhK deficiency are asymptomatic, although further long-term studies are needed to fully assess the impact of this disorder in adults.

Phenotypic variability within each subtype is being uncovered with the availability of molecular testing. The incidence of all subtypes of PhK deficiency is approximately 1 : 100,000 live births.

X-Linked Liver Phosphorylase Kinase Deficiency (From *PHKA2* Variants)

X-linked liver PhK deficiency is one of the most common forms of liver glycogenosis in males. In addition to liver, enzyme activity can also be deficient in erythrocytes, leukocytes, and fibroblasts; it is normal in muscle. Typically, a 1-5 yr old boy presents with growth retardation, an incidental finding of hepatomegaly, and a slight delay in motor development. Cholesterol, triglycerides, and liver enzymes are mildly elevated. Ketosis may occur after fasting. Lactate and uric acid levels are normal. Hypoglycemia is typically mild, if present, but can be severe. The response in blood glucose to glucagon is normal. Hepatomegaly and abnormal blood chemistries gradually improve and can normalize with age. Most adults achieve a normal final height and are usually asymptomatic despite a persistent PhK deficiency. It is increasingly being recognized that this disorder is not benign as previously thought, and there are patients with severe disease and long-term hepatic sequelae. In rare cases, liver fibrosis can occur and progress to cirrhosis.

Liver histology shows glycogen-distended hepatocytes, steatosis, and potentially mild periportal fibrosis. The accumulated glycogen (β particles, rosette form) has a frayed or burst appearance and is less compact than the glycogen seen in type I or III GSD. Fibrous septal formation and low-grade inflammatory changes may be seen.

The gene for the common liver isoform of the PhK α subunit, *PHKA2,* is located on the X chromosome (αL at Xp22.2). Mutations in the *PHKA2* gene account for 75% of all PhK cases. X-linked liver PhK deficiency is further subdivided into 2 biochemical subtypes: XLG1, with measurable deficiency of PhK activity in both blood cells and liver, and XLG2, with normal in vitro PhK activity in blood cells and variable activity in liver. It is suspected that XLG2 may be caused by missense variants that affect enzyme regulation, whereas nonsense variants affecting the amount of protein result in XLG1. Female carriers are unaffected.

Autosomal Liver and Muscle Phosphorylase Kinase Deficiency (From *PHKB* Variants)

PhK deficiency in liver and blood cells with an autosomal recessive mode of inheritance has been reported. Similar to the X-linked form, chief symptoms in early childhood include hepatomegaly and growth retardation. Some patients also exhibit muscle hypotonia. In a few cases where enzyme activity has been measured, reduced PhK activity has been demonstrated in muscle. Mutations are found in *PHKB* (chromosome 16q12-q13), which encodes the β subunit, and result in liver and muscle PhK deficiency. Several nonsense variants, a single-base insertion, a splice-site mutation, and a large intragenic mutation have been identified. In addition, a missense variant was discovered in an atypical patient with normal blood cell PhK activity.

Autosomal Liver Phosphorylase Kinase Deficiency (From *PHKG2* Variants)

This form of PhK deficiency is caused by pathogenic variants in the testis/liver isoform (TL) of the γ subunit gene *(PHKG2)*. In contrast to X-linked PhK deficiency, patients with variants in *PHKG2* typically have more severe phenotypes, with recurrent hypoglycemia, prominent hepatomegaly, significant liver fibrosis, and progressive cirrhosis. Liver involvement may present with cholestasis, bile duct proliferation, esophageal varices, and splenomegaly. Other reported presentations include delayed motor milestones, muscle weakness, and renal tubular damage. The spectrum of involvement continues to evolve as more cases are recognized. *PHKG2* maps to chromosome 16p12.1-p11.2; many pathogenic variants are known for this gene.

Phosphorylase Kinase Deficiency Limited to Heart

These patients have been reported with **cardiomyopathy** in infancy and rapidly progress to heart failure and death. Recent studies have shown that this is not a case of cardiac-specific primary PhK deficiency as suspected previously, but rather linked to the γ_2 subunit of adenosine monophosphate (AMP)–activated protein kinase (see later). The γ_2 subunit is encoded by the *PRKAG2* gene.

Diagnosis

PhK deficiency may be diagnosed by demonstration of the enzymatic defect in affected tissues. PhK can be measured in leukocytes and erythrocytes, but because the enzyme has many isozymes, the diagnosis can be easily missed without studies of liver, muscle, or heart. Individuals with liver PhK deficiency also usually have elevated transaminases, mildly elevated triglycerides and cholesterol, normal uric acid and lactic acid concentrations, and normal glucagon responses. Gene sequencing is used for diagnostic confirmation and subtyping of GSD IX.

The *PHKA2* gene encoding the α subunit is most frequently involved, followed by the *PHKB* gene encoding the β subunit. Variants in the *PHKG2* gene underlying γ-subunit deficiency are typically associated with severe liver involvement with recurrent hypoglycemia and liver fibrosis.

Treatment and Prognosis

The treatment for liver PhK deficiency is symptomatic. It includes a diet high in complex carbohydrates and proteins and small, frequent feedings to prevent hypoglycemia. Cornstarch can be administered with symptom-dependent dosage and timing (0.6-2.5 g/kg every 6 hr). Oral intake of glucose, if tolerated, should be used to treat hypoglycemia. If not, IV glucose should be given.

Prognosis for the X-linked and certain autosomal forms is typically good; however, long term complications are being recognized. Patients with mutations in the γ subunit typically have a more severe clinical course with progressive liver disease. Liver involvement needs to be monitored in all patients with GSD IX by periodic imaging (abdominal ultrasound or MRI every 6-12 mo) and serial hepatic function tests.

Liver Glycogen Synthase Deficiency

Liver glycogen synthase deficiency type 0 (**GSD 0**) is caused by deficiency of **hepatic glycogen synthase** (GYS2) activity, leading to a marked decrease of glycogen stored in the liver. The gene *GYS2* is located at 12p12.2. Several pathogenic variants have been identified in patients with GSD 0. The disease appears to be rare in humans, and in the true sense, this is not a type of GSD because the deficiency of the enzyme leads to decreased glycogen stores. Patients present in infancy with early-morning (prebreakfast) drowsiness, pallor, emesis, and fatigue and sometimes convulsions associated with hypoglycemia and hyperketonemia. Blood lactate and alanine levels are low, and there is no hyperlipidemia or hepatomegaly. Prolonged *hyperglycemia* , glycosuria, lactic acidosis, and hyperalaninemia, with normal insulin levels after administration of glucose or a meal, suggest a deficiency of glycogen synthase. Definitive diagnosis may be by a liver biopsy to measure the enzyme activity or identification of pathogenic variants in *GYS2* .

Treatment consists of frequent meals, rich in protein and nighttime supplementation with uncooked cornstarch to prevent hypoglycemia and hyperketonemia. Most children with GSD 0 are cognitively and developmentally normal. Short stature and osteopenia are common features. The **prognosis** seems good for patients who survive to adulthood, including resolution of hypoglycemia, except during pregnancy.

Hepatic Glycogenosis With Renal Fanconi Syndrome (Fanconi-Bickel Syndrome)

Fanconi-Bickel Syndrome is a rare autosomal recessive disorder is caused by defects in the facilitative glucose transporter 2 (GLUT-2), which transports glucose in and out of hepatocytes, pancreatic β cells, and the basolateral membranes of intestinal and renal epithelial cells. The disease is characterized by proximal renal tubular dysfunction, impaired glucose and galactose utilization, and accumulation of glycogen in liver and kidney.

The affected child typically presents in the 1st yr of life with failure to thrive, rickets, and a protuberant abdomen from hepatomegaly and nephromegaly. The disease may be confused with GSD I because a Fanconi-like syndrome can also develop in type I patients. Adults typically present with short stature, dwarfism, and excess fat in the abdomen and shoulders. Patients are more susceptible to fractures because of early-onset generalized osteopenia. In addition, intestinal malabsorption and diarrhea may occur.

Laboratory findings include glucosuria, phosphaturia, generalized aminoaciduria, bicarbonate wasting, hypophosphatemia, increased serum alkaline phosphatase levels, and radiologic findings of rickets. Mild fasting hypoglycemia and hyperlipidemia may be present. Liver transaminase, plasma lactate, and uric acid levels are usually normal. Oral galactose or glucose tolerance tests show intolerance, which could be explained by the functional loss of GLUT-2 preventing liver uptake of these sugars. Tissue biopsy results show marked accumulation of glycogen in hepatocytes and proximal renal tubular cells, presumably from the altered glucose transport out of these organs. Diffuse glomerular mesangial expansion along with glomerular hyperfiltration and microalbuminuria similar to nephropathy in GSD Ia and diabetes have been reported.

This condition is rare, and 70% of patients with Fanconi-Bickel syndrome have consanguineous parents. Most patients have homozygous pathogenic variants; some patients are compound heterozygotes. The majority of variants detected thus far predict a premature termination of translation. The resulting loss of the C-terminal end of the GLUT-2 protein predicts a nonfunctioning glucose transporter with an inward-facing substrate-binding site.

There is no specific treatment. Symptom-dependent treatment with phosphate and bicarbonate can result in growth improvement. Growth may also improve with symptomatic replacement of water, electrolytes, and vitamin D; restriction of galactose intake; and a diet similar to that used for diabetes mellitus, with small, frequent meals and adequate caloric intake.

Muscle Glycogenoses

The role of glycogen in muscle is to provide substrates for the generation of ATP for muscle contraction. The muscle GSDs are broadly divided into 2 groups. The first group is characterized by hypertrophic cardiomyopathy, progressive skeletal muscle weakness and atrophy, or both, and includes deficiencies of **acid α-glucosidase** , a lysosomal glycogen-degrading enzyme (**type II** GSD), lysosomal-associated membrane protein 2 (**LAMP2**), and AMP-activated protein kinase γ_2 (**PRKAG2**). The 2nd group comprises muscle energy disorders characterized by muscle pain, exercise intolerance, myoglobinuria, and susceptibility to fatigue. This group includes myophosphorylase deficiency (McArdle disease, **type V** GSD) and deficiencies of phosphofructokinase (**type VII**), phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase, and muscle-specific phosphorylase kinase. Some of these latter enzyme deficiencies can also be associated with *compensated hemolysis* , suggesting a more generalized defect in glucose metabolism.

Type II Glycogen Storage Disease (Lysosomal Acid α-1,4-Glucosidase Deficiency, Pompe Disease)

Pompe disease, also referred to as GSD type II or **acid maltase deficiency** , is caused by a deficiency of acid α-1,4-glucosidase (acid maltase), an enzyme responsible for the degradation of glycogen in lysosomes. This enzyme defect results in lysosomal glycogen accumulation in multiple tissues and cell types, predominantly affecting cardiac, skeletal, and smooth muscle cells. In Pompe disease, glycogen typically accumulates within lysosomes, as opposed to its accumulation in cytoplasm in the other glycogenoses. However, as the disease progresses, lysosomal rupture and leakage lead to the presence of cytoplasmic glycogen as well.

Pompe disease is an autosomal recessive disorder. The incidence was thought to be approximately 1 in 40,000 live births in Caucasians and 1 in 18,000 live births in Han Chinese. Newborn screening for Pompe disease in the United States suggests that the prevalence is much higher than previously thought (between 1 in 9,132 and 1 in 24,188). The gene for acid α-glucosidase *(GAA)* is on chromosome 17q25.2. More than 500 pathogenic variants have been identified that could be helpful in delineating the phenotypes. A splice-site variant (IVS1-13T → G; c.-32-13T>G) is commonly seen in late-onset Caucasian

patients.

Clinical Manifestations

Pompe disease is broadly classified into infantile and late-onset forms. **Infantile Pompe disease** (IPD) is uniformly lethal without enzyme replacement therapy (ERT) with *alglucosidase alfa.* Affected infants present in the 1st day to weeks of life with hypotonia, generalized muscle weakness with a *floppy infant* appearance, neuropathic bulbar weakness, feeding difficulties, macroglossia, hepatomegaly, and hypertrophic cardiomyopathy, which if untreated leads to death from cardiorespiratory failure or respiratory infection, usually by 1 yr of age.

Late-onset Pompe disease (LOPD; juvenile-, childhood-, and adult-onset disease) is characterized by proximal limb girdle muscle weakness and early involvement of respiratory muscles, especially the diaphragm. Cardiac involvement ranges from cardiac rhythm disturbances to cardiomyopathy and a less severe, short-term prognosis. Symptoms related to progressive dysfunction of skeletal muscles can start as early as within 1 yr of age to as late as the 6th decade of life. The clinical picture is dominated by slowly progressive proximal muscle weakness with truncal involvement and greater involvement of the lower limbs than the upper limbs. The pelvic girdle, paraspinal muscles, and diaphragm are the muscle groups most seriously affected in patients with LOPD. Other symptoms may include lingual weakness, ptosis, and dilation of blood vessels (e.g., basilar artery, ascending aorta). With disease progression, patients become confined to a wheelchair and require artificial ventilation. The initial symptoms in some patients may be respiratory insufficiency manifested by somnolence, morning headache, orthopnea, and exertional dyspnea, which eventually lead to sleep-disordered breathing and respiratory failure. Respiratory failure is the cause of significant morbidity and mortality in LOPD. Basilar artery aneurysms with rupture also contribute to mortality in some cases. Small-fiber neuropathy presenting as painful paresthesia has been identified in some LOPD patients. Gastrointestinal disturbances such as postprandial bloating, dysphagia, early satiety, diarrhea, chronic constipation, and irritable bowel disease have been reported. Genitourinary tract involvement is not uncommon and may present as bladder and bowel incontinence, weak urine stream or dribbling. If untreated, the age of death varies from early childhood to late adulthood, depending on the rate of disease progression and the extent of respiratory muscle involvement. With the advent of ERT, a new natural history is emerging for both survivors of infantile and LOPD.

Laboratory Findings

These include elevated levels of serum creatine kinase (CK), aspartate transaminase (AST), alanine transaminase (ALT), and lactate dehydrogenase (LDH). Urine glucose tetrasaccharide, a glycogen breakdown metabolite, is a reliable biomarker for disease severity and treatment response. In the infantile form a chest x-ray film showing massive cardiomegaly is frequently the first symptom detected. **Electrocardiographic findings** include a high-voltage QRS complex, Wolff-Parkinson-White (WPW) syndrome, and a shortened PR interval. Echocardiography reveals thickening of both ventricles and/or the intraventricular septum and/or left ventricular outflow tract obstruction. Muscle biopsy shows the presence of vacuoles that stain positively for glycogen; acid phosphatase is increased, presumably from a compensatory increase of lysosomal enzymes. EM reveals glycogen accumulation within a membranous sac and in the cytoplasm. Electromyography reveals myopathic features with excessive electrical irritability of muscle fibers and pseudomyotonic discharges. Serum CK is not always elevated in adult patients. Depending on the muscle sampled or tested, the muscle histologic appearance and electromyography may not be abnormal.

Some patients with infantile Pompe disease who had peripheral nerve biopsies demonstrated glycogen accumulation in the neurons and Schwann cells.

Diagnosis
